ROMANIAN RESEARCH, A MESSAGE OF ROMANIA'S PEACEFUL POLICY

MIHAIL FLORESCU

Minister of Chemical Industry

Following the tradition established by so many precedents, each voyage of comrade Nicolae Ceaușescu and of comrade Elena Ceaușescu abroad is watched by the citizens of our fatherland with that human vibration and rightful pride resulted from the belief that a proper cause to everyone is being served in far off places : the promotion of the fundamental interests of the Romanian people and implicitly the aspirations for the better, for peace and understanding between all peoples. It may be definitely stated that these attributes also characterized the visit paid by comrade Nicolae Ceaușescu together with comrade Elena Ceaușescu to the United States of America at the invitation of President Richard Nixon and of his wife, Mrs. Patricia Nixon.

This visit ranges in the context of the whole foreign policy of Romania which, while unswervingly militating for the constant strengthening of many-sided relations of friendship and alliance with socialist countries, also acts toward developing relations with all the countries in the world, regardless of their social system, in the spirit of peaceful coexistence, of requirements for détente and for a general progress in our present world. An expression of the relations of friendship and cooperation settled among our countries and peoples, the visit to the USA was concluded with particularly satisfactory results for the further development of these relations, also making an ample contribution to the general cause of peace and of international cooperation.

The profitable nature of relations of cooperation based on the rigorous observance of equality in rights is also revealed by the very evolution of Romanian-American relations which have recorded a favourable ascending course in recent years, at all levels : economic, scientific, cultural, political and in other domains.

Thus, it was again outlined that the relations of peaceful coexistence cannot and must not be considered in a static, passive way, but rather as an active, dynamic policy for strengthening the relations of cooperation, for permanently stimulating collaboration, understanding and rapprochement between peoples.

On a scientific plane, the central event of the visit was the award of the Diploma of Honorary Member of the American Institute of Chemists to Dr. Engineer Elena Ceaușescu. The ceremony of the award of this special distinction took place at the National Academy of Science of the USA.

Comrade Elena Ceaușescu was welcomed by the president of the National Academy of Science, Philip Handler. Opening the ceremony attended by a large number of well-known personalities from different states of the USA, the speaker said :

"I paid a visit to Romania last year. I got acquainted with the scientific activity developed in your country. I was left with the best impressions. The present opportunity of welcoming a remarkable scientist of this country is a joy for us all".

This appreciation is based on significant achievements all along the activity carried out as a researcher and director of ICECHIM.

Studies developed under the direct leadership of comrade Dr. Eng. Elena Ceaușescu, involving the stereospecific polymerization of isoprene, some methods for the purification of monomers and of solvents used in obtaining macromolecular compounds through various approaches of stereospecific polymerization and in emulsion through polycondensation as well as studies involving the characterization of polymers by modern analysis methods have found a wide application in industry and research.

Investigations carried out in the field of polymer synthesis are of a particular interest since a part of the studied elastomers having superior properties, natural rubber-substitutes, will be shortly developed in industry, thus enlarging the range of synthetic rubber produced in our country.

The studies and investigations in the field of the synthesis of some plastifiers involved in PVC compounds are also worth mentioning. The occurrence of macromolecular compounds determined the working out and the development of specific analysis methods capable of revealing the macro and microstructure of polymers, in view of establishing relations between their structure and properties and, hence, of anticipating the fields of utilization.

In this sense valuable work has been achieved in the field of the structural characterization of polymers and characterization methods.

The ceremony at the US Academy of Science was continued by the speech of the president of the American Institute of Chemists, Ernest Gilmont, who said :

"We award today the Diploma of Honorary Member of the American Institute of Chemists to Mrs. Elena Ceaușescu, as an acknowledgement of the remarkable manner in which she manages a research institute of high repute, for her outstanding merits in developing some important studies, for her particular contribution to the progress of scientific life and for the achievements in the field of education not only in her own country but also throughout the world. She is the first foreign scientist being awarded the Honorary Diploma. Mrs. Elena Ceaușescu's accomplishments in raising the chemical profession at higher levels on international plane is an important contribution to the international development of chemistry. Mrs. Elena Ceaușescu has worked in a highly efficient manner in the spirit of objectives also pursued by the American Institute of Chemists. Due to her activity, new prospects are being opened in the field of chemistry at present. She has done very much in order to increase the prestige and the distinction of this profession".

The president of the Branch of the district of Columbia of the A.I.C., Dr. Miloslav Rechigi Jr., presented next the statement for the award of the Diploma of Honorary Member.

"It is a privilege for us", he said, "to have the opportunity of expressing our recognition to one of the greatest chemical researchers. I say that, as we, members of our association, have come here in order to do honour to a brilliant exponent not only in Romania but also on a worldwide scale, of a profession highly thought of by all those future-oriented personalities".

"Elena Ceauşescu has graduated from the Polytechnic Institute in Bucharest obtaining the titles of chemical engineer and a doctorate in chemistry in 1957 and 1965, respectively. She is a specialist in the field of macromolecular synthesis compounds, in the chemistry of polymers and rubber and in the kinetics of polymerization. At present she holds the position of Director General at the Central Institute of Chemical Research in Bucharest. In this capacity, Dr. Elena Ceauşescu manages and coordinates multiple activities in the field of chemistry and the application of some advanced technologies in Romania's chemical industry. At the same time, Dr. Elena Ceauşescu is a member of the Executive Bureau of the National Council for Science and Technology, a governmental organization responsible for the coordination of scientific and technological development in Romania".

"As a recognition of her scientific achievements, Dr. Elena Ceauşescu has been elected a honorary member of the International Society of Chemical Engineering, an active member of the Academy of Science in New York, a honorary member of the Association of Chemists and Chemical Engineers in Costa Rica, a honorary member of the Council of the Central University in Ecuador and a honorary professor at the National Technical University of Lima".

"The results of numerous scientific investigations carried out by Dr. Elena Ceauşescu or achieved under her leadership have been inserted in various scientific publications or presented at Congresses and Symposia in Romania and abroad".

"Apart from her scientific career and her responsibilities in the management of the institute, Elena Ceauşescu plays an active part in the political life of her country and has participated in official visits abroad".

"Beside the role of first lady of her country, she is a politician and a statesman. Based on our criteria we consider her to be a politician whose activity is particularly efficient and successful. Recently, Mrs. Elena Ceauşescu has been elected in the Executive Committee of the Communist Party of her country. As far as I know she must be the most active of the first ladies throughout the world. Last but not least, I must also mention the fact that Mrs. Ceauşescu takes pride in her two sons and in her daughter".

"With such an impressive background and with such a brilliant career, Mrs. Ceauşescu certainly ranges among the most distinguished personalities".

"It certainly is a pleasure to have you among us".

"We are honoured by your presence" (the last words have been uttered in Romanian).

In answer, comrade Elena Ceauşescu addressed a cordial greeting to those present, to American chemists, on behalf of Romanian scientists and of chemical researchers and on her own part, and then thanked for the award of the Diploma of Honorary Member which she considered to be a high appreciation given to Romanian science, to the activity of Romanian chemists, as well as an expression of the friendly relations between the two countries and peoples.

In our days, comrade Elena Ceauşescu further emphasized, scientific knowledge increasingly becomes a common asset of the whole civilization, and its development places more and more imperative requirements on the expansion of contacts and of exchanges of information, on the promotion of a large cooperation among scientists and scholars all over the world.

Romania assigns a prime significance to the development of science, a major promoting factor in the multilateral progress of the economy and in raising the people's standard of living. During the last three decades since Romanian people has chosen the socialist form of development, great efforts have been made for the stimulation of scientific research, for the training of the necessary staff and the establishment of a wide network of research units. In the frame of the general activity of scientific research, a special attention has been paid to research in the field of chemistry, this being one of the decisive sectors of modern technical progress also involving the best use of our country's natural wealth.

By fulfilling the objectives regarding the development of the chemical industry and of research, Romania strongly supports the development of collaboration and of cooperation between Romanian scientists and researchers from other countries. In this sense, all the conditions have been satisfied for fruitful relations of cooperation to be developed between Romanian and American scientists, between the chemists of the two countries. In our days, cooperation and collaboration between scientists become more and more necessary not only as a basic condition of scientific progress in general, but also as a concrete contribution to the cause of understanding and rapprochement between nations, as a direct contribution to relaxation, cooperation and international peace.

In conclusion, expressing her confidence to the effect that the development of the Romanian-American scientific cooperation would mean an actual contribution to the fulfilment of desiderata of peace and progress of the two peoples, to the efforts for creating a better world, comrade Elena Ceauşescu addressed wishes of new successes to American chemists, in their activity devoted to science.

At the end of the ceremony, the president of the National Academy of Science underlined that he shared the views of the Director of the Central Institute of Chemical Research in Bucharest regarding the high responsibility incumbent upon scientists, expected to do their utmost for the understanding, cooperation and respect among peoples, as well as the considerations regarding the prospects of the Romanian-American scientific cooperation and expressed once again his warm thanks to comrade Elena Ceauşescu for her presence among American chemists.

The value of the awarded distinction is also stressed by the fact that only 64 such honorary diplomas have been granted up to the present during the 50 years which had elapsed since the foundation of this high forum of American chemists. Comrade Dr. Eng. Elena Ceauşescu is the first foreign statesman who has been awarded this high distinction. It also crowns the outstanding scientific merits of the Romanian school of chemistry, of a representative Romanian scientist.

The statement regarding the award of the diploma of honorary member of I.A.C., read in front of numerous representative scientists in the field of chemistry in USA, included the determining article concerning the award of this distinction. It states :

"Those persons are honorary members who have particularly distinguished themselves in the field of chemistry through services done to the chemical profession and to the country and also through professional achievements" (Article II, Section 3 of the document of constitution).

This high distinction has been recently granted to Dr. Philip Handler, president of the National Academy of Science and to Dr. Glenn T. Seaborg, Nobel-Prize winner for chemistry in 1951.

With regard to the American Institute of Chemists, it was founded in 1923, the president in charge being Dr. Ernest R. Gilmont. The institute numbers 8,000 members from all the 50 states and coordinates the activity of 31 governmental institutions.

A particular emphasis must be laid on the merit in organizing the research activity in the chemical industry of our country on efficient bases, an achievement attained in recent years under the direct leadership of comrade Dr. Eng. Elena Ceauşescu.

As the chemical production developed at a rapid rate, the fundamental and applicative scientific research in chemistry was expanded and the need was felt for some organizing frames expected to increase the efficiency of results obtained in the field of research, a closer bond between research and technological designing.

As a result of thorough studies developed under the direct guidance of Dr. Eng. Elena Ceauşescu, bases were set for the organization of the Central Institute of Chemical Research which controls all the central institutes and the research institutes in industry and coordinates the whole research activity in the chemical field in higher education institutes. A better coordination has been achieved in this manner, in developing research plans, in concentrating forces on the major issues in the development of the chemical industry.

The direct relation between research and technological designing will speed up the passage to industrial production. The development of technological processes which closely link research to the designing activity, the chemical engineering calculations and those relating to equipment design will permit a simplification of the entire cycle — from laboratory research to the production of industrial installations — so as to reduce it as much as possible while attaining the highest possible technical level, achieving a rational technological flow and a high economic efficiency.

It must be mentioned that the National Council of Science and Technology has introduced this system into the major industrial branches, following the model achieved at the Central Institute of Chemical Research.

The award of high scientific distinctions to a famous representative of the Romanian school of chemistry, comrade Dr. Eng. Elena Ceaușescu, also illustrates the high appreciation given by chemists from the USA and from other states to Romanian chemists, to all those who, by their activity in plants, research and designing institutes, have raised the chemical industry of our country to one of the highest levels of the world-wide chemical industry, a fact attested by the competitivness of our chemical products on the international market and also the unanimous appreciations of scientists expressed on the occasion of the presentation of some licences and inventions at various events abroad.

THE RADIOLYSIS OF THE COMPLEX OXALATES IN AQUEOUS SOLUTIONS. II[1]

KINETICS AND MECHANISM OF THE RADIOLYSIS OF COBALT-TRISOXALATO-COMPLEX IN NEUTRAL AQUEOUS SOLUTION WITH α-Po^{210} IRRADIATIONS

I. G. MURGULESCU and J. PĂUN
University of Bucharest, Department of Physical Chemistry,
Radiation Chemistry Laboratory, Bd. Republicii 13, Bucharest, Romania

Received June 13, 1973

The decomposition of the Co-trisoxalato-complex in neutral aqueous solution by irradiation with high L.E.T. ionizing radiation (α-Po^{210}) has been studied. The radiochemical decomposition reaction follows a zero order kinetic law. The $G(-[Co(C_2O_4)_3]^{3-})$ value increases with the increasing solute concentration from 0.22 to 0.52, being in accordance with the known influence of L.E.T. value on the radiochemical yield of the solute chemical transformation in radiation chemistry of aqueous solutions. The predominant process in the radiolysis of this compound is the reduction of the trisoxalato-complex ion by the hydrated electrons and hydrogen atoms:

$$[Co(C_2O_4)]^{3-} + e_{aq} \longrightarrow [Co(C_2O_4)_2]^{2-} + C_2O_4^{2-}$$

$$[Co(C_2O_4)]^{3-} + H \longrightarrow [Co\,(C_2O_4)_2]^{2-} + C_2O_4H^-$$

so that: $G\,(-[Co\,(C_2O_4)_3]^{3-}) = G_{e_{aq}^-} + G_H$

The kinetics and mechanism of the radiolysis of Co-trisoxalato-complex in neutral aqueous solution with low L.E.T. ionizing radiation has been the subject but of a few investigations.[1,2] From the puls radiolysis works, Baxendale[3,4] has shown that the Co-trisoxalato-complex ion is a very good hydrated electron scavanger and reported that in the reduction process of $[Co(C_2O_4)_3]^{3-}$ ion no short-lived transient was observed spectrophotometrically.

In order to study the effect of the changing of linear energy transfer (L.E.T.) on the radiochemical decomposition yield of Co-trisoxalato-complex, $G(-[Co(C_2O_4)_3]^{3-})$, we have used α-Po^{210} particles as high L.E.T. ionizing radiations.

EXPERIMENTAL

The complex compound was prepared by the Sörensen's method.[5] For the preparation of the solutions twice distilled water was used. We have worked at three different concentrations: 10^{-3}M ; 2×10^{-3} M and 4×10^{-3} M. The decomposition of the complex in solution during the irradiation was followed spectrophotometrically by measuring the optical density of the irradiated solution at 573 nm.

For α-particles irradiation we have used 1 Curie Po^{210} type PDD source produced by the Radiochemical Center, Amersham, England. The source was made by electrodeposition of polonium on a circular area of platinum of 10 mm diameter. The metal disk was slightly recessed in an aluminium holder and covered by a very thin mica window of ~ 1 mg/cm^2 mass thickness. The source holder could be raised or lowered by means of a screw, thus enabling the distance between the source and the surface of the irradiated liquid to be varied in a controlled manner.

The irradiation cell had an irradiation zone in the form of a flat cylinder 3 cm in diameter and 1 cm deep with a very thin mica window in the center of one face. For irradiation of the solution, the cell was placed closely under the source holder so that only 1 mm gap was traversed by the α-particles in going from one to another. All mica windows were prepared by cleavage of sheets of mica which before being fitted were microscopically examined and their thicknesses determined. During irradiation, the content was agitated by a magnetically operated stirrer. The irradiation array including the source, source holder and irradiation cell is presented in figure 1.

The mean energy of α-particles on reaching the solution was calculated by using the values for the stopping power of mica given by Riezler[6] and the range-energy relationships by Jesse and Sadauskis.[7]

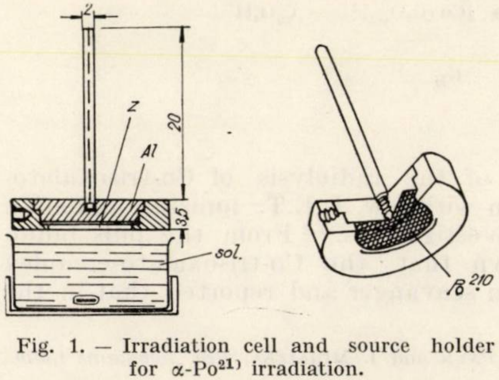

Fig. 1. — Irradiation cell and source holder for α-$Po^{21)}$ irradiation.

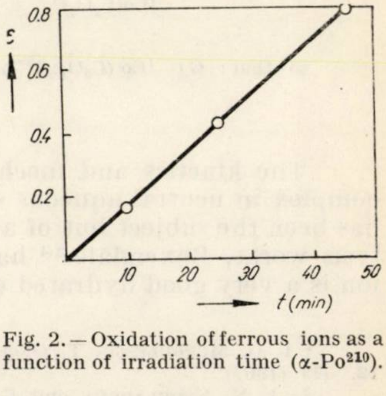

Fig. 2. — Oxidation of ferrous ions as a function of irradiation time (α-Po^{210}).

[6] W. Riezler, *Ann. Phys.*, **35**, 350 (1939).

[7] W. P. Jesse and J. Sadauskis, *Phys. Rev.*, **78**, 1 (1950).

The standard Fricke ferrous sulfate dosimetric solution was used to calibrate the Po^{210} source using a value of 4.7 for $G(Fe^{3+})$. In figure 2 is given the increase of the optical density of irradiated dosimetric solution at 304 nm. The dose rate was 2.2×10^{17} eV/g min in a volume of 1.5 ml.

RESULTS

On irradiation with α-radiations, the Co-trisoxalato-complex in neutral aqueous solution decomposes slowly following a zero order kinetic law in the whole concentration range studied. In figure 3 is given the decrease of the complex concentration with the irradiation dose for three different concentrations : 10^{-3}, 2×10^{-3} and 4×10^{-3} M, in the presence of air.

The radiochemical yield $G(-[Co(C_2O_4)_3]^{3-})$ increases with the initial solute concentration from 0.22 to 0.44. In the absence of air, at a concentration of 4×10^{-3}M, we got $G(-[Co(C_2O_4)_3]^{3-}) = 0.52$.

In the presence of $C_2O_4^{2-}$ ions, at a concentration of 2×10^{-3}M, the decomposition is also linear with the irradiation dose but, the decomposition rate is lower, as can be seen from figure 4.

In the presence of the scavanger for reducing species, such as : NO_2^- and NO_3^- ions, the radiochemical decomposition rate is lower. The

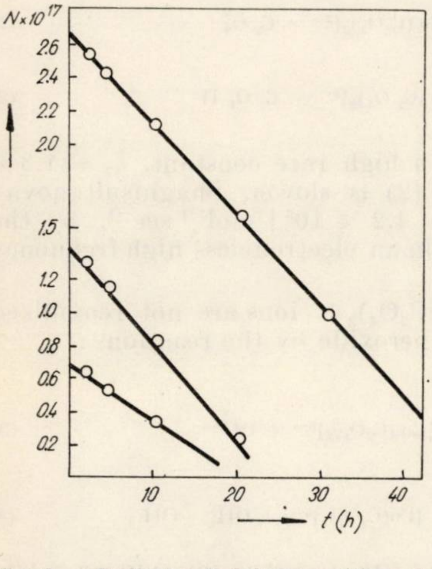

Fig. 3. — Radiochemical decomposition rate of Co-trisoxalato-complex in neutral aqueous solution at different concentrations.

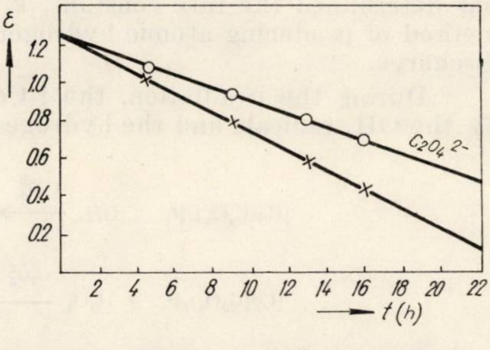

Fig. 4. — Influence of $C_2O_4^{2-}$ ions on the decomposition rate of Co-trisoxalato-complex in neutral aqueous solution, in the presence of air.

effect is greater in the presence of NO_2^- ions. In figure 5 is given the influence of NO_2^- and NO_3^- ions at a concentration of 2×10^{-3} M, on the decomposition rate of the complex in 2×10^{-3} M solution, in the presence of air.

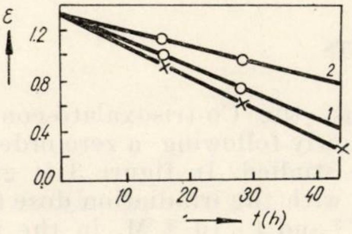

Fig. 5. — Influence of NO_2^- and NO_3^- ions on the decomposition rate of Co-trisoxalato-complex in neutral aqueous solutions, in the presence of air ($1 - NO_3^-$; 2, NO_2^-).

DISCUSSION

The decrease of the radiochemical decomposition rate of oxalato-complex in the presence of reducing species scavengers as well as the formation of CO^{2+} ions in irradiated solutions suggest that the main process taking place in the radiolysis is the reduction of $[Co(C_2O_4)_3]^{3-}$ ions, by the hydrated electrons and hydrogen atoms resulting from the radiolysis of water :

$$\bar{e}_{aq} + [Co(C_2O_4)_3]^{3-} \xrightarrow{k_1} [Co(C_2O_4)_2]^{2-} + C_2O_4^{2-} \qquad (1)$$

$$H + [Co(C_2O_4)_3]^{3-} \xrightarrow{k_2} [Co(C_2O_4)_2]^{2-} + C_2O_4H^- \qquad (2)$$

The reaction (1) is fast, having a high rate constant, $k_1 = 1.3 \times \times 10^{10}\ \text{l} \cdot \text{mol}^{-1}\,\text{sec}^{-1}$ [3,4]. The reaction (2) is slower. Shaghisultanova [8] has determined the rate constant, $k_2 = 4.2 \times 10^6\ \text{l} \cdot \text{mol}^{-1}\,\text{sec}^{-1}$, by the method of producing atomic hydrogen in an electrodeless high frequency discharge.

During the irradiation, the $[Co(C_2O_4)_2]^{2-}$ ions are not reoxidized by the OH. radicals and the hydrogen peroxide by the reactions :

$$[Co(C_2O_4)_2]^{2-} + OH. \xrightarrow{C_2O_4^{2-}} [Co(C_2O_4)_3]^{3-} + OH^- \qquad (3)$$

$$[Co(C_2O_4)_2]^{2-} + H_2O_2 \xrightarrow{C_2O_4^{2-}} [Co(C_2O_4)_3]^{3-} + OH^- + OH. \qquad (4)$$

There is so no clear evidence for the reaction (3). Allen [9] points only out that the product of reaction $Co^{2+} + OH$ may be written as $CoOH^{2+}$

---

[9] A. Allen and D. Katakis, *J. Phys. Chem.*, **68**, 1359 (1964).

which does not immediately rearrange to the stable $Co^{3+}(aq)$ ion, remaining for a finite time in a more active form.

The reaction (4) has been studied by Wormser[10] who showed that it proceeds slowly, in a high excess of hydrogen peroxide, in the presence of high $C_2O_4^{2-}$ ions concentration ($\sim 1M$). This condition is not fulfiled in our irradiation experiments, because there were present no $C_2O_4^{2-}$ ions and the concentration of hydrogen peroxide built up during the radiolysis was not higher than the resulting $[Co(C_2O_4)_2]^{2-}$ ions concentration. As it is known, by irradiation with high L.E.T. radiations, the concentration of hydrogen peroxide is approximately 10^{-3} M.

Therefore, taking into consideration the reactions (1) and (2) only, the reaction rate becomes :

$$\frac{dx}{dt} = k_1\, C_{e^-_{aq}} \cdot (a - x) + k_2 \cdot C_H \cdot (a - x) \qquad (I)$$

where a is the initial solute concentration, $C_{e^-_{aq}}$ and C_H are the concentrations of hydrated electrons and hydrogen atoms, respectively. Assuming the well-known mechanism for the radiolysis of water[11], by applying the steady state principle to the estimation of reducing species concentrations, it results finally[1]:

$$\frac{dx}{dt} = k \cdot C_{H_2O} = k_0 \qquad (II)$$

where k_0 is the overall rate constant for a zero order process.

Experimentally, k_0 has been calculated by the equation :

$$k_0 = \frac{a_0}{\varepsilon_0} \cdot \frac{\Delta\varepsilon}{\Delta t}\ (\text{molec. cm}^{-3} \cdot \text{sec}^{-1}) \qquad (III)$$

where a_0 is the initial solute concentration, ε_0 the optical density of the solution, before irradiation at the concentration a_0, $\Delta\varepsilon$ the decrease of optical density for an irradiation time Δt. In table 1 are given the values for k_0, at three different solute concentrations, in the presence of air.

The increase of the radiochemical decomposition yield, $G(-[Co(C_2O_4)_3]^{3-})$ with the increasing complex concentration indicate that the $[Co(C_2O_4)_3]^{3-}$ ions react progressively with the hydrated electrons and the hydrogen

atoms existing freely in the bulk of solution. At higher solute concentration there are present sufficient oxalato-complex ions to scavange all the reducing species so that the radiochemical decomposition yield of the complex equals the reducing species yield $G_{e^-_{aq}} + G_H$ from the water radiolysis :

$$G(-[Co(C_2O_4)_3]^{3-}) = G_{e^-_{aq}} + G_H$$

At the concentration of 4×10^{-3} M in the absence of air we obtained $G(-[Co(C_2O_4)_3]^{3-}) = 0.52$. Taking $G_{e^-_{aq}} = 0.34$ and $G_H = 0.22$ as given from the experimental data,[12] in accordance with the theoretical values calculated by the diffusion kinetics theory, [13] we obtain the theoretical value of the yield $G(-[Co(C_2O_4)_3]^{3-}) = 0.56$ which is near to our experimental value.

The low value of the radiochemical decomposition yield $G(-[Co(C_2O_4)_3]^{3-})$ by high L.E.T. radiation is consistent with the decrease of the yield of solute chemical transformation with increasing L.E.T., as being due to the decrease of the primary radical yields from the water radiolysis with increasing L.E.T. To illustrate this, in table 2 is given the variation of the yield with the L.E.T.-value for γ-Co^{60} and α-Po^{210} radiations.

[13] P. Dyne and J. Kennedy, *Canad. J. Chem.*, **36**, 1518 (1958); **38**, 61 (1960); A. Kupperman, Radiation Research, "Proceedings of the Third International Congress of Radiation Research", Cortina d'Ampezzo, Italy, 1966, Northholland, Amsterdam, 1967, p. 212.

Table 2

Variation of $G(\text{-}[Co(C_2O_4)_3]^{3-})$ with L.E.T.-value in neutral aqueous solution, 4×10^{-3} M, in the absence of air

Radiation	L.E.T. (eV/Å) in water	$G_{e_{aq}^-}$	G_H	$G(-[Co(C_2O_4)_3]^{3-})$
$\gamma-Co^{60}$	0.02	2.65	0.55	3.15
$\alpha-P0^{210}$	8.80	0.34	0.22	0.52

An interesting feature of the radiolysis of aqueous solutions by high L.E.T. radiations is the small difference between the values of the primary reducing species yields $G_{e_{aq}^-}$ and G_H, where $\frac{G_{e_{aq}^-}}{G_H} = 1.54$ in comparison with the low L.E.T. radiations, where $\frac{G_{e_{aq}^-}}{G_H} = 4.81$ (see table 2). This means that the hydrogen atoms will have by α-irradiation a greater contribution to the radiolysis process. This fact is confirmed by our results concerning with the influence of the scavangers for hydrated electrons and hydrogen atoms, such as NO_2^- and NO_3^- ions. As can be seen from figure 5, NO_2^- ions reduce stronger than NO_3^- ions the rate of the decomposition of complex ions. This effect is smaller by γ-irradiation.[14] Although both ions are almost equally efficient hydrated electron scavangers, $k_{e_{aq}^- + NO_3^-} = 1.1 \times 10^{10}$ l·mol^{-1} sec^{-1}, $k_{e_{aq}^- + NO_2^-} = 8.1 \times 10^{9}$ l·mol^{-1} sec^{-1}, the NO_2^- ions are better hydrogen atoms scavangers than NO_3^- ions, $k_{H+NO_3^-} =$ $= 9.3 \times 10^{6}$ l*mol^{-1} sec^{-1}, $k_{H+NO_2^-} = 1 \times 10^{9}$ l·mol^{-1} sec^{-1}.[15]

As the yields of hydrated electrons and hydrogen atoms $G_{e_{aq}^-}$ and G_H are much smaller at high values of L.E.T., it is to be expected that the influence of oxygen on $G(\text{-}[Co\,(C_2O_4)_3]^{3-}$ will be reduced at high L.E.T., which was experimentally observed.

γ-RADIOLYSIS OF GASEOUS ISOBUTYLENE. THE INFLUENCE OF EXPERIMENTAL CONDITIONS ON THE RADIOCHEMICAL YIELDS OF THE MAIN RADIOLYSIS PRODUCTS

I. BICĂ and MONICA CĂLDĂRARU

Institute of Physical Chemistry, str. Galaţi 31, Bucharest, Romania

Received April 27, 1973

The γ radiolysis of gaseous isobutylene on a wide range of pressures (150–760 torr) and at different irradiation doses was studied. The influence of pressure, irradiation dose and air traces on the yield of hydrogen and methane formation is discussed. Some ways which may determine the molecular hydrogen formation are also suggested.

1. INTRODUCTION

A great number of works issued lately deal with the radiolysis of gaseous alkenes. [1–6] Some important information about the irradiated gaseous isobutylene are obtained from Collin and Herman [9,10], Herman [11], Viswanathan and co-workers[7] and Volpi and co-workers'[8] works.

The effect of some experimental factors as gas density, irradiation dose and degasing procedure on the formation of radiolysis products has been studied less extensively. The aim of this work is to go thoroughly into the effects of these factors, as well as to advance an explanation of the molecular hydrogen formation, which is not well understood as yet.

2. EXPERIMENTAL

Isobutylene of Gerling Holtz and Co. quality was used without any purification (gas chromatographic analysis indicated a 99.7 % purity). The γ irradiations were performed in a 220 cm^3 Pyrex spherical vessel with the source placed in its center. The vessel degasing was obtained by heating (400°) and simultaneous pumping ($6 \cdot 10^{-5}$ torr) for four hours. The reaction cell was carefully washed to remove the polymer traces formed in the last experiment.

The source was a Co^{60} 480 ci with increased specific activity. Dosimetry was made with propylene as gaseous dosimeter using $G_{(H_2)} = 1.1.$[12] A 3×10^{16} eV/g dose rate was used.

The reaction products were analysed on a Pye dual collumn Gas Chromatograph, series 104, equipped with thermal conductivity detector, using Ar as carrier gas.

For C_2-C_4 hydrocarbons, a 5.4 m and 4 mm collumn filled with 20 % squalane on 60–80 mesh Chromosorb P was used, while a silica gel collumn 2.7 m and 4 mm was selected for H_2 and CH_4 analysis. The identification of the reaction products was done with suitable pure compounds. The quantitative determinations were carried out by the direct calibration method.

3. RESULTS

In this work we were particularly interested in following the H_2 and CH_4 production, as well as isobutylene conversion rate. Because of their very little importance in the analysed mixture, under our experimental conditions, the other products were determined only qualitatively.

In our work we have also observed some traces of liquid products on the wall of the reaction vessel, their amount increasing visibly with the irradiation dose.

Our work was divided into three sets of experiments. The first set dealt with the irradiation dose effect on the yields of principal products, when the internal pressure in the reaction vessel was kept constant (760 torr). Irradiation in the second series of experiments was made with a

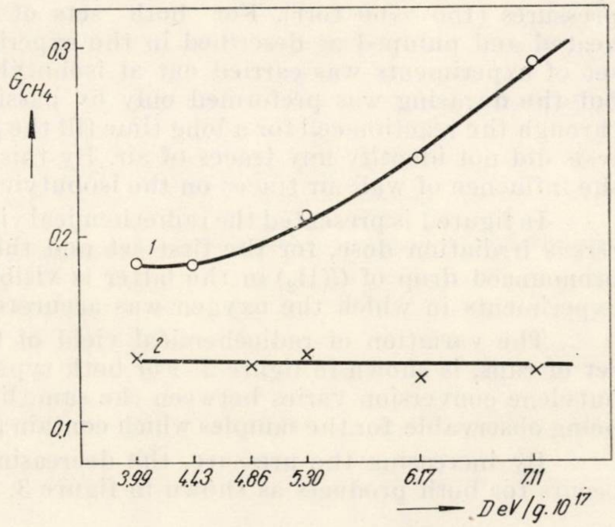

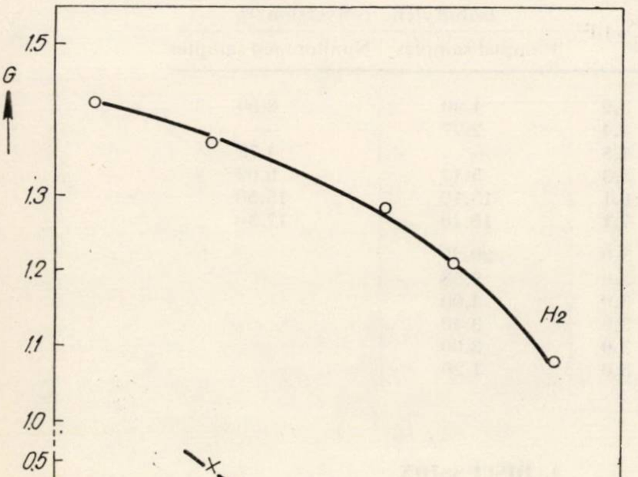

Fig. 3. — Radiochemical yields variation of H_2 and CH_4 *versus* pressure, for the second set of experiments. $D = 3.6 \cdot 10^{17}$ eV/g.

constant irradiation dose ($3.6 \cdot 10^{17}$ eV/g) but at different isobutylene pressures (150–760 torr). For both sets of experiments the cell was heated and pumped as described in the experimental section. The third set of experiments was carried out at isobutylene atmospheric pressure, but the degasing was preformed only by passing an isobutylene stream through the reaction cell for a long time till the gas chromatographic analysis did not identify any traces of air. By this procedure we determined the influence of wall air traces on the isobutylene radiolysis.

In figure 1 is presented the radiochemical yield variation of H_2, $G(H_2)$, *versus* irrdiation dose, for the first set and third set of experiments; a pronounced drop of $G(H_2)$ in the latter is visible in comparison to those experiments in which the oxygen was accurately eliminated.

The variation of radiochemical yield of CH_4, $G(CH_4)$, in the same set of runs, is shown in figure 2. For both types of experiments, the isobutylene conversion varies between the same limits, a very small increase being observable for the samples which contain air traces (table 1).

By increasing the pressure, the decreasing of radiochemical yields occurs for both products as shown in figure 3.

Table 1

Variation of isobutylene conversion in different experimental conditions

Pressure torr	Dose eV/g $\cdot 10^{17}$	Isobutylene conversion %	
		Pumped samples	Nonpumped samples
760	3.9	1.90	2.00
760	4.4	2.77	—
760	4.8	—	4.72
760	5.3	5.17	9.02
760	6.1	13.10	13.50
760	7.1	15.40	17.30
150	3.0	29.20	
310	3.0	9.08	
417	3.0	4.00	
540	3.0	3.40	
630	3.0	3.00	
760	3.0	1.20	

4. DISCUSSION

The drop of radiochemical yield of H_2 and CH_4 as well as of isobutylene conversion is an evidence that the collisional deactivation becomes more important with the increasing pressure. The pressure increase also determines a great probability of the ionic clusters formation; this process will mainly lead to condensation products.

As resulted from Magee and Funabashi's theory, [13] the formation of neutral molecules clusters around a central ion leads to a dissipation of the molecular energy over the whole assembly, which will determine its stabilization. Therefore, we can explain the decrease in yield of decomposition products (as H_2 and CH_4) with the increase of pressure, while the amount of the condensation products is higher at atmospheric pressure. This agrees with Tratchman's work,[14] which showed that the same phenomena occur in propylene radiolysis.

---

[13] J. L. Magee and K. Funabashi, *Radiation Res.*, **10**, 662 (1959).

As in figure 1, $G\ (H_2)$ varies relatively slightly with the irradiation dose; as can be seen from figure 2, $G\,(CH_4)$ is obviously increasing. In the presence of air traces, we observe a decrease of radiochemical yields of both products. This can be explained by analysing the source of product formation.

The primary radiochemical processes which occur at the isobutylene radiolysis are:

$$i-C_4H_8 \rightsquigarrow i-C_4H_8^{+*}\ (\text{or } i-C_4H_8^{+}) + \bar{e} \tag{A}$$

$$\rightsquigarrow i-C_4H_8^{*} \tag{B}$$

Related to these processes, the following reactions may be responsible for hydrogen formation as radiolysis product:

$$i-C_4H_8^{+*} \longrightarrow C_4H_6^{+} + H_2\ (\text{or } 2H) \tag{1}$$

$$i-C_4H_8^{+} \longrightarrow C_4H_6^{+} + H_2 \tag{2}$$

$$\longrightarrow C_4H_7^{+} + H \tag{3}$$

$$i-C_4H_8^{*} \longrightarrow C_4H_6 + 2H\ (\text{or } H_2) \tag{4}$$

$$\longrightarrow CH_2CCH_2 + CH_3 + H\ (\text{or } CH_4) \tag{5}$$

$$\longrightarrow CHCCH_3 + CH_3 + H\ (\text{or } CH_4) \tag{6}$$

$$\longrightarrow C_4H_7 + H \tag{7}$$

$$i-C_4H_8^{*} + i-C_4H_8 \longrightarrow C_8H_{14} + H_2 \tag{8}$$

The most probable secondary reactions of the hdyrogen atom resulting from (1), (4)—(7) are:

$$H + i-C_4H_8 \longrightarrow H_2 + C_4H_7 \tag{9}$$

$$\longrightarrow i-C_4H_9 \tag{10}$$

---

[14] M. Tratchman, *J. Phys. Chem.*, **70**, 3382 (1966).

The high ratio of the rate constants, k_{10}/k_9,[15] suggests that molecular hydrogen formation *via* a (9) type reaction could be considered as improbable. On the other hand, the works of Hatano *et al.*[16,17] evidenced that for a system containing "hot" hydrogen atoms, the alkene can be implied in a (9) type reaction; so, it can be responsible for molecular hydrogen formation. When an excited molecule produces many fragmentation products, the excitation energy is dissipated; so, it is very improbable for atomic hydrogen to be "hot", and this is the case for the reactions (5) and (6). All the other reactions may in principle generate such atoms. It follows that they may contribute to the increase of the probability of reaction (9).

The decrease of $G(H_2)$ in the presence of air traces (it means in the presence of oxygen, which is known as radical scavenger) is much higher (40%) than that obtained by Collin and Herman, [9] (10%) at low pressure and with NO as radical scavenger, but is the same with Tratchman's results in propylene radiolysis.[14] These facts can be explained by the reasons given below.

By increasing the pressure, the balance of contributions in molecular hydrogen formation changes (the molecular detachment becomes less important). On the other hand, O_2 traces also disturb a number of ionic reactions, as Niedzielski *et al.*[18] evidenced for ethylene radiolysis.

For a possible reaction as

$$i-C_4H_8^+ + i-C_4H_8 \longrightarrow C_8H_{14}^+ + H_2 \qquad (11)$$

the presence of O_2 traces will influence the molecular hydrogen formation.

As can be shown from figure 1, with increase of the irradiation dose, the influence of O_2 traces on the hydrogen yield becomes less important. The explanation of this effect is the following: by increasing the irradiation doses, the number of molecules which undergo radiolysis effect becomes more important in comparison to the constant amount of O_2 in the wall.

Concerning the methane formation, our results are in good agreement with those of Herman and Collin,[10] on the important contribution of primary molecular detachment

$$(CH_3)_2CCH_2 \longrightarrow CH_4 + CH_3CCH \qquad (12)$$

This is proved by the constance of $G(CH_4)$ in the presence of air traces, when the irradiation dose is increased. On the other hand, in our experimental conditions, other processes can become also important, and that is the reason for the steep increase of $G(CH_4)$ with increasing the irradiation dose in the absence of air traces (figure 2). Thus, "hot" hydrogen addition to isobutylene can lead to the methane formation, *via* an unstable intermediate complex

---

[15] K. R. Jennings and R. J. Cvetanovic, *J, Chem. Phys.*, **35**, 1233 (1964).

[16] Y. Hatano and S. Shida, *J. Chem. Phys.*, **46**, 4784 (1967).

[17] Y. Hatano, S. Shida and S. Sato, *Bull. Chem. Soc. Japan*, **41**, 1120 (1968).

[18] J. Niedzielski and J. Gawlowski, *Radiochem. Radioanal. Letters*, **2**, 291 (1969).

$$i - C_4H_8 + H \longrightarrow [i - C_4H_9] \longrightarrow CH_4 + C_3H_5 \qquad (13)$$

That is supported by the appearance of CD_3H and CH_3D in the radiolysis of $i\text{-}C_4H_8 - i - C_4D_8$ mixture.[10]

The methyl radical addition to isobutylene can finally lead to methane formation.

It is possible that among the secondary processes which are eliminated by oxygen traces, there are some ion-molecule reactions, which might be responsible for methane formation.

5. CONCLUSIONS

The experimental conditions have a considerable influence on the nature and amount of radiolysis products of isobutylene.

High pressure leads to formation of addition products, while at low pressure the decomposition processes are more important.

The irradiation dose has a small effect on $G(H_2)$, but is very important for $G(CH_4)$, because of the secondary processes.

Oxygen traces are important for the formation of the main products like hydrogen and methane.

THE GALVANOSTATIC STUDY OF THE ELECTROCHEMICAL ADSORPTION PROCESS ON THE CHLORINE-ACTIVE CARBON ELECTRODE IN MOLTEN SALTS. I

ANODIC AND CATHODIC POLARIZATION CURVES

S. STERNBERG and VALERIA PETRESCU
Polytechnical Institute, Str. Polizu 1, Bucharest, Romania

Received February 1, 1973

The adsorption — desorption process of the chlorine on the active carbon electrode in the AgCl—KCl system has been studied at : 400°, 500°, 600°, 700°. The existence of the thermal desorption current, that increases with increasing temperature, is evidenced. The efficiency of the charge — discharge process was determined as a function of the charge time process, t_c, and the temperature T. The existence of a remanent potential that depends on the charge and discharge current intensities I_c, I_d, on the charge time process, t_c, and the temperature T, is pointed out.

1. INTRODUCTION

The utilization of the galvanostatic charge — discharge curves method in the study of the electrochemical adsorption — desorption phenomenon of iodine on the active carbon was described in a previous paper.[1] In the present paper the same method is applied to the study of chlorine — active carbon electrode.

The scheme of the installation and the mode of obtaining the active carbon was described in previous papers.[1,2,3] A semiactive carbon electrode in the molten salt electrolyte AgCl + KCl, $x_{\mathrm{AgCl}} = 0.7$, was used at 400°, 500°, 600°, 700°.

The active carbon electrode is subjected to an anodic polarization process at a constant current intensity ($I_c = 0.1$ A) for 60 minutes obtaining the charge curve (anodic polarization curve) *oa* plotted in fig. 1. Then, the active carbon electrode was subjected to cathodic galvanostatic polarization (the intensity of current $I_d = 0.1$ A) in order to produce the electrochemical desorption of the adsorbed chlorine. In this way it was obtained the discharge curve (cathodic polarization curve) *ab* (fig. 1).

---

[1] S. Sternberg and I. Galasiu, *Rev. Roumaine Chim.*, in press.
[2] S. Sternberg and I. Galasiu, *Rev. Roumaine Chim.*, **15**, 1169 (1970).
[3] S. Sternberg and I. Galasiu, *Rev. Roumaine Chim.*, **17**, 1697 (1972).

The shape of the charge — discharge curve can be explained in the same way as the corresponding curve in the case of the active carbon-iodine electrode. On the zone *oa* of the anodic polarization curve (charge process) the discharge reaction of the chlorine ions takes place, producing the adsorbed chlorine, probably in atomic state:

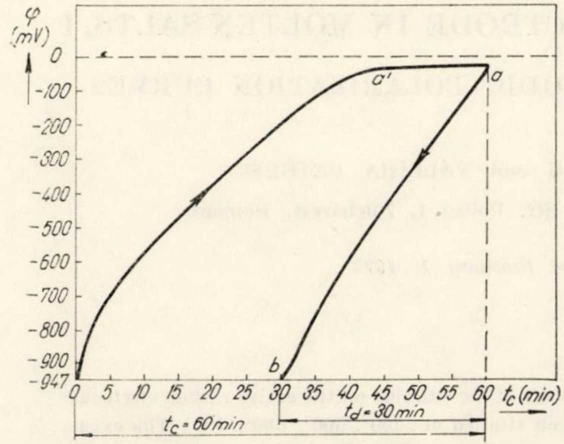

Fig. 1. — Anodic and cathodic polarization curves with $t_c = 60$ minutes; $I_c = I_d = 0.1$ A; $T = 400°$.

$$\mathrm{Cl^- = Cl\ (ads) + e^-} \qquad \text{(a)}$$

But, as it will be shown later, on this zone (*oa*) the efficiency $\eta = Q_d / Q_c$ (Q_d — quantity of electricity in the discharge process, Q_c — quantity of electricity in the charge process) is smaller than the unity. This action can be explained by the existence of a "thermal desorption" which can take place by the scheme:

$$\mathrm{2Cl\ (ads) \rightarrow Cl_2\ (ads) \rightarrow Cl_2\ (gas\ or\ dissolved\ in\ the\ salt)} \qquad \text{(b)}$$

During the discharge process *ab* (fig. 1), the process described by equation (a) occurs, but in the reversed direction. On the other hand, the thermal desorption is present too.

For a given system and a given temperature, the charge—discharge curves are different depending on the charge and discharge current intensity values (I_c and I_d) and depending also on the length of the charging process (t_c). These curves differ from each other because of the charging losses $Q_{cl} = \int_0^{t_c} dQ_{cl}$ and of the discharging losses $Q_{dl} \int_0^{t_d} dQ_{dl}$. These losses account for the hysteresis shape of the curves typically for irreversible processes.

The length of the discharge process t_d is smaller than the length of the charging process t_c, due to the mentioned losses and so the irreversibility of the process is made evident (by hysteresis curves *oa′ ab*, fig. 1).

2. ANODIC AND CATHODIC POLARIZATION CURVES

In fig. 2 (*a*, *b*) there are represented the discharge — charge curves obtained for several values of t_c, at the temperatures 400°, 500°, 600°, 700° and for different values of the current intensites $I_c = I_d = 0.05-0.15$ A.

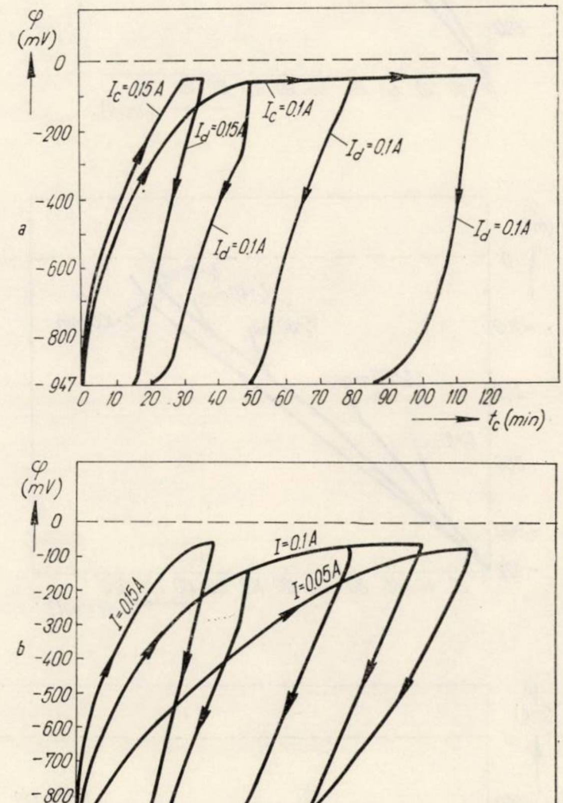

Fig. 2. — Anodic and cathodic polarization curves; *a*. $T = 400°$, $I_c = I_d = 0.15$ A and $I_c = I_d = 0.1$ A; *b*. $T = 500°$, $I_c = I_d = 0.15$ A, $I_c = I_d = 0.1$ A and $I_c = I_d = 0.05$ A.

We can see that the hysteresis curves obtained are different. After a certain length of the charge process the active carbon electrode potential tends to a plateau. The potential value at the plateau decreases and the time necessary to reach it increases with the temperature increase. At the same temperature, the value of the plateau potential decreases and the time

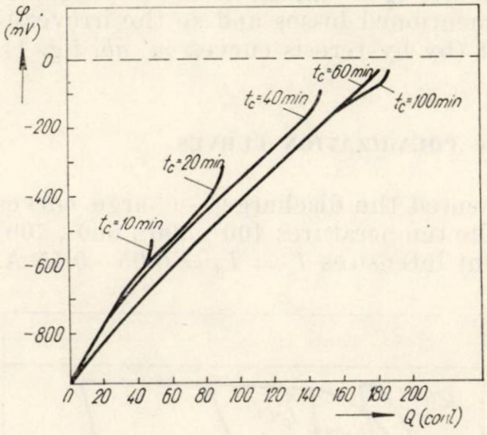

Fig. 3. — φ/Q curve for 400°, $I_c = I_d = 0.1$ A.

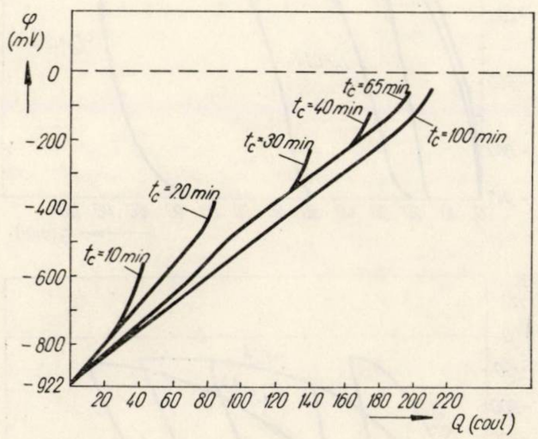

Fig. 4. — φ/Q curve for 500°, $I_c = I_d = 0.1$ A.

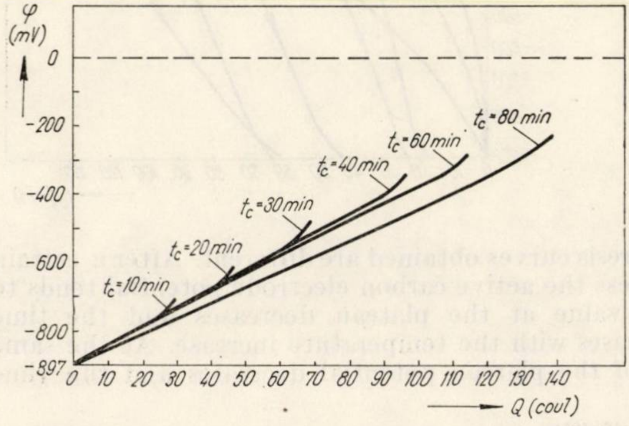

Fig. 5. — φ/Q curve for 600°, $I_c = I_d = 0.1$ A.

necessary to reach it increases with the decreasing of the intensity of the charge current.

In figs. 3−6 φ/Q curves are represented for different temperatures (400°−700°). These curves are obtained by overlapping in the origin of the discharge curves for different lengths of charging. At the beginning of every discharge curve, there is a zone with a steeper slope followed by a slower slope. When the length of the charge process increases we can notice the tendency of disappearance of the zones with the steep slope, the discharge curve having a slow slope on the whole of its length.

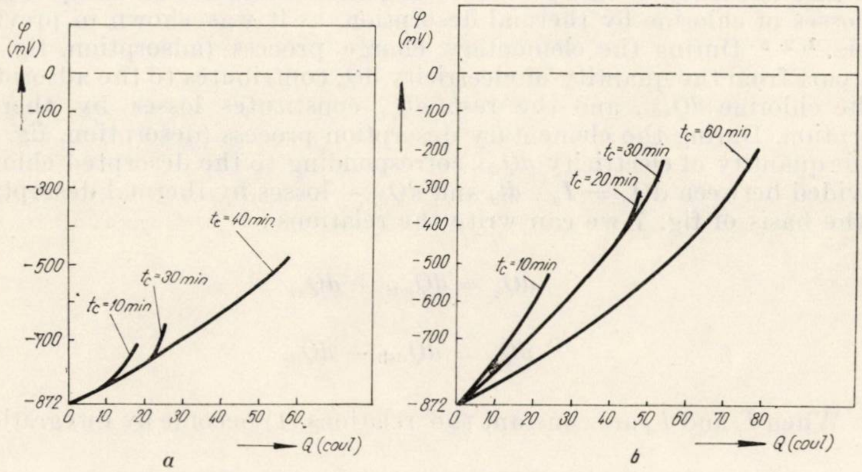

Fig. 6. — φ/Q curve for 700° ; a . $I_c = I_d = 0.1$ A ; b . $I_c = I_d = 0.2$ A.

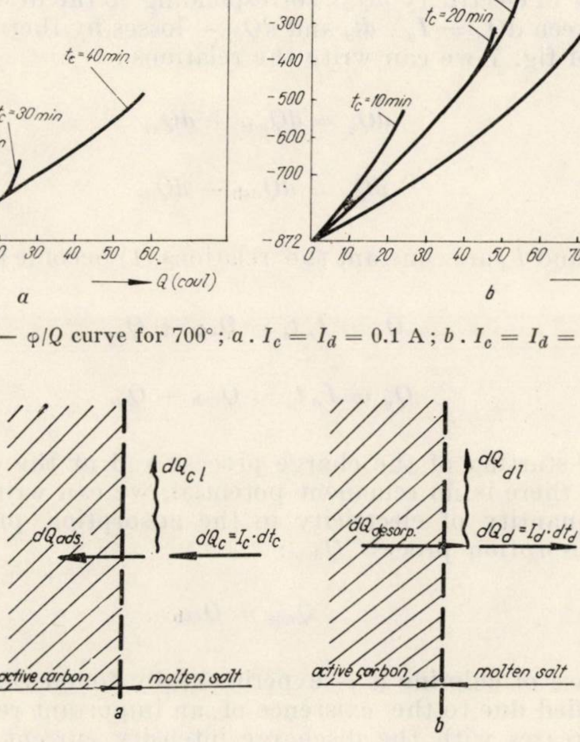

Fig. 7. — Scheme of the electrochemical adsorption — desorption process of the chlorine on the active carbon electrode (a — adsorption ; (b — desorption).

The appearance of the zones with steep slope and their tendency to decrease could be explained by a mechanism pointed out by the study of the so-called remanent potential phenomenon, which has appeared in this system more obviously.

In the following we will show how and to what degree the adsorption — desorption process is affected by the remanent potential phenomenon.

The electrochemical adsorption — desorption process of the chlorine on the active carbon electrode in molten salt is diagrammatically presented in fig. 7.

The efficiency of this process is in general smaller than unity due to the losses of chlorine by thermal desorption, as it was shown in previous papers.[1, 2, 3] During the elementary charge process (adsorption, fig. 7*a*) $\mathrm{d}t_c$ a part from the quantity of electricity $\mathrm{d}Q_c$ contributes to the adsorption of the chlorine dQ_{ads}, and the rest dQ_{cl} constitutes losses by thermal desorption. During the elementary desorption process (desorption, fig. 7*b*) $\mathrm{d}t_d$ the quantity of electricity dQ_{dsb} corresponding to the desorpted chlorine is divided between $\mathrm{d}Q_d = I_d \cdot dt_d$ and dQ_{dl} — losses by thermal desorption. On the basis of fig. 7 we can write the relations :

$$dQ_c = dQ_{\mathrm{ads}} + dQ_{cl} \tag{1}$$

$$dQ_d = dQ_{\mathrm{dsb}} - dQ_{dl}$$

When I_c and I_d are constant the relations (1) become by integration :

$$Q_c = I_c\, t_c = Q_{\mathrm{ads}} + Q_{cl} \tag{2}$$

$$Q_d = I_d\, t_d = Q_{\mathrm{dsb}} - Q_{dl} \tag{3}$$

If at the starting of the charge process and at the end of the discharge process there is no remanent potential, we can write the equality between the quantity of electricity in the adsorption process Q_{ads} and that in the desorption process Q_{dsb} :

$$Q_{\mathrm{ads}} = Q_{\mathrm{dsb}} \tag{4}$$

In the case of chlorine it is experimentally found that the equality (4) is not satisfied due to the existence of an important remanent potential which increases with the discharge intensity current. The presence of the remanent potential is explained by the fact that during the discharge process which takes place with finite intensity, a part from the adsorbed chlorine remains in the active carbon although at the surface of the active carbon electrode the potential becomes zero. After interrupting the discharge current a part of the chlorine which remains in the carbon electrode, migrate by diffusion towards the surface, generating the increase of the electrode potential up to the remanent potential value. If we denote by Q_{rem}, the quantity of electricity which could be obtained by desorption of the remained chlorine in the carbon electrode, after the potential had become zero in the discharge process, we can write the following relation :

$$Q_{\text{ads}} = Q_{\text{dsb}} + Q_{\text{rem}} \tag{5}$$

This relation is available when the remanent potential of the carbon electrode is zero at the beginning of the anodic polarization process. Substituting Q_{dsb} from (5) into (3) it is obtained :

$$Q_d = Q_{\text{ads}} - Q_{\text{rem}} - Q_{dl} \tag{6}$$

We have found that the presence of the remanent phenomenon acts like a loss which is added to the thermal desorption loss Q_{dl}, decreasing the quantity of electricity Q_d which is obtained during the discharge process.

In the experimental study of the chlorine adsorption — desorption process on active carbon electrode it is necessary in the first place to find an estimation modality of the remanent potential Q_{rem}. On the other hand, it is to be found a modality to bring the carbon electrode in the potential state zero in order to ascertain the reproductibility of the results. If this condition is not satisfied, the charge — discharge curves look like those in fig. 8.

Starting the anodic polarization process *ab* from the point *a*, in which the remanent potential is $\varphi_{\text{rem.o}}$, the anodic polarization curve will have a shape depending just on this remanent potential. Consequently, the length of the charge process up to the plateau will depend also on $\varphi_{\text{rem.o}}$ .After the discharge process (cathodic polarization process) *bc*, at interrupting the discharge current I_d we have found that the carbon electrode potential increases (the curve *cd*, fig. 8) amounting to a plateau which corresponds to a final remanent potential $\varphi_{\text{rem.f}}$. It is evident that the starting of a new anodic — cathodic polarization cycle from the point *d*, in which the final remanent potential $\varphi_{\text{rem.f}}$ becomes now the initial remanent potential, different from $\varphi_{\text{rem.o}}$, will lead to the anodic — cathodic polarization curve *db'c'*, different from the previous one *abc*.

Thus in these conditions we cannot obtain the reproducibility of the results.

Admitting the hypothesis that the remanent potential is due to the diffused chlorine in the active carbon pores, which has no time to go out totally during the cathodic polarization process (with $I_d = 0.1$ A), we have considered that it is possible to "extract" the chlorine using a relatively small discharge current (0.02 A).

In fig. 9 it is shown the process by which we can estimate Q_{rem}. After the cathodic polarization process with $I_d = 0.1$ A having the length t_d (the process *ab*) the current is interrupted and a t_{relax} time is expected, in which the carbon potential increases "by itself" (by the diffusion of the chlorine from the inner side of the pores to their outer side) up to a plateau corresponding to the remanent potential φ_{rem}. Then, the carbon electrode is discharged with a relatively small current $I_d = 0.02$ A, result-

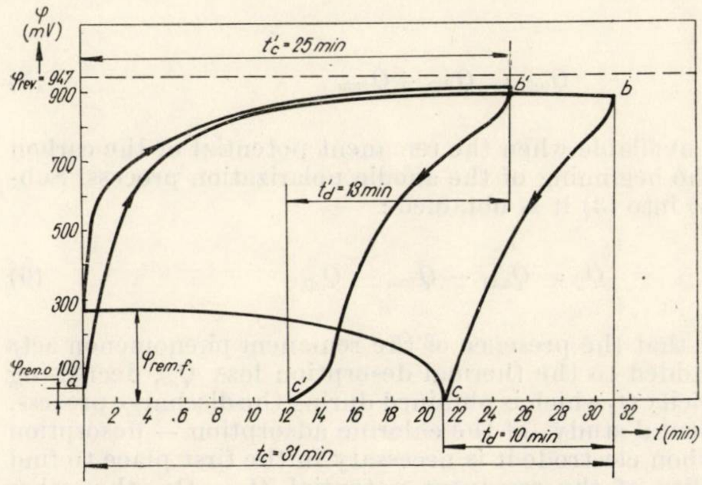

Fig. 8. — Charge — discharge curves when the carbon electrode is not in the potential state zero ; $T = 400°$.

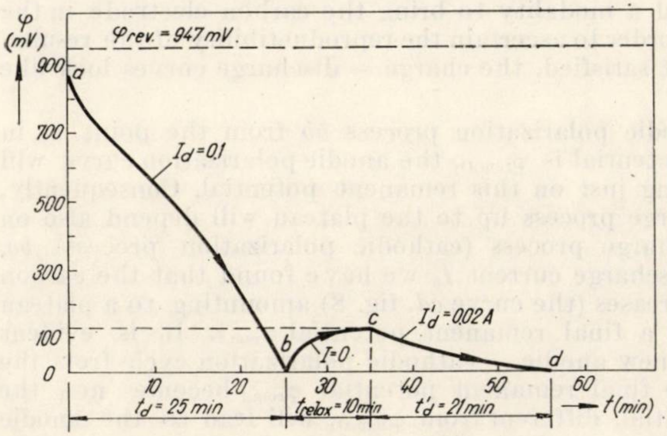

Fig. 9. — Process by which one can estimate Q_{rem} ; $T = 400°$; $I_c = 0.1$ A ; $t_c = 40$ minutes.

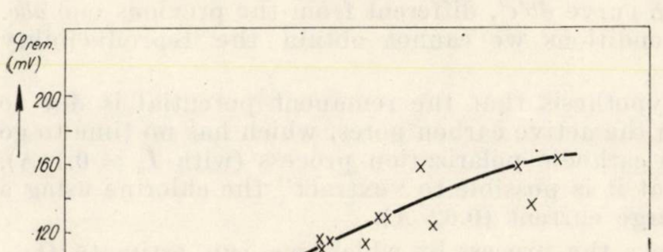

Fig. 10. — Dependence between $\Delta t_{\text{rem}}(Q_{\text{rem}})$ and φ_{rem}, $T = 400°$.

ing a t_d time. Thus, it is possible to estimate Q_{rem} by the relation :

$$Q_{\text{rem}} = I'_d \ t'_d \tag{7}$$

It is possible also to calculate the remanent correction of the t_d time, denoted by Δt_{rem}, which represents how smaller is the t_d discharge length compared to the situation in which the remanent phenomenon could not exist :

$$\Delta t_{\text{rem}} = Q_{\text{rem}}/I_d = I'_d t'_d / I_d \tag{8}$$

As is found experimentally the remanent correction increases with the discharge current intensity and has considerable values.

Using this method, besides the fact that we estimate Δt_{rem}, we can bring the carbon in the zero remanent potential state ($\varphi_{\text{rem}} = 0$) and in this way one can start a new charge—discharge cycle obtaining the reproducibility of the process by identical initial and final conditions. We have found experimentally that the remanent correction Δt_{rem} is dependent on the remanent potential φ_{rem} . It is evident that this fact is expected in the above mentioned hypothesis by which one considers the chlorine diffusion in pores as a cause of the remanent phenomenon. In fig. 10 it is shown the dependence between Δt_{rem} (Q_{rem}) and φ_{rem}.

It is expected that Δt_{rem} must depend on the discharge current intensity I_d and the quantity of electricity consumed in the charge process Q_c. This fact was observed experimentally (fig. 11).

3. CURRENT EFFICIENCY

It can be seen that Δt_{rem} increases linearly with the increase of I_d, for a Q_c constant. On the other hand, for I_d constant Δt_{rem} increases with the increase of Q_c. It is to be noted that the values of Q_{rem} are not at all negligible. Thus, for $I_d = 0.1$ A at $Q_c = 60$ coul corresponds a $Q_{\text{rem}} = 12$ coul, which represents $Q_{\text{rem}} = 20\%\ Q_c$. For $I_d = 0.1$ A and $Q_c = 24$ coul corresponds a $Q_{\text{rem}} = 8.1$ coul, which represents 33.8% from Q_c. It results that the remanent phenomenon affects considerably the efficiency of the anodic-cathodic polarization process :

$$\eta = Q_d / Q_c \tag{9}$$

This fact was observed experimentally. In the study of the dependence of the efficiency on the anodic polarization process length t_c, it is necessary to find out the variance of Δt_{rem} by t_c in order to estimate a

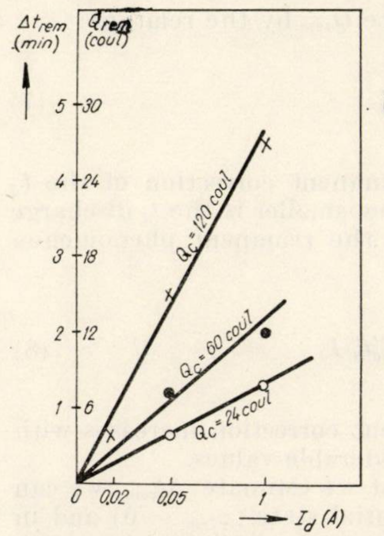

Fig. 11. — Δt_{rem} depends on the I_d and the Q_c.

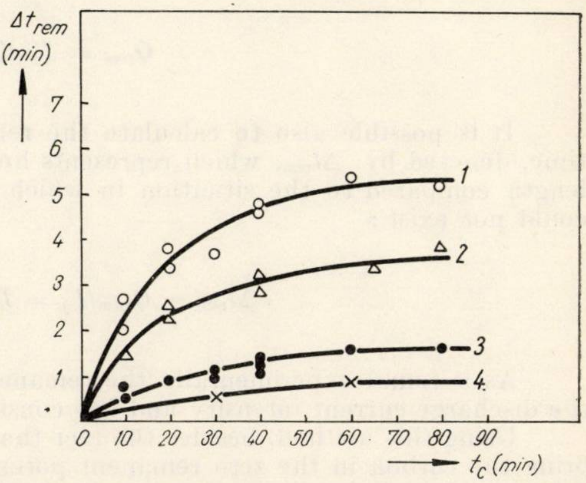

Fig. 12. — It is plotted Δt_{rem} as a function of t_c; *1*, 400°; *2*, 500°; *3*, 600°; *4*, 700°.

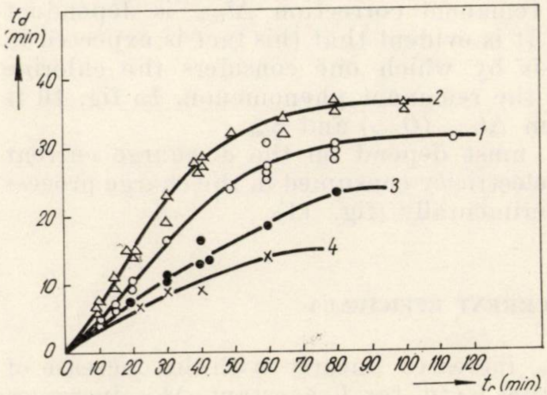

Fig. 13. — Dependence between t_d and t_c; *1*, 400°; *2* 500°; *3*, 600°; *4*, 700°.

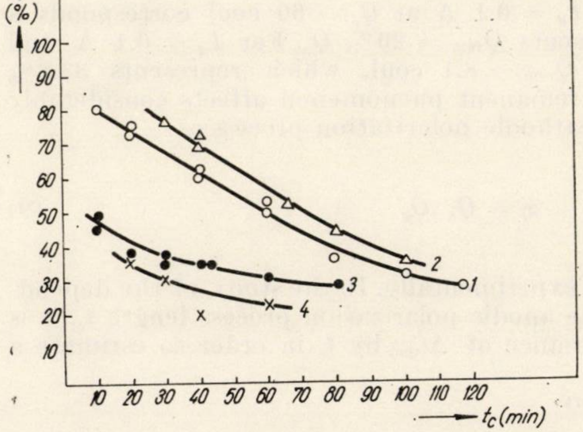

Fig. 14. — Dependence between efficiency η and t_c; *1*, 400°; *2*, 500°; *3*, 600°; *4*, 700°.

corrected efficiency :

$$\eta_{\text{cor}} = \frac{Q_d + Q_{\text{rem}}}{Q_c} = \frac{(t_d + \Delta t_{\text{rem}})\, I_d}{t_c\, I_c} \tag{10}$$

In fig. 12 is plotted Δt_{rem} as a function of t_c. We observe that Δt_{rem} increases up to the value of $t_c = 60$ minutes, and then it tends to a plateau. This can be explained by the fact that the adsorbed chlorine quantity tends to a plateau at the same time with the increase of t_c (fig. 13). Consequently, it is to be expected that Q_{rem} should not increase above a maximum value as well, whichever the t_c charge time would be. The remanent correction decreases with the increase of the temperature. At 700° it becomes practically negligible (approximately equal to one minute)

The efficiency :

$$\eta = Q_d/Q_c = t_d/t_c \tag{11}$$

was computed using the experimental data.

In fig. 14 it is plotted the efficiency as a function of charge length for different temperatures (400°, 500°, 600°, 700°). We can see that the efficiency increases from 400° to 500° and over 500° decreases very quickly. The decrease of efficiency with the increase of charge length can be explained by the increase of thermal desorption losses while the electrode potential tends to a plateau (on the plateau the thermal desorption loss in the anodic polarization process becomes equal even with the charge current).

For the same temperatures we have computed the remanent correction, using the above method and we have estimated the corrected efficiency by relation (10) ($I_c = I_d = 0.1$ A)

$$\eta_{\text{cor}} = \frac{t_d + \Delta t_{\text{rem}}}{t_c} \tag{12}$$

In order to emphasize the influence of the remanent phenomenon on the efficiency, the dependence of efficiency η and of the corrected efficiency is represented as function of the charge length at the temperature 400° (fig. 14). We observe that the influence of the remanent phenomenon is more obvious at small charge times.

In fig. 16 it is plotted the corrected efficiency (computed by relation (12)) as function of temperature for different charge lengths. For a certain charge time, a maximum of the corrected efficiency for a temperature of about 500° appears. The appearance of the above mentioned maximum can be explained by the existence of two factors with contrary influences due to the increase of the temperature. On the one hand, the increase of temperature produces the decrease of the viscosity which favoures the penetration of the salt deeper into the pores wetting in this way a larger active surface. This would correspond to an increase of the adsorbed chlorine quantity. On the other hand, the increase of the temperature favoures the increase of the thermal desorption losses, at the charge and discharge processes as well, which explains the tendency of a quick decrease of the efficiency over a certain value of the temperature.

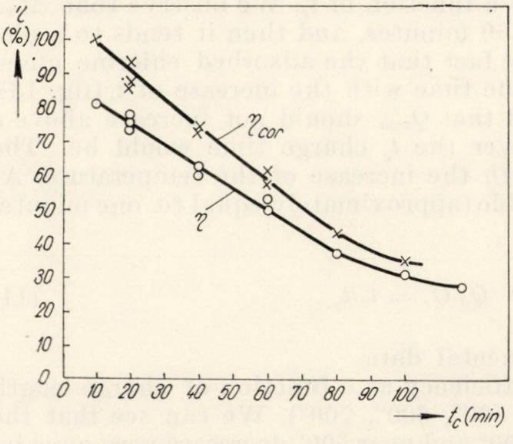

Fig. 15. — Efficiency η and corrected efficiency η_{cor} as a function of t_c ; $T = 400°$.

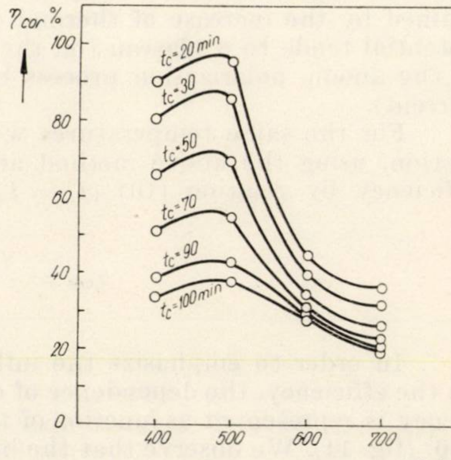

Fig. 16. — The corrected efficiency as function of the temperature for different charge lengths.

We can observe that the maximum corrected efficiency decreases and the efficiency curve tends to a flat curve while the charge time increases. The decrease of the maximum can be explained by the increase of the charge losses with the increase of the charge time. The thermal desorption losses in the anodic polarization process became at the plateau equal to the charge current intensity.

Received March 7, 1973

The $[Co(DH)_2(NO_2)(CN)]^-$ complex (where DH_2 stands for dimethylglyoxime : $C_4H_8N_2O_2$) has been obtained from the non-electrolyte $[Co(DH)_2(NO_2)(H_2O)]$ by a substitution reaction with KCN. From the aqueous solution of the resulting $K[Co(DH)_2(NO_2)(CN)]$ the complex acid and 8 new salts were separated by means of double decomposition reactions. On the basis of i.r. spectrum some structural problems are discussed. The basic hydrolysis of the $[Co(DH)_2(NO_2)(CN)]^-$ anion was colorimetrically studied and the calculated kinetic parameters were compared with those of other $[Co(DH)_2XY]^-$–type complexes.

The first dimethylglyoximin-nitro-cobalt (III)-chelate: $Na[Co(DH)_2(NO_2)_2].H_2O$ has been prepared by Chugaev [1] by a substitution reaction from $Na_3[Co(NO_2)_6]$ with dimethylglyoxime. The synthesis and characterization of some new derivatives of the $H[Co(DH)_2(NO_2)_2]$ acid were reported in our previous papers.[2–4]

The sodium salt undergoes an aquation process in acidic solutions. The aquation product, the aquo-nitro-non-electrolyte $[Co(DH)_2(NO_2)(H_2O)]$, can be used for a series of anatation reactions. The coordinated water molecule can be replaced by monovalent anions, as Cl^-, Br^-, I^-, NCS^-, N_3^-, NCO^-, $NCSe^-$ and even by SO_3^{2-} and $S_2O_3^{2-}$. Several mixed bis-dimethylglyoximine-nitro-cobalt (III) complex acids obtained in this way: $H[Co(DH)_2Cl(NO_2)]$, $H[Co(DH)_2Br(NO_2)]$ and $H[Co(DH)_2I(NO_2)]$ were described by Ablov and co-workers.[5–6]

Mixed cyano-complexes of this type have not been yet reported. Other mixed cyano-complexes of the trivalent cobalt, as $H_2[Co(CN)_5(H_2O)]$,[7] $H[Co(CN)_4(H_2O)_2]$ [8] and the halogeno-pentacyano-acids : $H_2[Co(CN)_5X]$ ($X = Cl, Br, I$) [9] are well known and the exchange of the coordinated halogens was kinetically studied.[10,11]

We observed that the anatation reaction of $[Co(DH)_2(H_2O)(NO_2)]$ with stoichiometric amount of KCN leads to the formation of the easily soluble $K[Co(DH)_2(CN)(NO_2)]$. From the aqueous solution of this potassium salt, some new derivatives have been obtained with the hydrochlorides of some heterocyclic amines and complex cations of the diacido-tetramine type. The best precipitating agents for the above cyano-nitro-complex are the $[Co(DH)_2(amine)_2]^+$ type cations, as well as for the other monobasic complex acids of the $H[Co(DH)_2X_2]$ type.

The hexamine- and monoacido-pentamine cobalt(III)- and chromium(III)-complexes are unsuitable for this precipitation reaction. Some derivatives of the $H[Co(DH)_2(CN)(NO_2)]$ acid are characterized in table 1.

The i.r. spectrum of $K[Co(DH)_2(CN)(NO_2)]$, presented in fig. 1, shows the presence of strong intramolecular O—H..O hydrogen bridges, similar to those observed in the case of the analogous dimethylglyoxime derivatives:[12] (ν_{O-H} : 2400 cm^{-1}(w) and δ_{O-H} 1720—1750 cm^{-1} (m).

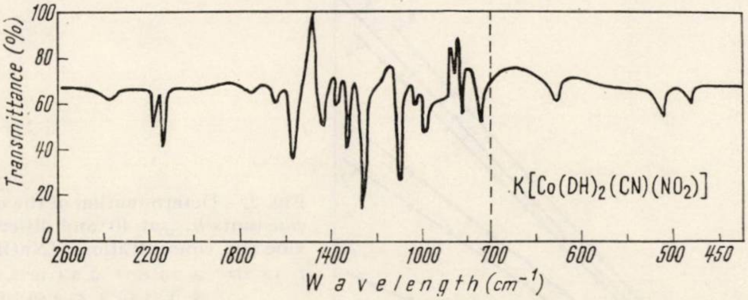

Fig. 1. — I. R. spectrum of $K[Co(DH)_2(CN)(NO_2)]$.

Valence vibrations of nitro group : ν_{as} and $\nu_s (NO_2)$ and the deformation vibrations δ_{O-N-O}, ρ_w (NO_2) appear at 1433 (v.s.), 1338 (s), 830 (s), 625 (m), cm^{-1}, respectively, as in the case of other nitro-cobalt (III)-complexes: $Na_3[Co(NO_2)_6]$,[13] $K[Co(DH)_2(NO_2)_2]$, not influenced by the coordination effect.

The strong absorption bands at 2182 and 2150 cm^{-1} are due to the valence vibrations of the coordinated cyano-group. The considerable shift of these vibrations as compared to those of the KCN (2080 cm^{-1}) can be explained by means of the resonance theory and pleads for the existence of Co—C bond.[14,15]

In aqueous solution of the cyano-nitro-complex a ligand exchange reaction occurs leading to the liberation of NO_2^-.

This process is similar to those observed in the case of other corresponding dimethylglyoxime- and alycyclic 1,2-dioxime derivatives, previously investigated.[16-18]

Aquation kinetics of the $[Co(DH)_2(CN)(NO_2)]^-$ ion in basic solutions was experimentally studied. Kinetic measurements were carried out at different temperatures in the presence of different amounts of NaOH at a constant ionic strength of $\mu = 1$ M maintained with $NaNO_3$. The concentration of the liberated NO_2^- ions was followed by colorimetric measurements.

The graphical plot of log C_0/C *versus* time showed a good linearity up to 50–60% of the reaction, as seen in fig. 2. From the slopes of these straight lines, first order rate constants were derived. These overall rate constants k_{exp} are given in table 2.

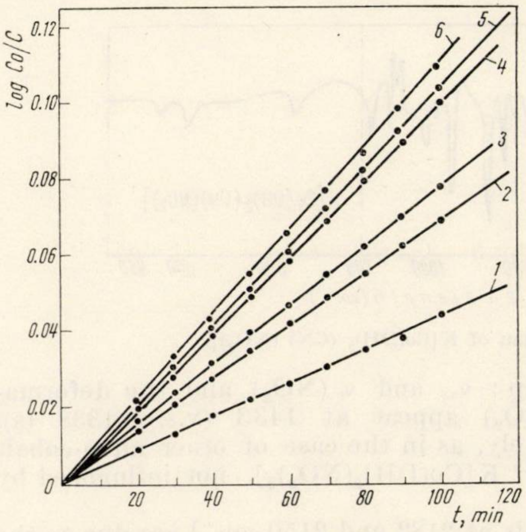

Fig. 2.—Determination of the overall rate constants k_{exp} at 40° and different hydroxide ion concentrations [NaOH] mole/l : *1*, $1.8 \cdot 10^{-3}$, *2*, $3.6 \cdot 10^{-3}$, *3*, $5.4 \cdot 10^{-3}$, *4*, $9.0 \cdot 10^{-3}$, *5*, $1.35 \cdot 10^{-2}$, *6*, $1.80 \cdot 10^{-2}$

At a given temperature, the overall rate constant k_{exp} increases with increasing hydroxide ion concentration and at higher basicities approaches a limiting value.

Table 2

Overall first order aquation rate constants for $[Co(DH)_2(CN)(NO_2)]^-$ at various hydroxide ion concentrations

$[NaOH] \cdot 10^3$ mole/l	$k_{exp} \cdot 10^5$, s^{-1}			
	29°	35°	40°	45°
1.8	—	0.94	1.67	—
3.6	0.83	1.35	2.65	
5.4	0.99	1.61	3.00	
7.2	1.04	1.81	—	5.60
9.0	1.12	1.90	3.84	6.45
13.5	1.19	2.13	3.95	7.14
18.0	1.25	—	4.20	7.41

The experimental data given in table 2 suggest the existence of a pre-equilibrium and the parallel aquation of two complex species with differing rates. In our experimental conditions there is an equilibrium between the species $[Co(DH)_2(CN)(NO_2)]^-$ and $[Co(DH)(D)(NO_2)(CN)]^{2-}$, i.e. a deprotonation of a coordinated dimethylglyoxime molecule occurs :

$$[Co\ (DH)_2\ (CN)\ (NO_2)]^- \overset{K}{\rightleftharpoons} [Co(DH)(D)(CN)(NO_2)]^{2-} + H^+ \qquad (1)$$

where K stands for the acidity constant of the $[Co(DH)_2(CN)(NO_2)]^-$ complex.

In this case the following aquation processes may take place:

$$[Co(DH)_2(CN)(NO_2)]^- + H_2O \xrightarrow{k_A} [Co(DH)_2(CN)(H_2O)] + NO_2^- \qquad (2)$$

$$[Co(DH)(D)(CN)(NO_2)]^{2-} + H_2O \xrightarrow{k_B} [Co(DH)(D)(CN)(H_2O)]^- + NO_2^- \qquad (3)$$

(k_A and k_B stand for the rate constants of the reactions (2) and (3)).

In each of these reactions, the aquation leads to the formation of an aquo-complex, but in alkaline solutions they must undergo a fast deprotonation and the final products are $[Co(DH)_2(CN)(OH)]^-$ and $[Co(DH)(D)(CN)(OH)]^{2-}$, respectively.

This scheme is to some extent similar to the S_N1 CB or S_N2 CB mechanisms proposed by Garrick[19] and extended by Basolo and Pearson.[20] It has also been suggested and discussed in our previous paper[18] in order to explain the kinetic behaviour of other nitro-complexes.

The following simple relation can be derived for the overall rate constant k_{exp} as a function of rate constants for the two species and the acidity constant of the conjugated acid:

$$k_{exp} = (k_B - k_A)\frac{[OH^-]}{K_w/K + [OH^-]} + k_A \qquad (4)$$

where K_w stands for the ionic product of water.

Since $k_A \ll k_B$, and at higher $[OH^-]$ values the equilibrium is shifted to the conjugated base, the aquation of the conjugated acid can be neglected ($k_A = 0$) and equation (4) may be written in the following form:

$$\frac{1}{k_{exp}} = \frac{K_w}{K\,k_B}\cdot\frac{1}{OH^-} + \frac{1}{k_B} \qquad (5)$$

Using the equation (5), K and k_B can be determined by a graphical method. If the above scheme is correct and the contribution of reaction (2) is very small, the plot of $\frac{1}{k_{exp}}$ *versus* $1/[OH^-]$ must give a straight line. The ordonate intercepts of these straight lines give $1/k_B$ and their slopes equal $K_w/K.\,k_B$, which allows us to derive both K and k_B from the experimental data (See fig. 3).

[19] F. J. GARRICK, *Nature*, **139**, 507 (1937).

[20] F. BASOLO and R. G. PEARSON, "Mechanism of Inorganic Reactions", 2nd ed., John Wiley, New York, 1967, p. 183.

These K and k_B values, derived from the data presented in table 2, are given in table 3.

The plot of log K *versus* $1/T$ showed a rather good linearity and allowed to derive enthalpy and entropy values for the reaction (1). By means of the least square method the following values have been obtained : $\Delta H^{\ddagger} = 4.8 \pm 0.8$ kcal/mole, $\Delta S^{\ddagger} = 35.8 \pm 2.5$ Cl.

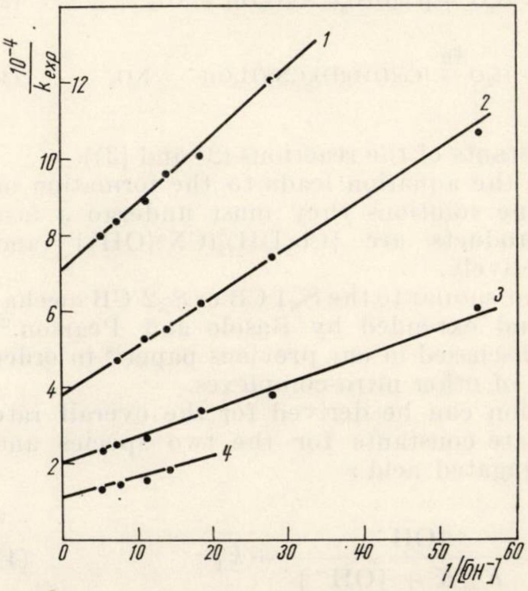

Fig. 3. — Determination of K and k_B values at different temperatures : *1*, 29° ; *2*, 35°, *3*, 40°, *4*, 45°.

Table 3

Equilibrium constants of reaction (1) and rate constants of reaction (3)

t°C	$K \times 10^{12}$	$k_B \times 10^5$, s^{-1}
29	5.52	1.42
35	6.37	2.62
40	7.76	5.21
45	8.04	9.71

By using the linear relationship between log k_B/T and $1/T$, the activation enthalpy and entropy values have been calculated for the aquation reaction of the conjugated base.

The following values have been obtained by means of the least square method :

$$\Delta H^{\ddagger} = 22.5 \pm 0.4 \text{ kcal/mole}, \quad \Delta S^{\ddagger} = -6.5 \pm 1.2 \text{ Cl}$$

In order to compare these results with those obtained for other similar nitro-complexes, the rate constants, acidity constants and kinetic parameters for the different studied species are presented in table 4.

The equilibrium constants K show $[Co(DH)_2(OH)(NO_2)]^-$ to be a weaker acid than $[Co(DH)_2(NO_2)_2]^-$ and $[Co(DH)_2(CN)(NO_2)]^-$, in agreement with the large *trans*-effect of both NO_2 and CN groups as compared to that of OH, owing to the larger electron withdrawing ability of the formers.

Table 4

Equilibrium data and kinetic parameters for the basic hydrolysis of some nitro-dimethylglyoximino-cobalt(III) complexes

Species	$K \times 10^{12}$	$k \times 10^4$, s^{-1}	$\Delta H^{\neq}$ kcal/mole	$\Delta S^{\neq}$, Cl	Reference
	at 40°C				
$[Co(DH)(D)(CN)(NO_2)]^{2-}$	7.76	0.52	22.5	−6.5	this paper
$[Co(DH)(D)(NO_2)(NO_2)]^{2-}$	7.29	2.25	22.1	−4.7	18
$[Co(DH)(D)(OH)(NO_2)]^{2-}$	1.47	1.83	27.6	12.4	18

Assuming a dissociation mechanism, the activation enthalpy values are rather easily interpreted. Each of the complex species presented in table 4 has the same electric charge, and their structure differs only by the nature of the *trans*-situated ligand.
In the case of both $[Co(DH)(D)(NO_2)_2]^{2-}$ and $[Co(DH)(D)(CN)(NO_2)]^{2-}$ a considerable decrease of the activation enthalpy occurs, as compared to the $[Co(DH)(D)(OH)(NO_2)]^{2-}$ -ion. This decrease can be explained in terms of the π-acceptor property of the NO_2 and CN groups. The formation of π-bonds between these groups and the central Co atom considerably reduces the strength of the σ-bond between the central atom and the leaving NO_2-group.

It can be observed from table 4 that aquation reactions with the lowest activation enthalpies have negative activation entropy values, whereas the activation entropy of the reaction with the highest activation enthalpy is clearly positive. This quite parallel increase of both $\Delta H^{\neq}$ and $\Delta S^{\neq}$ is an example for the kinetic compensation effect and presumably it indicates the mechanism of all these reactions to be the same, *viz.* the dissociation of the ligand to be replaced is followed by the coordination of a water molecule to the active intermediate with coordination number 5.

EXPERIMENTAL

PREPARATION OF $K[Co(DH)_2(CN)(NO_2)]\ 1/2\ H_2O$

50 mmole of $[Co(DH)_2(H_2O)(NO_2)]$ and 50 mmole of KCN in 50–60 ml water are shaken for 5–10 minutes. The brown-red crystals of the $[Co(DH)_2(H_2O)(NO_2)]$ disappear and sparkling light brown thin plates are separated from the solution.

The very easily soluble crystalline precipitate is filtered and dried on porous porcelain plate without washing.

Analysis. *Calcd.* : Co 14.40, H_2O 2.20, N 20.53

SYNTHESIS OF $M[Co(DH)_2(CN)(NO_2)]$ AND $[M^{III}(AMINE)_4X_2]$ $[Co(DH)_2(CN)(NO_2)]$

5 mmole of MNO_3 and of the corresponding diacido-tetramine salt in 50—100 ml water are treated with 5 mmole of $K[Co(DH)_2(CN)(NO_2)]$ in 50 ml water. The crystalline precipitate is filtered after 1—2 hr, washed with a small amount of water and dried in air.

SYNTHESIS OF $[Co(DH)_2(AMINE)_2]$ $[Co(DH)_2(CN)(NO_2)]$ TYPE BINARY SALTS

To a solution of 5mmole of $Co(DH)_2$ (amine)$_2$-acetate in 60—80 ml alcohol 60—70%, a solution of 5 mmole of $K[Co(DH)_2(CN)(NO_2)]$ in 40—50 ml water is added. The characteristic crystalline precipitate is filtered after 1/2—2hr, washed with water and air dried.

Analysis. Cobalt was determined complexometrically, by using murexide as indicator in sodium acetate and dil. ammonia solution. Organic ligands were destroyed by heating with conc. sulfuric acid and several crystals of KNO_3. Nitrogen was determined by the Dumas method.

KINETIC MEASUREMENTS

Samples were dissolved in a pre-heated solution of NaOH and $NaNO_3$, containing the required amount to ensure a constant ionic strength of $\mu = 1$ M and the desired basicity, and they were kept in an ultrathermostat at working temperature maintained with an accuracy of ± 0.01°. From time to time, samples of 2 ml were taken out and added to an ice-cooled solution containing 2 ml 10^{-2} M sulphanilic acid, 2 ml of 2×10^{-2} M α-naphtylamine in 0.5% acetic acid and perchloric acid solution necessary for the neutralization of NaOH and for acidifying the solution. The mixture was kept at 0° for 5 min to allow completion of the diazotization reaction and it was diluted with 5×10^{-2} M borax solution up to 50 ml. After 2 min the absorbance of the solution was measured at 420 nm. For the determination of the NO_2^- concentrations a calibration curve has been used.

ADDITION COMPOUNDS OF ZIRCONYL CHLORIDE WITH AROMATIC SCHIFF BASES

N. S. BIRADAR, A. L. LOCKER and V. H. KULKARNI,
Department of Chemistry, Karnatak University, Dharwar-3, India

Received December 18, 1971

A few complexes of zirconyl chloride have been prepared with the Schiff bases derived from salicylaldehyde and aromatic monoamines, in acetone medium. These are yellow, amorphous substances, insoluble in common organic solvents. The elemental analysis shows that these are 1 : 2 adducts. It is shown with the aid of infrared spectra that these complexes contain Zr = O type bonds in them.

INTRODUCTION

The Schiff bases have been widely used as promising reagents for the transition metals.[1,2] During the past few years, though much information has been added to the growth of the chemical literature on zirconium (IV), [3–11] only little information has been published on zirconyl chloride Schiff base complexes.[12–14]

In these recent years, a number of papers has discussed ν(M = O) vibrations in a variety of complexes.[15-17] Kharitonov *et al.*,[18] Paul *et al.*,[19] and Patel and co-workers [20] have assigned Zr = O band in spectra of zirconyl complexes, yet the information about Zr = O bond in the zirconyl chloride Schiff base complexes is lacking.

These observations tempted us to undertake a systematic investigation on zirconyl chloride Schiff base complexes.

In this communication we intend to report the preparation and spectral study of a few zirconyl chloride addends with Schiff bases.

EXPERIMENTAL

MATERIALS AND METHOD

Zirconyl chloride of Riedel grade was made anhydrous according to the standard method.[21] Salicylaldehyde, aniline, *p*-toluidine, *p*-chloroaniline and *p*-anisidine used for preparing the Schiff bases were of reagent grade.

Solvent acetone of commercial grade was purified by repeated distillation and finally made anhydrous according to the known method.[22]

The Schiff bases were prepared by refluxing equimolar proportions of salicylaldehyde and aromatic amines in alcohol medium for about an hour. The solids separated on cooling were filtered and recrystallized from alcohol. All the Schiff bases were dried in vacuum over fused calcium chloride before use.

PREPARATION OF THE COMPLEXES

Zirconyl chloride in acetone was treated with a slight excess of Schiff base in the same solvent, and refluxed for about an hour. The solid separated was filtered and washed free from the reagent with the same solvent and dried in vacuum over anhydrous calcium chloride.

ANALYSIS

Zirconium in the complexes was determined gravimetrically as ZrO_2. Chloride was estimated gravimetrically as AgCl and nitrogen by the Kjeldalh method. The results of elemental analyses are shown in table 1.

Table 1

Analytical data on zirconyl chloride complexes. The values in parentheses are the calculated values

Ligand	Empirical formula	% Zr	% N	% Cl
Salicylidene-aniline	$(C_{13}H_{11}NO)_2ZrOCl_2$	15.84 (15.94)	4.66 (4.89)	12.19 (12.41)
Salicylidene-*p*-toluidine	$(C_{14}H_{13}NO)_2ZrOCl_2$	15.08 (15.20)	4.96 (4.66)	12.13 (11.83)
Salicylidene-*p*-chloroaniline	$(C_{13}H_{10}NOCl)_2ZrOCl_2$	14.28 (14.22)	4.30) (4.37)	11.08 (11.08)
Salicylidene-*p*-anisidine	$(C_{14}H_{13}NO_2)_2ZrOCl_2$	14.55 (14.43)	4.00 (4.43)	11.10 (11.23)

PHYSICAL MEASUREMENTS

The infrared spectra of complexes and the ligands in nujol mull were recorded on a Perkin—Elmer Infracord Spectrometer.

RESULTS AND DISCUSSION

It is evident from the results set out in table 1 that the Schiff bases under present investigation form 1 : 2 adducts with zirconyl chloride. All these are yellow, amorphous substances and insoluble in almost all common organic solvents. The insolubility of the compounds in DMF has made it difficult to determine the molar-conductance.

The important infrared frequencies along with their assignments are given in table 2.

Table 2

Infrared frequencies (in cm^{-1}) of zirconyl chloride complexes and their assignments

$(C_{13}H_{11}NO)_2ZrOCl_2$	$(C_{14}H_{13}NO)_2ZrOCl_2$	$(C_{13}H_{10}NOCl)_2$ $ZrOCl_2$	$(C_{14}H_{13}NO_2)_2$ $ZrOCl_2$	Assignments
2941	2941	2941	2941	CH stretch
1645	1639	1639	1639	C=N stretch
1587 1550 1471	1600 1538 1471	1613 1550 1471	1600 1538 1471	C=C stretch
1282	1282	1290	1282	Phenolic C-O stretch
917	917	917	909	Zr=O stretch

The three strong intensity bands in the region 1600—1471 cm^{-1} are due to the aromatic C=C stretching vibrations.

An intense band around 1613 cm^{-1}, assigned to the C=N stretch of the free Schiff base, [23] is observed in the region 1645—1639 cm^{-1} in the complexes. The shift of the order of about 32—25 cm^{-1} towards the higher frequency suggests the possible coordination of the Schiff base through the azomethine nitrogen. These observations agree with our previous observations.[24–27]

---

[23] N. S. Biradar and V. H. Kulkarni, *J. Inorg. Nuclear Chem.*, **33**, 2451 (1971).

The broad weak band with fine structure in the region 2800—2600 cm^{-1}, due to the intramolecular hydrogen bonded —OH, and the intense band around 1280 cm^{-1}, due to the phenolic C—O stretch of the free base, [28,29] are retained in the complexes indicating that the *ortho*-hydroxy group of the base has not taken part in the complex formation.

It has been established that when a compound contains $M = O$, the infrared spectrum has a narrow band in the region 1100—800 cm^{-1} belonging to the $M = O$ stretch, whereas the broad intense band in the corresponding region shows the presence of a polymeric M—O—M chain.[18] Paul and co-workers[19] have assigned a strong band at 870 cm^{-1} to the $Zr = O$ stretch in the case of $ZrOCl_2$. They have not found this band in the complexes but they have found the bands in the regions 1000—900 cm^{-1} and 720—680 cm^{-1}. These bands have been attributed to the $Zr{\equiv}O^+$ and $Zr{=}O^-$ species in the complexes. Patel and co-workers [20,30] have assigned a narrow intense band around 980 cm^{-1} to the $Zr = O$ stretch. In view of all these observations, we have assigned a narrow intense band around 917 cm^{-1} to the $Zr{=}O$ stretch. The absence of the 720—680 cm^{-1} band in the spectra of the complexes precludes the possibility of complex being ionic in nature.

Taking into consideration all the above discussion we think that zirconium has a coordination number five in these complexes.

CONTRIBUTION TO THE STUDY OF THE BINARY SYSTEM $In_2O_3-TiO_2$

CONST. GH. MACAROVICI, EUGENIA PERŢE, M. STRĂJESCU and MARIA BIROU

Institute of Chemistry, Cluj, Str. Donath 65–103, Romania

Received April 21, 1973

The binary system $In_2O_3-TiO_2$ is studied by thermogravimetric, thermodifferential and roentgenographic methods. Some of the results obtained disagree with those found in the literature and the differences are tentatively explained.

The data on the interaction of In_2O_3 with TiO_2 to be found in literature are contradictory. Roth[1] shows that heating up to 1500° the mixture of indium and titanium oxides, the expected In_2TiO_5 combination is not formed because part of the indium is volatilized and does not participate in the reaction. Other authors, [2] studying the characteristic features of binary oxide type compounds with a pyrochloric structure, examine the $In_2Ti_2O_7$ compound, and in another paper [3] it is pointed out that indium titanate of the In_2TiO_5 form is obtained as a result of an interaction between the respective oxides, but the conditions of the synthesis are not given. Rozdin *et al.* [3] explain the character of the $In_2O_3-TiO_2$ system by carrying out a thermal and a roentgenographic study. All derivatograms are identical, indifferently to the molar ratio between the components and, queerely, the thermal effects corresponding to the formation of indium titanate, In_2TiO_5, are not recorded, though the authors deduce the existence of the latter by means of the X ray diffraction spectra. To conclude, they hold that no $In_2Ti_2O_7$ type compound, but only a In_2TiO_5 formula combination, is formed. The paper gives the derivatogram of the compound with a 66,7% TiO_2 mole content and the roentgenogram with a 50% TiO_2 mole content.

As the system is of some interest and wishing to find out whether an indium titanate appears in any working conditions without the process being thermally recorded, we have carried out a systematic study, by means of the same method of thermal analysis and roentgen diffraction spectra.

1. FORMATION MECHANISM OF OXIDIC COMPOUNDS

Taking into account the fact that the individual precipitation pH of titanium and indium hydroxides has near values, as well as the fact that the respective ions do not form complex ammoniacates, made the use of ammonium hydroxide as precipitation agent possible. The precipitation reaction being total, allows to obtain some co-precipitates with an easily adjustable and well established composition, which is then found again in the double oxidic phases. The products obtained are of white colour, microcrystalline or cryptocrystalline.

Using an Erdely-Paulik type derivatograph, up to 1000°, without maintaining in isothermal conditions at maximal temperature, we have gathered information on the reaction mechanism of the studied mixtures, from the co-precipitate form to the oxidic form. The thermograms obtained are given in figures 1, 2 and 3.

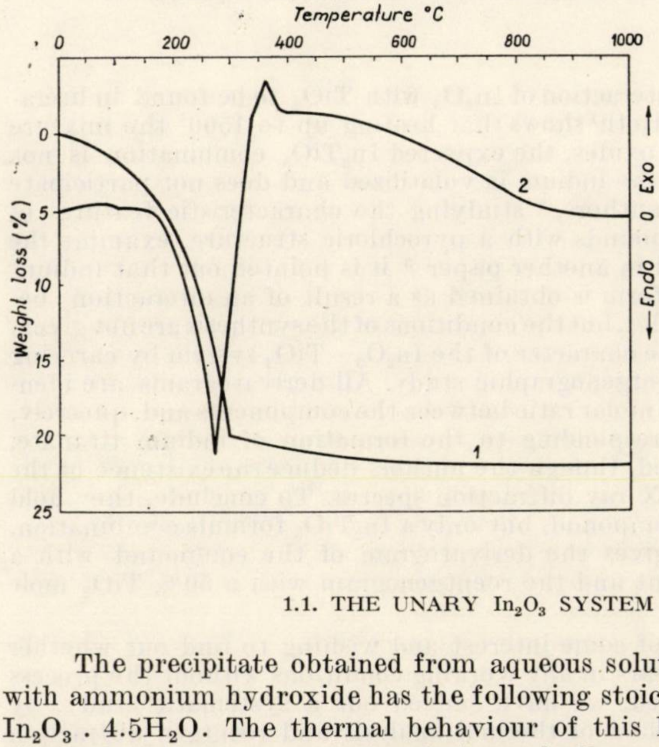

Fig. 1. — Thermogravimetric (*1*) and thermodifferential (*2*) curves of In_2O_3.x H_2O.

1.1. THE UNARY In_2O_3 SYSTEM

The precipitate obtained from aqueous solutions of indium nitrate with ammonium hydroxide has the following stoichiometric composition : $In_2O_3 . 4.5H_2O$. The thermal behaviour of this hydrated indium oxide (figure 1.2) shows a marked endothermal effect at 270°, that correlated to the loss of weight on the TGA curve, corresponds to the dehydration phenomenon. The exothermal effect, with its maximum at 360°, is brought about by the crystallization of the indium trioxide. The sequence of the reactions is given in diagram n° 1.

Diagram N⁰ 1

400		20.62	14.00	270 m 310w	360	In_2O_3 crystallization
500			0.50			
600–1000						Constant

Value calculated for x = 4.5

1.2. THE UNARY TiO_2 SYSTEM

The product obtained by precipitating the titanium ion with heated ammonium hydroxide, from an aqueous solution of titanium tetrachloride, is an amorphous gel with the $TiO_2 . H_2O$ composition. After thermal treatment up to 1000° (figure 2) TiO_2 (rutile) was obtained. The thermodifferential analysis curve shows a marked endothermal effect at 150°, corresponding to a loss of weight on the TGA curve owing to the de-

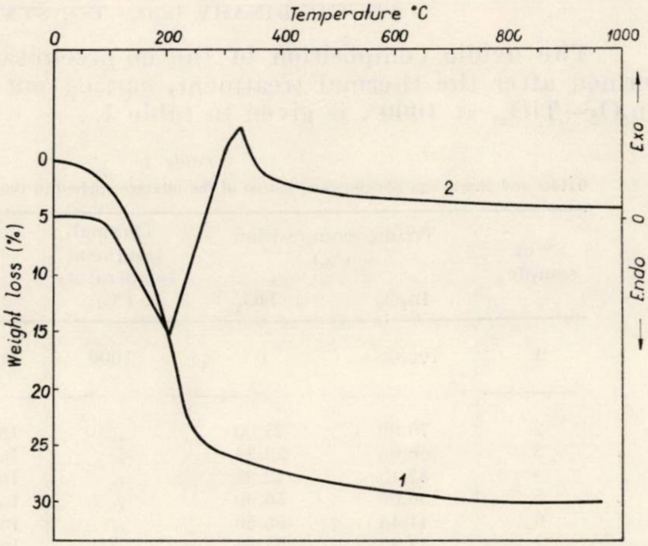

Fig. 2. — Thermogravimetric (*1*) and thermodifferential (*2*) curves of $TiO_2 . x H_2O$.

hydration of the anatase, and an exothermal effect at 325°, owing to the recrystallization of the titanium bioxide. Diagram n° 2 renders the sequence of the phenomena which are taking place.

Diagram N° 2

Formation mechanism of TiO_2 from $TiO_2 \cdot xH_2O$

Temperature scale (°C)	TGA			DTA		Phenomenon
	Temp. (°C)	Calcd. %	Obtained %	Temperature (°C)		
				endo	exo

400			1.75	280 s	280 i 325 m 400 w	Crystallization of anatase
600 – 800					800	anatase → rutile
800 – 1000						Constant

Value calculated for x = 2.

1.3. THE BINARY $In_2O_3-TiO_2$ SYSTEM

The oxidic composition of the co-precipitates and of the phases formed after the thermal treatment, carried out on the binary system $In_2O_3-TiO_2$, at 1000°, is given in table 1.

Table 1

Oxidic and phasal equilibrium composition of the mixture studied in the In_2O_3"TiO_2" binary system

N° of sample	Oxidic composition (%)		Thermal treatment temperature (°C)	Equilibrium phase
	In_2O_3	TiO_2		
1	100.00	0	1000	In_2O_3
2	75.00	25.00	,,	$In_2TiO_5 + In_2O_3$
3	66.66	33.34	,,	In_2TiO_5
4	57.13	42.87	,,	$In_2TiO_5 + In_2O_3$
5	50.00	50.00	,,	$In_2TiO_5 + TiO_2$
6	44.44	55.56	,,	$In_2TiO_5 + TiO_2$
7	42.87	57.13	,,	$In_2TiO_5 + TiO_2$
8	40.00	60.00	,,	$In_2TiO_5 + TiO_2$
9	33.33	66.67	,,	$In_2TiO_5 + TiO_2$
10	25.00	75.00	,,	$In_2TiO_5 + TiO_2$
11	0	100.00	,,	TiO_2

By comparing the derivatograms of the synthetized samples we notice a similarity in the display of the phenomena taking place the whole way.

For the majority of the differential thermal DTA curves, the differences are insignificant for the starting and ending temperatures of the same effects so that we may treat them simultaneously. Differences are only recorded in the systems in which the quantity of indium is in excess to that of titanium (figure 4.8 and 4.9).

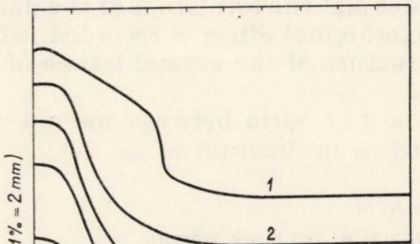

Fig. 3. — Thermogravimetric curves of indium and titanium co-precipitates:

1) 2In : 1Ti; 2) 1In : 1Ti; 3) 4In : 5Ti; 4) 3In : 4Ti; 5) 2In : 3Ti; 6) 1In : 3Ti; 7) 1In : 2Ti; 8) 4In : 3Ti; 9) 3 In : 1 Ti.

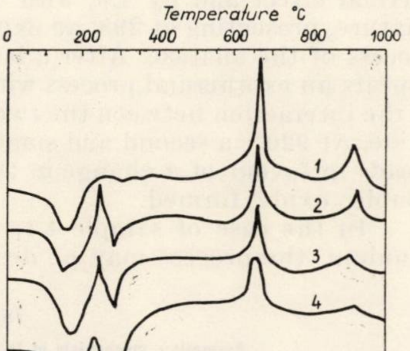

Fig. 4. — Thermodifferential curves of indium and titanium co-precipitates:

1) 2In : 1Ti; 2) 1In : 1Ti; 3) 4In : 5Ti; 4) 3In : 4Ti; 5) 2In : 3Ti; 6 1In : 3Ti; 7) 1In : 2Ti; 8) 4In : 3Ti; 9) 3 In : 1Ti.

As noticed in figure 3, the dehydration of the indium and titanium hydroxide precipitates takes place between 60° and 400°; this loss is marked by one respectively two steps on the curve, depending on the molar ratio between the components.

Two endothermal and two exothermal effects are recorded on the DTA curves (figure 4), excepting the 4.8 and 4.9 samples. The first endothermal effect, appearing between 60° and 210°, with a maximum at 140–150°, tends to go over into an exothermal effect, as a result of the crystallization process of the anatase. The dehydration phenomenon not being closed, and being a rather strong endothermal process, there appears a second endothermal effect, between 260° and 330°, with a maximum at 290°. An exception is made by the system 4.1, which has only one endothermal effect and by 4.6, with the highest quantity of titanium in the mixture, presenting at 295° an exothermal effect due to the crystallization process of the anatase. After a latent stage between 350° and 600°, there appears an exothermal process with a maximum at 665°, as a consequence of the interaction between the two oxides and the formation of the double oxide. At 920°, a second and smaller exothermal effect is recorded, which pleads in favour of a change in the structure of the crystal lattice of the double oxide formed.

In the case of sample 4.1, with a 2 : 1 ratio between indium and titanium, the process may be described as in diagram n° 3.

Diagram N° 3

Formation mechanism of In_2TiO_5 from $In_2O_3 \cdot xH_2O$ and $TiO(OH)_2$

Temperature scale (°C)	T G A			D T A		Phenomenon
	Temp. (°C)	Calcd. %	Obtained %	Temperature (°C) endo	exo	
200	60			60 i 150 m		$TiO(OH)_2 + In_2O_3 \cdot xH_2O \rightarrow TiO_2 +$ $+ In_2O_3 + (x + 1) H_2O$
400		20.14	20.00	300 w		
600 800					675	$TiO_2 + In_2O_3 \rightarrow In_2TiO_5$
800 1000					920	Change of the crystal lattice structure

Value calculated for x = 1.

For the samples 4.8 and 4.9 with the ratio between indium and titanium 1 : 2 and, respectively, 1 : 3, only the dehydration process marked by the two endothermal effects is recorded, the formation reaction of the indium titanate not being noticed.

The X-ray diffraction spectra, recorded by means of a TU-R-60 (Dresden) apparatus, are in full agreement with the results of the thermal analysis, meanwhile confirming the crystalline state of the products.

The samples heated under 400° present a diffuse roentgen diffraction spectrum. This attests their amorphous structure, determined by the processes dehydration and destruction of their crystalline lattice. Over 650°, clear spectral lines take shape, as a consequence of the appearance of the crystalline phase in the system and, as the temperature rises, the spectra are better outlined and more intense.

The individuality of the spectrum of compound 4.1 (figure 5) confirms the assumption that in the thermal decomposition process a double oxide is formed. By the plotting of the X-ray diffraction spectrum of the titanium bioxide, of the indium trioxide and of the product with a 2 In : 1Ti ratio, calcinated at 1000°, we notice the formation of a new compound to which we have assigned the formula In_2TiO_5. We have plotted only this diffraction spectrum, because the spectra of all the other samples show besides the roentgen diffraction lines belonging to the metatitanate, In_2TiO_5, characteristic lines either of the titanium bioxide, or of the indium trioxide, depending on the ratio between them.

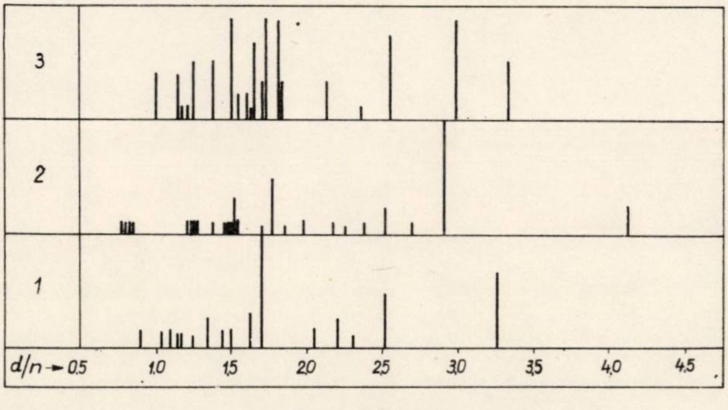

Fig 5. — Roentgen diffraction spectra of :
1) TiO_2; 2) In_2O_3; 3) In_2TiO_5.

By comparing the results obtained by us with those of Rozdin *et al.*, [3] we ascertain the following facts :

— The thermodifferential curves present two exothermal effects each pointing out, as expected, the formation process of the metatitanate.

— The curves similar to those of the sovietic scientists were obtained only for the samples with titanium excess in the mixture.

We consider that the mentioned differences may be due to the different ways of obtaining the co-precipitates, as well as to those of carrying out the thermal analysis.

COMPLEX COMBINATIONS OF THE TRANSITION METALS WITH TERTIARY STIBINES. II[1]

SPECTRAL STUDIES OF Pd(II) COMPLEX COMBINATIONS WITH TRITOLYLSTIBINES

D. NEGOIU* and LIDIA PARUTA**

* Faculty of Chemistry, University of Bucharest, Splaiul Independenţei, 89, Romania

** Centre of Physical Chemistry, Str. Dumbrava Roşie, 23, Bucharest-9, Romania

Received February 17, 1973

The paper discusses the ultraviolet visible and the IR spectra, assignments of the absorption bands in the electronic spectra being suggested. There are also made estimations about the geometric or bond isomers of some of the studied complexes.

In the electronic spectra of these compounds, bands with charge transfer and $d-d$ bands were noticed, and they were assigned by comparing them with the electronic spectra of some similar compounds.

The spectral data can be interpreted only if, besides the charge transfer $\sigma(L\rightarrow M)$, we consider its back donation through the π bond $(M\rightarrow L)$. Following the P, As, Sb series, it was to be expected that the π bond should be the strongest when the donor atom is approximately of the same size and uses the same type of d orbitals as the metal atom.

As the covalent radius assumes higher values from $P\rightarrow$Sb, it follows that the strength of the π bond also assumes higher values in the order $P<As<Sb$.

If we take into consideration the increase of the electronegative character and, therefore, the decrease of the attraction between the donor atom and the electrons of the d orbital in the metal atom we notice that the degree of the π bond assumes lower values in the reverse order $P>>As>Sb$. Therefore, along this series of donor atoms the π contribution to the strength of the donor-acceptor bond will remain approximately the same.

The appearance of such a π bond, where the central metal ion is the donor, leads to the strengthening of the M → stibine bond and contributes to the reduction of the accumulated negative charge on the central metallic ion as a result of the coordination of the stibine.

---

[1] Part I. D. Negoiu and L. Paruta-Hrehoriac, *Rev. Roumaine Chim.*, **18**, 2059 (1973).

Consequently, being a donor of strong σ bond, as well as an acceptor of π bond, the stibines will be able to stabilize both upper and lower valency states of certain elements.

The acceptor character is as important as the donor character. As a consequence of the strong field the stibines produce, there will be noticed a difference of energy between the metal *d* orbitals of low energy and those of higher energy.

The most stable compounds appear in the metal ions when the orbitals of low energy are completely occupied by electrons while those of high energy are vacant.

Cullen and Hochstrassen [2] found in the 210–340 μm domain of substituted arylphosphine and arylarsine electronic spectra two systems of bands which they characterize according to the substitution influence in the ligand and the polarity of the solvent.

The first system of bands that appears at about 270 mμ is neither influenced by the nature of the substituent nor by the solvent polarity; this system is assigned to an electronic transition similar, according to its structure, to the $\pi-\pi^*$ transition, of a high energy, that appears at about 200 mμ in the benzene monosubstituent.

The second system of bands appears at 220–250 mμ and depends on the polarity of the solvent and on the nature and position of the substituents; it may be assigned to the $n - \pi^*$ transition because one electron in the uncoupled pair of stibium atoms passes to a π. antibonding orbital in the benzene ring.

Sidman [3] points out that this transition is due to the excitation of an electron of a nonbonding orbital (n) which is placed on an atom in an antibonding orbital (the π^* orbital) antisymmetric to the reflexion in the plane of the molecule, and which is extended over several atoms in the molecule.

According to Platt,[4] this type of a transition is of little intensity, the fact being due to the difference between n and π^* orbital properties.

The n and π^* orbitals have simultaneous negative or positive high amplitudes in any region, as their lobes are orientated in different directions.

That is the reason why in solvents with a high dielectric constant the band is shifted towards higher wavelengths.

In hydroxylic solvents [5] one notices a shift of the $n-\pi^*$ transition towards blue. The phenomenon is due to the hydrogen bond formed by the hydroxylic solvent in which n electrons are implied.

It was experimentally established that for the methyl substituted arylstibines the transition $n - \pi^*$ is shifted towards red, showing an intensification of the conjugation interreaction between the vacant electronic doublet of the stibium atom and the aromatic nucleus. This shift toward red progressively appears according to the number of the substituents.

Our data about the tri-*p*-tolylstibine complexes also show the presence of two bands (fig. 1) : one band, which is distinct at 220 mμ, depends on the nature and on the position of the substituent and on the nature of the solvent ; it is assigned to the transition of one electron uncoupled stibium atom pair to a π antibonding orbital in the benzene nucleus ($n \to \pi^*$). The second band, which appears at 270 mμ, is less intense and is assigned to a $\pi - \pi^*$ transition similar to the higher energy at → 200 mμ in the nonsubstituted benzene nucleus.

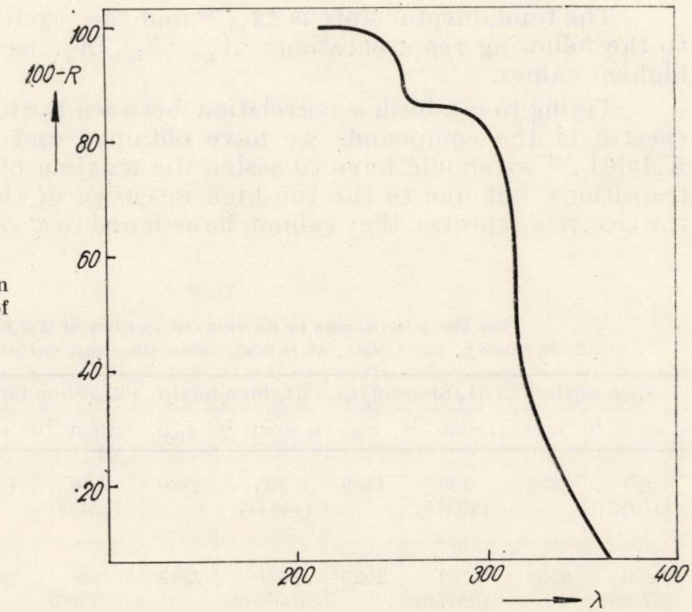

Fig. 1. — The reflection spectrum in ultraviolet of the tri-*p*-tolylstibine.

Gray and Balhausen,[6] starting from a calculation of mononuclear orbitals, show the possibility for the metal ion with a d^8 configuration to form square-planar combinations with simple ligands.

The five degenerate orbitals of the free metal ion are split into four different levels in the square-planar complex.

Several methods have been used to estimate the splitting of the *d* orbitals in the square-planar complex and to explain the spectral bands.

Fenske, Martin and Ruedenberg [7] have made a more complete calculation for the Pt (II) ion.

In the square-planar complex, starting with the splitting of the five degenerate *d* levels into four distinct levels, one asserts that the $d_{x^2-y^2}$ orbital, being placed in the direction of the bonds, is the less stable one.

We have also reached the conclusion that the d_{xz} and d_{yz} orbitals are more stable than the d_{xy} orbital and less stable than the d_{z^2} orbital.

---

[6] H. B. Gray and J. C. Balhausen, *J. Amer. Chem. Soc.*, **85**, 262 (1963).

[7] R. S. Fenske, D. S. Martin and K. Ruedenberg, *Inorg. Chem.*, **1**, 441 (1962).

The energy and, therefore, the position of the d_{z^2} orbital is not completely established.

Chatt and co-workers[8] have found the following succession of the energy levels : $d_{z^2} < d_{xy}$, $d_{yz} < d_{xy} < d_{x^2-y^2}$. According to the electrostatic calculations, Fenske and Ruedenberg[7] as well as Gray and Balhausen[9] assert that in most of the square-planar complexes this succession runs in the following way : d_{xz}, $d_{yz} < d_{z^2} < d_{xy} < d_{x^2-y^2}$. One anticipates three $d-d$ spin transitions corresponding to the transitions to three lower levels than the free orbital $d_{x^2-y^2}$.

The fundamental state is $^1A_{1g}$ [10] and the excited states correspond to the following representations $^1A_{2g}$, $^1B_{1g}$, ^1E_g, as the energy assumes higher values.

Trying to establish a correlation between the bands in the electronic spectra of the compounds we have obtained and those of K_2PtCl_4 or K_2PdCl_4,[11] we should have to assign the maxima obtained to some $d-d$ transitions, but due to the too high intensity of the bands obtained in the electronic spectra, they cannot be assigned to $d-d$ transitions (table 1).

Table 1

The absorption maxima in the electronic spectrum of $[PdI_2L_2]$ compounds

L=Sb (o-tolyl)$_3$, Sb (m-tolyl)$_3$, Sb (p-tolyl)$_3$; wavelength (mμ), maximum frequency (cm^{-1})

Sb(*p*-tolyl)$_3$		PdI_2(Sb-*p*-tolyl$_3$)$_2$		PdI_2(Sb-*o*-tolyl$_3$)$_2$		PdI_2(Sb-*m*-tolyl$_3$)$_2$		Nature of transition
λ, ν(cm^{-1})	ε_{mol}	λ, ν(cm^{-1})	ε_{mol}	λ, ν(cm^{-1})	ε_{mol}	λ, ν(cm^{-1})	ε_{mol}	
227 (44052)	3628	230 (43478)	1809	225 (44444)	1880	230 (43478)	1784	characteristic bands of aromatic ring
270 (37037)	2553	280 (35750)	2623	280 (35750)	2312	280 (37750)	2523	
		346 (28901)	2663	350 (28428)	1392	340 (29411)	1457	charge transfer bands
		490 (20408)	1399	480 (20833)	507.5	495 (20202)	703.5	

The transitions of similar intensity to $\pi-\pi^*$ transitions proper to the ligand which appear in these complexes at 320–346 mμ and 410–490 mμ, are undoubtedly due to a change transfer from the molecular orbital e_g to the molecular orbital b^*_{1g} (fig. 2). These transitions belong indeed to the complex and not to the ligand and their high intensity ($\varepsilon_{mol} \sim 10^4$) makes them easily mistaken for $d-d$ transitions.

From the electronic spectrum of the above mentioned compounds, one can also notice that the band at 410–490 mμ is far more intensive than the one at 320–360 mμ (fig. 3) which is in agreement with the order of the energy levels presented in fig. 2.

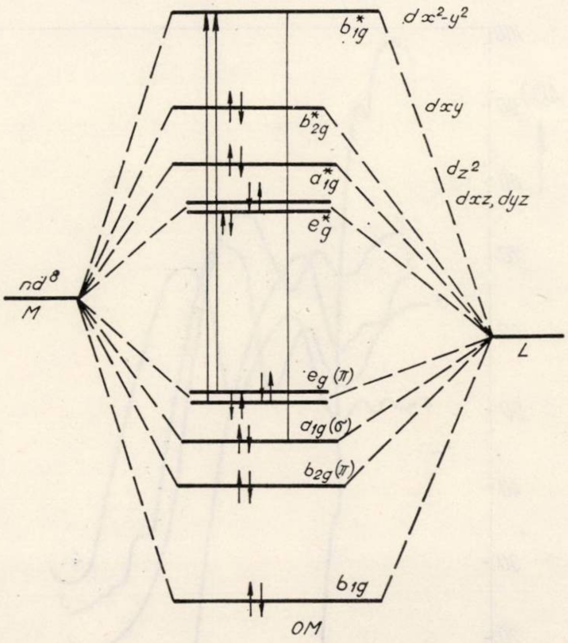

Fig. 2. – The simplified MO diagram for a square-planar complex, and the possible charge transfer transition.

The first band which is less intensive is due to two transitions with the same energy. If we refer to several halogen compounds of Pd(II) with the same ligand, of the $[PdX_2(Sb-p-tolyl_3)_2]$ type, where X = Cl^-, Br^-, I^- (table 2), one notices that the shift of the charge transfer bands is in complete agreement with the diminution of the optical electronegativities of the halide ions,[12,13] namely :

$$X_{Cl^-} = 3\,;\quad X_{Br^-} = 2.8\,;\quad X_{I^-} = 2.5$$

whereas the electronegative character of Pd(II) remains constant. In the square-planar complex, Jørgensen[14] gives for this ion the value X = = 2.2–2.4.

Jørgensen's main supposition is that the energies of the transitions with charge transfer can be directly related to the differences between

the donor orbital and the acceptor one. The energies can be evaluated from the analysis of the spectral data, and Jørgensen calls them optical electronegativities, their calculation formula being :

$$\nu_{CT} = 30{,}000\,(\lambda_{opt}\,L - \lambda_{opt}\,M)\ \mathrm{cm}^{-1}$$

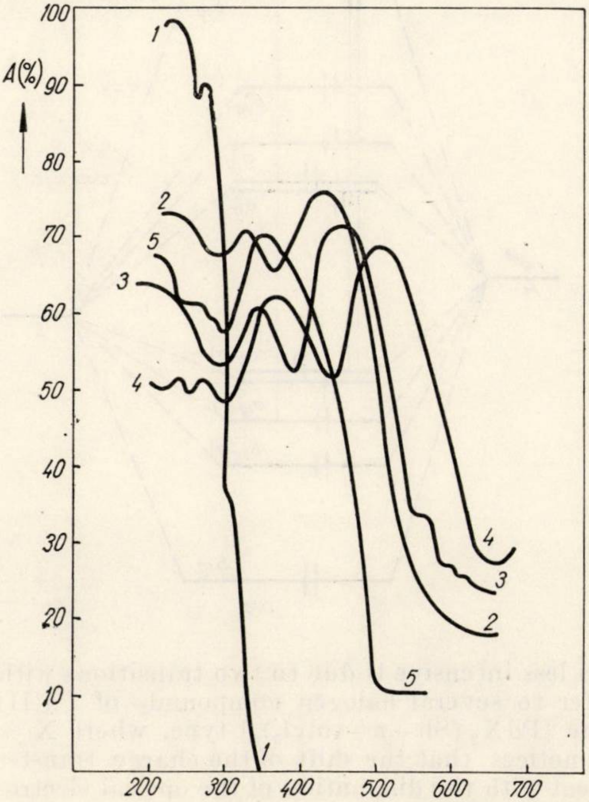

Fig. 3. — The absorption spectra in ultraviolet and visible of some complex of Pd(II) with tri-*p*-tolylstibine : *1*) Sb(*p*-tolyl)$_3$; *2*) PdCl$_2$ (Sb-*p*-tolyl$_3$)$_2$; *3*) PdBr$_2$(Sb-*p*-tolyl$_3$)$_2$; *4*) PdI$_2$(Sb-*p*-tolyl$_3$)$_2$; *5*) Pd(NO$_2$)$_2$(Sb-*p*-tolyl$_3$)$_2$.

where λ_{opt} L and λ_{opt} M are the electronegativities of donor and acceptor orbital of the ligand and respectively, of the metal. Moreover, the transition frequencies ν_{CT} are to be corrected by the variations of the interelectronic repulsions.

Table 2

λ and the maximum frequency (cm^{-1}) of the electronic spectrum of [PdX$_2$(Sb-*p*-tolyl$_3$)]$_2$ complexes

	PdCl$_2$(Sb-*p*-tolyl$_3$)$_2$		PdBr$_2$(Sb-*p*-tolyl$_3$)$_2$		PdI$_2$ (Sb-*p*-tolyl$_3$)$_2$		Pd(NO$_2$)(Sb-*p*-tolyl$_3$)$_2$	
λ	320 mμ	410 mμ	330 mμ	440 mμ	346 mμ	490mμ	345 mμ	490 mμ
ν	31.250	24.390	30.303	22.727	28.901	20.408	28.985	20.408

On the other hand, the bands being very large (fig. 3) no precise information could be found regarding the inductive effect of the methyl group on the *ortho-*, *meta-*, and *para-* positions, on the Sb—Pb bond in the respective complexes.

The differences between the absorption maxima of the three complexes are experimental errors of measuring.

THE VIBRATION SPECTRA OF Pd(II) COMPLEX COMBINATIONS WITH TRITOLYLSTIBINES

In IR spectroscopy is used to obtain information about the chemica bond type and stereochemistry of the respective compounds. Important data are obtained especially in the low frequencies domain where bands appear owing to the active vibrations metal-ligand in infrared.

The domain we have studied (300—800 cm^{-1}) is yet unsatisfactory as regards its inferior limit, because the vibration frequency $\nu(\mathrm{Pd-Br})_p$, $\nu(\mathrm{Pd-I})_t$, $\nu(\mathrm{Pd-I})_p$, $\nu(\mathrm{Sb-Pd-Sb})$, $\nu(\mathrm{Pd-Sb})$ takes values close to 200 cm^{-1} and no estimations about the geometrical configuration are possible.

Palmer[15] studied the vibration spectra of triphenylphosphine and triphenylarsine using for comparison the spectrum of the substituted benzene compounds C_6H_5X (X being a certain substituent); this spectrum has been largely studied by Whiffen[16] whose nomenclature is still used today.

Among the main vibrations this C_6H_5X molecule presents, we have chosen for the study of our complexes those below 800 cm^{-1}. Tables 3 and 4 contain the bands in the 200—800 cm^{-1} range of the triphenylphosphine and triphenylarsine spectra.

Table 3

In the second column, the intensities of the bands are presented using abbreviations : w — weak, i — intensive, v.i. — very intensive, m — medium, and in the third column there are the respective assignments.

The great complexity, i.e. the large number of active vibrations modes in IR, that have been noticed at the ligands we used, have limited our study on the absorption spectra of this domain, to several chloro-, bromo-, and iodo-derivatives of tritolylstibine.

The assignments of the bands due to the valency vibrations of the chemical bonds were made by comparing them with the spectra of the isostructural pairs of complexes PdX_2L_2 where : L = phosphine, arsine and stibine.

The related literature points out that the vibration spectra of the square-planar of Pd(II) and Pt(II) have a single band corresponding to the metal-chlorine valency vibration.[17–21]

For complexes with *trans* configuration $[PdCl_2L_2]$, L = phosphine and arsine we found that the vibration valency $\nu(Pd-Cl)$ absorbs between 350–358 cm^{-1}.

For the complexes prepared by us, the valency vibration $\nu(Pd-Cl)$ takes frequently the value of 360 cm^{-1}. Theoretically, the complexes with *cis* configuration would present two vibrations for $\nu(M-Cl)$ and $\nu(M$-ligand) which are active in IR. This is a proof of the *cis* configuration.

In the Cs_2PdCl_4 spectrum one single band has been noted at 327 cm^{-1} and is assigned to the valency vibration $\nu(Pd-Cl)$. In the $[PdCl_4]^{2-}$ ion spectrum the vibration $\nu(Pd-Cl)$ is placed at 357 cm^{-1}. As can be noticed from tables 9 and 10 in the vibration spectra of the binuclear compounds $[Pd_2Cl_4(Sb-p-tolyl_3)_2]$ and $[Pd_2I_4(Sb-p-tolyl_3)_2]$ similar positions are found for the main metal-donor and metal-halogen bands. This proves the same strength of the Sb-carbon bond.

The vibration spectra of the nitro- and dinitroderivative complexes were also studied.

As is known, the free nitro ion presents three vibration modes, all of them active in IR and belonging to the C_{2v} symmetry group : asymmetrical vibration (ν_{as}) at 1328 cm^{-1}, the N–O symmetrical vibration (ν_s) at 1261 cm^{-1} and the deformation vibration NO_2 (δ) at 828 cm^{-1}. After coordination, no matter if it is produced through nitrogen or oxygen, the number of the IR band remains constant.

The general effect of the coordination is the shift of these frequencies, given the frequencies of the free ion. It is these shifts that can be used in many cases to establish the coordination mode of the NO_2^- ion.

[21] D. M. Adams and P. J. Chandler, *J. Chem. Soc.*, **1969**, 588.

Revue Roumaine de Chimie, **19**, *1*, 57–66 (1974)

Thus, the coordination through nitrogen leads to the increase of the two frequencies ν_{as} and ν_s, whereas the coordination through oxygen leads to the increase of the ν_{as} frequency and the diminution of the ν_s. The only frequency remaining almost constant in both cases is the bending frequency.

Following formation tendency and the effect of the π bond of different ligands on the nitrite ion in palladium (II) and platinum (II) complex combinations, Burmeister and Timmer [22] have shown that there is a correlation between the neutral ligands capacity to form a π bond and the valency frequencies N—O of the nitrite coordinate ion.

In the complex combinations in which the neutral ligands present a strong tendency to form a π bond, there appears the possibility to pass from the coordination through nitrogen of the ion NO_2^-, to the coordination through oxygen. [23]

Following the vibration spectra of the $[Pd(NO_2)_2(Sn\text{-}p\text{-tolyl}_3)_2]$ and $[Pd_2(NO_2)_4\ (Sb-p-\text{tolyl}_3)_2]$ compounds we may draw the conclusion that in the binuclear compounds the bond is made in both modes.

In the vibration spectrum of $[Pd(NO_2)_2\ (Sb-p-\text{tolyl}_3)_2]$ we find frequencies characteristic to the coordination through nitrogen, whereas in the vibration spectrum of $[Pd_2(NO_2)_4(Sb-p-\text{tolyl}_3)_2]$ the frequencies are characteristic both for the coordination through nitrogen and oxygen.

Therefore, in the binuclear compound the two Pd atoms are linked in a bridge bond through O—N—O groups, and the terminal groups are linked to the Pd atom through a nitrogen bond.

CARBONIUM ION REACTIONS. VIII*

BENZOBICYCLOOCTENE DERIVATIVES THROUGH π-ROUTE

ILEANA DRĂGUŢAN, C. DRĂGHICI, ANA HANEŞ, ANGELA DUMITRIU,
ECATERINA CIORĂNESCU and C. D. NENITZESCU**

Organic Chemistry Center, Bucharest, Spl. Independenţei, 202 B, Romania

Received August 4, 1973

Competition between phenonium- and π-route in the acetolysis of 1,2-benzocyclohepta-1,3-dienyl-7-methyl tosylate (**2-OTs**) is studied. Benzene ring assistance prevails over double bond assistance, giving rise to 1,2-benzocycloocta-1,3-dien-7-yl acetate (**7-OAc**) as the main product, both in the buffered and unbuffered acetolysis. Significant proportions of π-route products are formed : benzobicyclo[3.2.1]octene derivatives in the presence of NaOAc and benzobicyclo[2.2.2]octene derivatives in strongly acidic medium, in agreement with the known data about the thermodynamic stability of these systems. Assuming no cross-over between the two ionization routes, the results are rationalized by the intervention of both phenonium and bridged ions.

Solvolytic reactions involving participation of a remote carbon-carbon double bond have been extensively explored during the last decade.[1,2] Reaction rate enhancement as compared to saturated analogs indicates anchimeric assistance provided by the double bond. Formation of cyclic compounds and stereospecificity of the reaction, sometimes observed, have been explained in terms of bridged ions or nonclassical ions generated by "π-route".[1d] It is not surprising that great attention has been paid to the study of these reactions which can provide additional information about the much disputed nonclassical ions.[1,2,3]

In 1960 Le Ny [1a] found that cyclohept-4-enylmethyl *p*-nitrobenzenesulphonate (**1-OBs**) underwent acetolysis 60 times faster than the corresponding saturated compound and yielded almost quantitatively bicyclo[3.2.1]oct-2-yl acetate (*endo*/*exo* = 9/1).

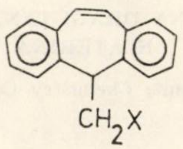
2



3

A different behaviour was observed in the case of the system **3** where the seven-membered ring is fused to two benzene rings. [4] The acetolysis of dibenzocycloheptatrienylmethyl tosylate (**3-OTs**), in the presence of sodium acetate, leads mainly to an acetate with dibenzocyclooctatriene skeleton, originating from a ring expansion reaction. Only a small part of the acetolysis product (6–8%) consists of bridged compounds, formed by double bond participation. [4]

In this context it seemed to us instructive to study the solvolytic behaviour of the **2** system where double bond participation could be more important than in the case of **3** and closer to that of **1**. On the other hand, the formation of compounds with benzobicyclooctene skeleton could be synthetically useful in this less studied class. In the present paper we report the results obtained from the acetolysis of **2-OTs**.

RESULTS

Benzosuberone (**4**)[5,6] was used as starting material for the synthesis of alcohol **2-OH**. Bromination of **4** with NBS and dehydrobromination with collidine afforded benzosuberenone (**5**)[7]. The purification of this unsaturated ketone was very difficult. By fractional distillation a bromine free product could be obtained, but it still contained small quantities (4–5%) of saturated ketone **4**; pure ketone **5** was separated by

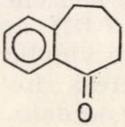
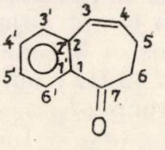
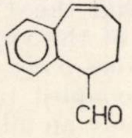
preparative v.p.c. By Darzens reaction[6,8] with chloroacetic ester the ketone **5** was converted to the aldehyde **6**; the latter was subsequently reduced with $LiAlH_4$ to the alcohol **2-OH**, from which tosylate **2-OTs** was prepared in the usual manner. IR and NMR spectra of compounds **6**, **2-OH** and **2-OTs** are in perfect agreement with the expected structures.



4



5



6

The acetolyses of **2-OTs** were carried out at 90° (10 hr, 12 half-lives) in the presence and in the absence of sodium acetate. The reaction product (96% and 83%, respectively, calculated on **2-OTs**) was analysed by gas-chromatography, after reduction with $LiAlH_4$ (table 1); the analysis of the acetate mixture showed the same composition.

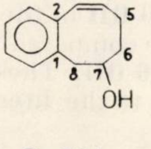
Table 1

Acetolysis products of 2-OTs (after $LiAlH_4$ reduction)

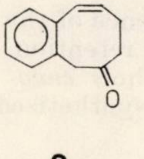
Tosylate **2-OTs** M	NaOAc M	% Products					
		endo-**13-OH**	*exo*-**10-OH**	*endo*-**10-OH**	**7-OH**	**2-OH**	Unidentified compounds
0.04	0.08	—	20.0	2.5	65.5	4.5	7.5[a]
0.04	—	17.0	4.5	3.0	61.5	2.0	12.0[b]

[a] 4% unknown alcohol, 3.5% many unidentified hydrocarbons.
[b] 4% unknown alcohol, 8% many unidentified hydrocarbons.

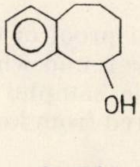
The major product is the same in both cases (61.5% and 65.5%, respectively), namely the alcohol **7-OH**. Two more alcohols are found in significant amounts, *exo*-**10-OH** (20%) in the buffered acetolysis and **13-OH** (17%) in the unbuffered one. The acetates **7-OAc**, *exo*-**10-OAc**, and **13-OAc** were separated by preparative v.p.c. Two other alcohols (4%), which could not be identified or separated, are included in the figures from the last column, the remainder representing the sum of 5-6 components, probably hydrocarbons. The starting alcohol **2-OH** was identified by comparison of its retention time with that of an authentic sample.



7-OH



8



9-OH

---

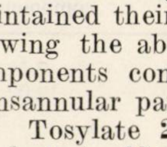
[8] R. Huisgen and G. Seidl, *Chem. Ber.*, **96**, 2740 (1963).

The structure of the alcohol **7-OH** was inferred from the IR and NMR spectra of this compound, of the corresponding acetate **7-OAc** and of the ketone **8**, obtained by the oxidation of the alcohol with chromic anhydride in pyridine. Thus, the C=O stretching frequency (1715 cm^{-1}) in the IR spectrum of ketone **8** and the singlet at $\delta = 3.7$ ppm, corresponding to the benzylic protons in the NMR spectrum of the same ketone, indicate that the C=O group is not adjacent to the benzene ring. The spectrum of the vinylic protons of ketone **8**, alcohol **7-OH** and acetate **7-OAc** shows a *cis* coupling of 12 Hz; only one of the vinylic protons is vicinally coupled to a CH_2 group ($J_{45} = 5$ Hz), whereas the other one presents only an allylic coupling ($J_{35} = 1.5$ Hz). Spectral data, therefore, indicate a 1,2-benzocycloocta-1,3-diene structure for these compounds. Further support of this assignment was afforded by catalytic hydrogenation of the solvolysis mixture (after $LiAlH_4$ reduction). The main component has, after this operation, the same retention time in v.p.c. as an authentic sample of 1,2-benzocycloocten-7-ol (**9-OH**), prepared according to Huisgen and Seidl.[8] Thus, our data indicate that the major solvolysis product is 1,2-benzocycloocta-1,3-dien-7-yl acetate (**7-OAc**), formed from **2-OTs** by ring enlargement.

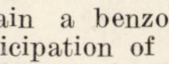
The starting alcohol **2-OH** from the mixture presents after hydrogenation the same retention time as the corresponding saturated alcohol[8].

The structure and configuration of alcohols **10-OH** *and* **13-OH** were established using the following data. Some components of the mixture maintained their retention times in v.p.c. after catalytic hydrogenation, showing the absence of double bonds. It seemed plausible that these components contain a benzobicyclooctene skeleton, originating from transannular participation of the double bond.

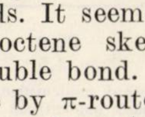
Tosylate **2-OTs** could give rise by π-route to two *exo-endo* pairs of alcohols, **10-OH** and **11-OH**, with a benzobicyclo[3.2.1]octene skeleton.



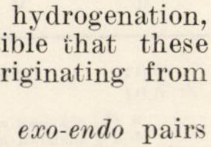
10-OH



11-OH



12



13-OH

A first proof of the presence of the alcohols **10-OH** in the acetolysis mixture was found when their retention times were compared with those of authentic samples of alcohols *endo*- and *exo*-**10-OH**. These alcohols were prepared from ketone **12** synthetized according to the literature.[9,10,11]

[9] W. Baker and W. G. Leeds, *J. Chem. Soc.*, **1948**, 974; A. H. Cook and R. P. Linstead, *ibid.*, **1934**, 956.

[10] H. E. Zimmerman, R. S. Givens and R. M. Pagni, *J. Amer. Chem. Soc.*, **90**, 6096 (1968).

[11] S. Julia, C. Huyhn and J. Olivie, *Bull. Soc. chim. France*, **1966**, 147.

$LiAlH_4$ reduction of ketone **12** afforded a mixture of alcohols *endo*-**10-OH** and *exo*-**10-OH** (9 : 1). The configuration of the *exo* and *endo* epimers was assigned by comparing their NMR spectra with those of alcohols *exo*- and *endo*-**10-OH** studied by Tanida *et al.* [12,13]

Acetate *exo*-**10-OAc** was subsequently isolated by preparative v.p.c. from the buffered acetolysis product and its NMR spectrum agrees with that found by the Japanese authors. [12]

As can be seen from table 1, the *exo*-2,3-benzobicyclo[3.2.1]-octen-4-ol (*exo*-**10-OH**) is formed in 20% proportion in the buffered acetolysis and only 4.5% in the unbuffered one. The *endo*-**10-OH** epimer appears in small quantities in both cases (2.5% and 3%).

In the unbuffered acetolysis another alcohol (acetate, respectively) is obtained in proportion of 17%. The NMR spectrum of the acetate **13-OAc**, isolated by preparative v.p.c., perfectly matches that of the *endo*-5,6-benzobicyclo[2.2.2]octen-2-yl acetate (**13-OAc**). [14]

The presence of a compound with a benzobicyclo[2.2.2.]octene skeleton in the unbuffered acetolysis product was to be expected. The interconversion between compounds with benzobicyclo[3.2.1]octene skeleton (**10** and **11**) and benzobicyclo[2.2.2]octene skeleton (**13**) has been studied by Tanida *et al.* [12] and Lansbury and Boggs. [15] In buffered medium sulphonic esters derived from the system **13** give rise to compounds with [3.2.1] skeleton. [12] Conversely, the latter (**10** or **11**) rearrange, in the presence of acids, to derivatives of the benzobicyclo[2.2.2]octene system. [15] Our results are in agreement with these observations : in the buffered acetolysis of **2-OTs** the kinetically controlled product (**10-OAc**), with [3.2.1] skeleton, is formed, whereas in the unbuffered one the acetate **13-OAc** with [2.2.2] skeleton arises from a thermodynamically controlled reaction.

DISCUSSION

Acetolysis of tosylate **2-OTs** in acetic acid buffered with equivalent amounts of sodium acetate shows first order kinetics. The rate constant together with those of some related compounds (at 80°) are listed in table 2.

All these tosylates, except tosylate **14-OTs** (taken as reference compound), contain in their molecule either a double bond or an aromatic ring, or both these groups able to assist ionization.

The comparison of the relative acetolysis rates of tosylates **1-OTs** and **15-OTs** shows that in this case the double bond is again superior to the fused benzene ring in assisting ionization [18].

The position of the double bond with respect to the leaving-group, its substituents and the steric factors influence decisively the ability of the double bond to function as an internal nucleophilic agent. In tosylate **2-OTs** the double bond is located in the 5,6-position relative to the departing group, a favourable position for participation.[19] Annelation of compound **1** is expected to diminish the nucleophilic reactivity of the double bond. The rates of the acetolysis reaction decrease indeed considerably in the series of compounds **1-OTs**, **2-OTs** and **3-OTs** (table 2).

Table 2

Acetolysis rates of 2-OTs and related tosylates (at 80°)

Tosylate	$10^5 \cdot k_1$ sec^{-1}	Rate rel. to **14-OTs**
14-OTs 	0.217[a]	1
15-OTs 	1.62[b]	7.5
16-OTs 	0.575[c]	2.65
1-OTs 	13.30[a]	61.2
2-OTs 	5.32	24.8
3-OTs 	0.177[c]	0.82

[a] *Calcd.* from data for the brosylate (ref. a) with $k_{ROBs}/k_{ROTs} = 3$;

[b] The rate constant determined by Huisgen *et al.*[16] is $1.96 \cdot 10^{-5}$ sec^{-1}; c) Extrapolated value using data from ref. 17.

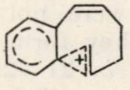
---

[19] P. D. Bartlett and G. D. Sargent, *ibid.*, **87**, 1297 (1965).

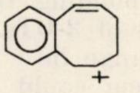
The k_u/k_s ratio, which is usually used for estimating the double bond participation, also decreases in the series of the three tosylate pairs (**1**/**14**, **2**/**15** and **3**/**16**) from 61.2 to 3.30 and 0.31. The failure to observe a rate acceleration cannot always be interpreted as absence of neighbouring group participation. Solvolysis product analysis showed that bridged compounds are formed both in the case of **2-OTs** (22–25%) and **3-OTs** (6–8%) (from **1-OBs** bicyclic compounds are quantitatively obtained). The smaller values (relative to **1-OTs**) found for the rate constants of tosylates **2-OTs** and **3-OTs** are a result of the various factors that operate : the rate-retarding inductive effect of β-aryl,[20] the conformational factors[17] and the additional strain associated with the fused benzene rings and ring closure, respectively.

A comparison in the series of saturated tosylates **14-OTs**, **15-OTs** and **16-OTs** shows that the relative rate increases by a factor of 7.5 for one and 2.65 for two fused benzene rings. As regards the reaction products, **14-OTs** undergoes acetolysis practically without rearrangement (only 4% cyclooctene is formed)[1a] and **15-OTs** with ring expansion, leading to benzocycloocten-4-ol. The intervention of a phenonium ion in this rearrangement has been experimentally and theoretically demonstrated by Huisgen *et al.*[8,16] Finally, the buffered acetolysis of tosylate **16-OTs** is also accompanied to a great extent (85%) by an expansion of the middle ring, proceeding probably by a similar mechanism.[4]

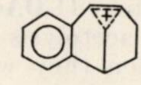
As pointed out in the case of **3-OTs**, acetolysis of **2-OTs** may be considered to proceed *via* two different paths : one leading to unbridged compounds (**7**, **2**) and another to bridged compounds (**13** and **10**). In order to account for them, we must admit that several intermediates are involved in these rearrangements. It is very likely that ionization of **2-OTs** is assisted by the phenyl group. The phenonium ion **17** can give rise either to acetate **7-OAc**, or to the unrearranged acetate **2-OAc**. The ring expansion **2**→**7** could also be imagined to proceed by a phenyl shift



17



18



19

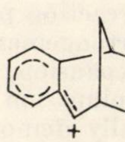
occurring in the primary ion (corresponding to **2-OTs**), followed by conversion into the secondary ion **18**. However, it is difficult to conceive that the vacant orbital of the developing primary ion and the aromatic ring, located in a geometrically favourable position, do not interact. (Examination of Dreiding models shows that in one of the conformers the CH_2OTs group occupies an axial position, suitable for the formation of the phenonium ion.) A similar mechanism has been suggested in the case of tosylate **15-OTs**[8] and **3-OTs**.[4]

---

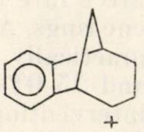
[20] S. Winstein, B. K. Morse, E. Grunwald, K. C. Schreiber and J. Corse, *J. Amer. Chem. Soc.*, **74**, 1113 (1952); D. J. Cram, *ibid.*, **86**, 3767 (1964).

The formation of compounds with benzobicyclooctene skeleton (**10-AOc** and **13-OAc**) suggests the intervention of a bridged nonclassical ion **19**, generated by double bond participation. The rearrangement **17**→**19** should be energetically unfavourable and it seems likely that the two ions do not equilibrate, but arise directly from **2-OTs** by two independent ionization routes : a phenonium route and a π-route. This mechanism accounts for the constant unbridged-bridged product ratio (2.5) in the buffered and unbuffered acetolysis.

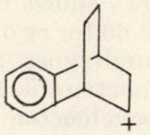
The intermediate **19** gives rise to a secondary ion **20**, stabilized by benzylic conjugation, and to a smaller extent to the secondary ion **21**. The kinetically controlled product will be that originating from **20**,[12] namely the acetates **10-OAc** with a benzobicyclo[3.2.1]octene skeleton



20



21



22

and indeed these acetates represent in the buffered acetolysis the main component resulted from participation. The formation of acetate **13-OAc** in the unbuffered acetolysis can be explained by the intervention of a classical ion **22** which may arise from **20** (alkyl migration) or **21** (aryl migration). The rearrangement **20**→**21** is energetically unfavourable but under thermodynamic control conditions, when repeated reionization occurs, the stable **13-OAc** can accumulate in the long run. The acetate *endo*-**13-OAc**, the most stable of the two epimers, is the major participation component (17%) in the unbuffered acetolysis.

Acetates **11-OAc**, corresponding to ion **21**, were not identified among the acetolysis products of **2-OTs**. Even if they form, in unbuffered solution they will rearrange into **13-OAc**[15] (*via* **21**→**22**). In the buffered acetolysis one of them could be the unidentified compound (4%, the last column, table 1). The behaviour and relations between compounds **10** and **13** are in agreement with those reported by the Japanese[12] and American[15] authors.

Returning now to the acetates **10-OAc**, the *exo*/*endo* ratio in which they are found (20/2.5) suggests an axial approach of AcO^- to the carbonium ion **20**, the *exo* side of which is less hindered sterically. The *exo*/*endo* ratio (1 : 9) obtained by $LiAlH_4$ reduction of ketone **12**, determined by "steric approach control"[21] (the transfer of hydride ion to the C=O group takes place from the less occupied side of the molecule) supports this idea. The *exo*-**10-OAc** isomer is a direct product of the acetolysis, as it has been reported[12] that under buffered conditions epimerization does not occur.

---

[21] W. G. Dauben, G. J. Fonken and D. S. Noyce, *J. Amer. Chem. Soc.*, **78**, 2579 (1956).

Acetolysis of tosylate **3-OTs** proceeds with middle ring expansion only in the presence of sodium acetate. In the presence of strong acids the dibenzocyclooctatrienol (formed by kinetically controlled reaction) undergoes ring contraction, leading back to **3** (the thermodynamically controlled product). In the dibenzo-derivative series, the systems with seven- and eight-membered middle rings are thus interconvertible.

Acetolysis of tosylate **2-OTs** is accompanied by ring expansion both in buffered and unbuffered solution. The formed benzocyclooctadienol (**7-OH**) remains unchanged in the presence of strong acids, behaving thus like its saturated analog **9-OH**.[22] The intervention of a dibenzohomotropylium cation in the rearrangements of the **3** system, admitted as very likely, [23] could explain its different behaviour as compared to the **2** system.

EXPERIMENTAL

Boiling points and melting points are uncorrected. IR spectra were recorded with a Carl Zeiss Jena UR 20 spectrophotometer, UV spectra with a Specord UV–VIS and NMR spectra with a Varian A–60A spectrometer, using TMS as internal standard. The v.p.c. analyses were performed on a Carlo Erba Fractovap model D using Carbowax 20 M columns (20% on Chromosorb W, 30–60 mesh), 2m × 4 mm, at 178°, with a hydrogen rate flow of 80 ml/min. Preparative v.p.c. was carried out on a Carlo Erba model GV, with columns similarly packed, 3m × 5mm, at 170°, with a hydrogen rate flow of 90 ml/min. The kinetic measurements were carried out essentially in the same way as previously described.[24]

1,2-Benzocyclohepta-1,3-dien-7-one (*Benzosuberenone*) (**5**). Ketone **5** was prepared [7] from benzosuberone (**4**) by N-bromosuccinimide bromination (molar ratio NBS/ketone **4** = 1.44, as compared to 1.17 [7a] which left 20% of the ketone **4** unchanged). In the dehydrobromination reaction [7a] a larger γ-collidine excess (10.3 mol/mol bromoderivative) and a higher temperature (145°) were used. The distilled product (75%, based on ketone **4**) had a 1.7% halogen content. Film distillation of the product on a small column (H = 200 mm; Φ = 8 mm), provided with a calibrated glass core, afforded bromine-free ketone **5** (67% yield). The removal of the halogenated compound could also be achieved by column chromatography on neutral alumina (100 g/8 g ketone), eluting with a 9 : 1 light-petroleum – ether mixture (70% yield). After this purification benzosuberenone still contained small quantities (4–5%) of ketone **4**. Pure benzosuberenone (99.2%) was obtained by preparative v.p.c. *IR spectrum* of the pure ketone **5** (CS_2 and CCl_4; cm^{-1}) : 738 ms, 786 vs, 873 s, 1196 ms, 1275 vs, 1318 s, 1348 s, 1440 vs, 1475 ms, 1598 s, 1688 vs (lit. [7a] 1680), 2838 ms, 2890 ms, 2921 s, 2966 s, 3025 s, 3068 s. *NMR spectrum* [CCl_4; δ (ppm)] : 2.20–2.65 m (2H, H_5), 2.68–3.0 m (2H, H_8), 6.15 m (2t) (1 olef. H, H_4), 6.45 m (2t) (1 olef. H, H_3), 7.0–7.6 m (3 arom. H), 7.8–8.0 q (1 arom. H, H_6).

7-Formyl-1,2-benzocyclohepta-1,3-diene (**6**). To a solution of potassium *tert*-butoxide in *tert*-butyl alcohol (obtained from potassium (4.7 g; 120 mmol) and 123 ml *tert*-butyl alcohol heated under reflux for 2 hr), cooled under dry nitrogen in a water-ice bath, a solution of ketone **5** (15 g; 95 mmol) and ethyl chloroacetate (14.1 g; 115 mmol) in 19 ml anhydrous benzene was added dropwise (over 0.3 hr), with mechanical stirring. Stirring was continued for one more hour maintaining the cooling bath and then for 3.5 hr at room temperature. Most of the solvent was removed *in vacuo* and the mixture was poured into water (50 ml) and extracted with benzene. The benzene solution was washed with water, dried on $MgSO_4$ and concentrated. 50 ml of a 15 % KOH—MeOH solution were added and the mixture was left overnight at room temperature. Methanol was distilled and the crystalline residue was dissolved in water and extracted with benzene. The alkaline aqueous solution was acidified with 89 % H_3PO_4 and the separated oil collected in ether. The water washed ethereal solution was dried on Na_2SO_4 and evaporated. The glycidic acid (13.8 g ; 67 %, based on ketone **5**) was mixed with a small amount of copper powder and decarboxylated at red. press. by careful heating on a hot water bath. When the evolution of CO_2 ceased, aldehyde **6** was distilled *in vacuo* (7.5 g ; 46 %), b.p. 132—5°/5 mm ; *IR spectrum* (CCl_4 ; cm^{-1}) : 1431 w, 1450 ms, 1498 w, 1730 vs, 2701 w, 2731 w, 2815 ms, 2862 ms, 2889 ms, 2931 ms, 3022 ms, 3068 ms. *NMR spectrum* [CCl_4 ; δ (ppm)] : 1.9—2.8 m (4 H, H_5, H_6), 3.5 m (1H, H_7), 5.6—6.05 m (2t) (1H olef., H_4), 6.4 m (2t) (1H olef., H_3), 6.9—7.3 (4H arom.), 9.55 d (1H, CHO). *DNFH* m.p. 115—120° (EtOH) (*Found* : C, 61.10 ; H, 4.87. $C_{18}H_{16}N_4O_4$ *requires* : C, 61.36 ; H, 4.54 %).

1,2-Benzocyclohepta-1,3-dienyl-7-methanol (**2-OH**). A solution of $NaBH_4$ (2.9 g ; 76 mmol) in 22 ml water and 1.7 ml 8 % aqueous NaOH was added to a solution of freshly distilled aldehyde **6** (10 g ; 58 mmol) in 280 ml methanol. The heat evolved causes an energetic refluxing of the methanol. The mixture was left to stand overnight. Methanol was removed *in vacuo* and the residue treated with water and extracted with ether to leave on evaporation a colourless viscous liquid (9.4 g ; 93 %). (*Found* : C, 82.21 ; H, 8.27. $C_{12}H_{14}O$ *requires* : C, 82.75 ; H, 8.04 %). *IR spectrum* (CS_2 and CCl_4 ; cm^{-1}) : 752 s, 786 s, 1021 vs, 1380 ms, 1431 ms, 1450 s, 1493 ms, 2835 ms, 2880 vs, 2931 vs, 3019 s, 3061 ms, 3077 ms, 3200—3590 (assoc. OH), 3611 ms, 3635 ms. *NMR spectrum* [CCl_4 ; δ (ppm)] : 1.9—2.6 m (4H, H_5, H_6), 2.85 s (O*H*), 2.85—3.2 m (1H, H_7), 3.6 d (2H, CH_2OH), 5.55—6.01 m (2t) (1 olef. H, H_4), 6.28 m (2t) (1 olef. H, H_3), 7.06 s (4 arom. H).

The tosylate **2-OTs** was prepared from the alcohol **2-OH** with *p*-toluenesulphochloride in pyridine and anhydrous ether ; 95 % yield, m.p. 50—51° (methanol). (*Found* : C, 69.72 ; H, 6.41 ; S, 9.63. $C_{19}H_{20}O_3S$ *requires* : C, 69.51 ; H, 6.09 ; S, 9.75 %). *IR spectrum* (CS_2 and CCl_4 ; cm^{-1}) : 752 ms, 781 s, 813 s, 824 s, 963 vs, 1000 ms, 1179 vs, 1199 vs, 1371 vs, 1430 w, 1448 w, 1496 w, 1600 w, 2840 w, 2931 ms, 3021 w, 3069 w. *NMR spectrum* [CCl_4 ; δ (ppm)] : 2.0—2.7 m (4H, H_5, H_6), 2.42 s (3H, CH_3), 3.4 m (1H, H_7), 4.15 m (2H, CH_2OTs), 5.78 m (2t) (1 olef. H, H_4), 6.25 m (2t) (1 olef. H, H_3), 7.0—7.8 m (8 arom. H).

UNBUFFERED ACETOLYSIS OF 1,2-BENZOCYCLOHEPTA-1,3-DIENYL-7-METHYL TOSYLATE (2-OTs)

A solution of tosylate **2-OTs** (2 g ; 6.1 mmol) in 40 ml anhydrous acetic acid was heated at 90° for 10 hr. The mixture was poured into water (30 ml), neutralized with Na_2CO_3 and extracted with ether. The ethereal solutions were washed with water, dried on $MgSO_4$ and evaporated. The oily residue (1.1 g ; 83 %) was dissolved in 25 ml ether and the solution was added dropwise to a suspension of 0.4 g $LiAlH_4$ in 25 ml ether, with mechanical stirring. The mixture was refluxed for 5 hr and left overnight. After decomposing the mixture with 10 % H_2SO_4 and separating the ethereal layer, the aqueous layer was extracted 3 times with ether. The ethereal solution was washed with water, dried on Na_2SO_4 and then evaporated leaving an oily material (1 g ; 95 %) (v.p.c. analysis in table 1). This oil was separated into fractions by column chromatography on neutral alumina (30 g), eluting with light-petroleum (b.p. 30—40°) for the first fraction and then with a 4 : 1 light-petroleum — ether mixture. The first fraction (500 ml) contained 0.02 g unidentified hydrocarbons (IR spectrum). Mixtures of alcohols **7-OH**, **10-OH** and **13-OH** (0.65 g) were found in the next three fractions (500 ml). From the fifth fraction (100 ml) 0.2 g *1,2-benzocycloocta-1,3-dien-7-ol* (**7-OH**) was obtained. *IR spectrum* (CS_2 ; cm^{-1}) : 738 vs, 746 vs, 761 ms, 788 vs, 1031 s, 1048 s, 1062 s, 2822 ms, 2868 s, 2898 s, 2928 vs., 3015 s, 3058 ms, 3200–3450 (assoc. OH), 3578 ms, 3606 ms.

Acetate **7-OAc** was isolated by preparative v.p.c. from the acetolysis mixture. (*Found* : C, 77.31 ; H, 7.80 ; $C_{14}H_{16}O_2$ *requires* : C, 77.74 ; H, 7.46 %). *IR spectrum* (CS_2 and CCl_4 ; cm^{-1}) : 742 s, 786 ms, 1030 vs, 1240 vs, 1375 s. 1452 ms, 1737 vs, 2836 w, 2901 ms, 2941 s, 3021 s, 3070 ms. *NMR spectrum* [CCl_4 ; δ (ppm)] : 1.55–2.6 m (4H, H_5, H_6), 2.0 s (3H, CH_3), 2.98 d (2H, H_8), 4.95 m (1H, H_7), 5.78 m (2t) (1 olef. H, H_4), 6.41 m (2t) (1 olef. H, H_3), 7.15 s (4 arom. H).

Continuing the elution, two more fractions (200 ml) (mixtures of alcohols **7-OH** and **2-OH** ; 0.1 g) were separated.

1,2-Benzocycloocta-1,3-dien-7-one (**8**). A solution of alcohol **7-OH** (0.2 g, 1.1 mmol) in 5 ml pyridine was added with cooling to a complex prepared from 0.4 g CrO_3 and 6 ml pyridine. The mixture was stirred for 5 hr, left overnight, decomposed with cold water and extracted with ether. The ethereal solution was washed with water, dil. HCl, again with water and dried on $MgSO_4$. The solvent was evaporated to leave 0.15 g (76 %) ketone **8**, yellow oil. *DNFH* m.p. 70–73°. *IR spectrum* (CCl_4 ; cm^{-1}) : 1325 ms, 1451 w, 1715 vs, 2835 w, 2872 w, 2932 ms, 2910 ms, 3020 ms, 3068 w. *NMR spectrum* [CCl_4 ; δ (ppm)] : 2.0–2.4 m (4 H, H_5, H_6), 3.70 s (2H H_8), 6.0 m (2t) (1 olef. H, H_4), 6.65 m (2t) (1 olef. H, H_3), 7.1–7.5 m (4 arom. H).

endo-5,6-Benzobicyclo[2.2.2]octen-2-yl acetate (**13-OAc**). Acetate **13-OAc** was isolated by preparative v.p.c. from the unbuffered acetolysis mixture. (*Found* : C, 77.84 ; H, 7.76. $C_{14}H_{16}O_2$ *requires* : C, 77.74 ; H, 7.46 %). *IR sepectrum* (CCl_4 ; cm^{-1}) : 1030 ms, 1065 ms, 1250 vs, 1741 vs, 2871 ms, 2948 s, 3029 w, 3045 vw, 3078 vw. *UV spectrum* (EtOH) λ_{max} mμ (log ε) : 256 (2.64), 261.5 (2.72), 268 (2.72) corresponding [25,26] to a benzobicyclo[2.2.2]octene structure.

BUFFERED ACETOLYSIS OF 1,2-BENZOCYCLOHEPTA-1,3-DIENYL-7-METHYL TOSYLATE (2-OTs)

A solution of tosylate **2-OTs** (2 g ; 6.1 mmol) and anhydrous sodium acetate (0.85 g ; 10.3 mmol) in 40 ml glacial acetic acid was heated at 90° for 10 hr. The reaction mixture was worked up as described above for the unbuffered acetolysis ; 1.3 g (96 %) of a reddish oil were obtained which was subsequently reduced with $LiAlH_4$. The alcohol mixture was analysed by v.p.c. (table 1).

exo-2,3-Benzobicyclo[3.2.1]octen-4-yl acetate (**10-OAc**) [12]. Acetate *exo*-**10-OAc** was isolated by preparative v.p.c. from the buffered acetolysis mixture. *UV spectrum* (EtOH) λ_{max} mμ(log ε) : 266 (2.79), 273.9 (2.78). *IR spectrum* (CS_2 and CCl_4 ; cm^{-1}) : 757 s, 947 ms, 982 ms, 1016 s, 1208 sh., 1232 vs, 1728 vs, 2871 ms, 2960 s, 3026 w, 3071 vw. The NMR spectrum of the complex *exo*-**10-OAc**–**Eu(DPM)$_3$** allowed the determination of the geminal coupling constant $J_{8a8b} = 12$ Hz.

REDUCTION OF 2,3-BENZOBICYCLO[3.2.1]OCTENE-4-ONE (12)

Ketone **12** was prepared according to literature.[9,10,11]

a) A solution of $NaBH_4$ (0.25 g; 6.6 mmol) in 5 ml water and 1 ml of a 8% aqueous NaOH were added to a solution of ketone **12** (0.7 g; 4 mmol) in 15 ml methanol. The mixture was left overnight at room temperature, then worked up in the usual manner. On evaporation of the solvent a colourless liquid (0.655 g; 93.5%) was obtained. V.p.c. analysis showed the composition : 91% *endo*-alcohol (*endo*-**10-OH**) and 9% *exo*-alcohol (*exo*-**10-OH**).

b) The reduction of ketone **12** (0.7 g; 4 mmol) with $LiAlH_4$ (0.3 g; 8 mmol) in 40 ml anhydrous ether afforded, after the usual working up, a yellowish liquid (0.6 g; 86%) containing 89% *endo*-alcohol (*endo*-**10-OH**) and 11% *exo*-alcohol (*exo*-**10-OH**).

CONDENSATION OF β-AROYLPROPIONIC ACIDS WITH ISATIN UNDER PERKIN CONDITIONS

A. M. EL-ABBADY *, M. A. OMARA and N. G. KANDIL

Department of Chemistry, University College for Women A'in Shams University, Cairo, A.R.E.

Received March 7, 1973

β-Aroylpropionic acids (I ; R = H, CH_3 and Cl) are condensed with isatin under Perkin conditions to give α-(N-acetyloxindolylidene)-γ-aryl-$\Delta^{\beta,\gamma}$-butenolides (II ; R = H, CH_3 and Cl) which on acid hydrolysis give the corresponding α-oxindolylidene-γ-aryl-$\Delta^{\beta,\gamma}$-butenolides (III ; R = H, CH_3 and Cl) respectively. Treatment of butenolides (II) with benzylamine affords the corresponding amides (IV ; R = H, CH_3 and Cl), which when heated with dilute hydrochloric acid give 1-benzyl-3-oxindolylidene-2-oxo-5-aryl-2,3-dihydropyrroles (V ; R = H, CH_3 and Cl). Furthermore, butenolides (II) react with hydrazine hydrate to give the corresponding 3-spiro-(N-acetyl-oxindol)-4-aroylmethyl-5-ketopyrazolidines (VI ; R = = H, CH_3 and Cl), which on acid hydrolysis yield 3-spiro-oxindol-4-aroylmethyl-5-ketopyrazolidines (VII ; R = H, CH_3 and Cl) respectively.

β-Aroylpropionic acids are known to condense with aldehydes [1-4] phthalic anhydride,[5] substituted phthalic anhydrides,[6] cyclohexanone and fluorenone [7] in acetic anhydride in the presence of sodium acetate [1] to give the corresponding butenolides.

In the present invetigation we report the condensation of β-benzoyl-, β-*p*-toloyl-, and β-*p*-chlorobenzoylpropionic acids (I) with isatin under the same conditions to give α-(N-acetyloxindolylidene)-γ-aryl-$\Delta^{\beta,\gamma}$-butenolides (II ; R = H, CH_3 and Cl) as dark red crystals in fairly good yields.

* Present address : Chemistry Department, Faculty of Science, Tanta University, Tanta, Egypt.

The constitution of these products is inferred from : (i) Their analytical data. (ii) Their infrared absorption spectra [8] which show strong bands at : 1790, 1780, 1730, 1710, 1615, 1600, 1550 and 1490 cm^{-1} characteristic of the stretching frequencies of the carbonyl groups of the conjugated five-membered lactones and amides as well as the C = C aromatic skeletal in plane vibrations, respectively. (iii) Their dark red colour. (iv) Their different reactions which are investigated below :

a. Acid hidrolysis of the N-acetyloxindolylidenebutenolides (II).

Hydrolysis of the produced butenolides (II; R = H, CH_3 and Cl) using dilute hydrochloric acid give the corresponding α-oxindol-ylidene-γ-aryl-$\Delta^{\beta,\gamma}$-butenolides (III; R=H, CH_3 and Cl) as reddish black solids.

The structure of these compounds is inferred from their analytical data, and their infrared absorption spectra which show strong bands at; 3360—3100 (br.), 1790, 1780, 1730; 1705, 1670, 1620, 1555 and 1495 cm^{-1}, characteristic of the stretching frequencies of NH, C = O and C = C, respectively.

b. Action of benzylamine on the N-acetyloxindolylidenebutenolides.

Treatment of α-(N-acetyloxindolylidene)-γ-aryl-$\Delta^{\beta,\gamma}$-butenolides (II) with benzylamine gives α-(N-acetyloxindolylidene)-β-aroyl-N-benzylpropionamides (IV; R = H, CH_3 and Cl) as yellow solids.

The structure of these amides is inferred from their analytical data, and their infrared spectra which show strong absorption bands at : 3400—3100 (br.), 1705, 1685, 1615, 1585, 1550 and 1490 cm^{-1} characteristic of the stretching frequencies of the NH, ketonic C = O, amide C = O and C = C respectively.

c. Lactimization of the α-(N-acetyloxindolylidene)-β-aroyl-N-benzylpropionamides.

When propionamides (IV) are boiled with hydrochloric acid, 1-benzyl-3-oxindolylidene-2-oxo-5-aryl-2,3-dihydropyrroles (V; R = H, CH_3 and Cl) are obtained as dark violet solids in excellent yields. The structure of these dihydropyrroles is based on : their analytical data, their deep violet colour and their infrared absorption spectra which show bands at : 3400—3000 (br.), 1705, 1675, 1615, 1600, 1540 and 1500 cm^{-1} characteristic of the stretching frequencies of the NH, C = O and C = C respectively.

The two propionamides (IV; R = CH_3 and Cl) are found to undergo lactimization even on standing (in the first case) and on crystallization (in the second case). This is indicated by the change in their colour from yellow to dark violet.

d. Action of hydrazine hydrate on the N-acetyloxindolylidenebutenolides.

Hydrazine hydrate reacts with butenolides (II) in ethanol at room temperature or under reflux to give 3-spiro (N-acetyl-oxindol)-4-aroylmethyl-5-ketopyrazolidines (VI; R = H, CH_3 and Cl). It seems that cyclization occurs on the double bond in a similar manner as the hydrazides of azlactones [8] when heated.

---

[8] "The Chemistry of Penicillin", Princeton University Press, Princeton, N. J., 1949, p. 736.

The structure of these compounds is inferred from the following observations :
(i) Their analytical data. (ii) They do not form acylazides when treated with nitrous acid. (iii) Their infrared absorption spectra which show strong bands at : 3400–3000 (br.), 1720, 1665, 1655, 1610, 1540 and 1500 cm^{-1} characteristic of the stretching frequencies of the NH, the C = O of ketones and amides, and the C = C respectively.

(iv) Stability of the pyrazolidine ring towards mineral acids.

e. Acid hydrolysis of 3-spiro (N-acetyloxindol)-4-aroylmethyl-5-ketopyrazolidines.

Hydrolysis of the produced 3-spiro-(N-acetyloxindol)-4-aroyl-methyl 5-ketopyrazolidines (VI) using dilute hydrochloric acid give the corresponding 3-spiro-oxindol-4-aroylmethyl-5-keto-pyrazolidines (VII; R=H, CH_3 and Cl) as yellow to brown solids. The structure of these products is inferred from the following facts:
(i) Their analytical data. (ii) The nonformation of acylazide.
(iii) Their infrared spectra which show absorption bands at: 3650–3100 (br.), 1715, 1660, 1610, 1580, 1550 and 1500 cm^{-1} characteristic of the stretching frequencies of NH, C=O of the ketones and amides, and C = C, respectively.

f. Action of sodium hydroxide solution on butenolides (II).

The butenolides (II) when refluxed with sodium hydroxide solution (10%) for one hour give a mixture of the corresponding aromatic acids (namely benzoic, *p*-toluic and *p*-chlorobenzoic acids, identified by microanalysis and mixed m.p. with authentic samples) and one and same unknown acidic product (VIII) containing nitrogen in all cases, m.p. above 310°, which is still under investigation.

This result is not in harmony with that obtained from arylidenebutenolides which were reported to give the corresponding α-arylidene-γ-ketoacids when treated with an alkali.[2]

EXPERIMENTAL [9]

CONDENSATION OF ISATIN WITH β-AROYLPROPIONIC ACIDS

General procedure

A mixture of finely powdered β-aroylpropionic acid (0.01 mole), sodium acetate (0.82 g 0.01 mole), isatin (1.47 g, 0.01 mole) and acetic anhydride 10 ml was heated on a hot plate till a clear solution was obtained. Heating was then continued on a boiling water-bath till a solid separated out. The mixture was cooled, filtered off and the precipitate was washed with petroleum ether (b.p. 40–60°). The product was crystallized from the suitable solvent.

α-(N-Acetyloxindolylidene)-γ-phenyl-$\Delta^{\beta,\gamma}$*-butenolide* (*II*; *R* = *H*). The product obtained was crystallized from acetic acid to give glittering dark red needles, m.p. 215°. Yield 1.4 g (46%).

Anal. *Calcd.* for: $C_{20}H_{13}NO_4$: C, 72.5; H, 3.9; N, 4.2.

Found: C, 72.1; H, 3.9; N, 3.9%.

α-(N-Acetyloxindolylidene)-γ-(p-tolyl)-$\Delta^{\beta,\gamma}$*-butenolide* (*II*; *R*=CH_3) The product obtained was crystallized from acetic acid in glittering dark red needles, m.p. 239°. Yield 2.1 g (65.6%).

Anal. *Calcd.* for $C_{21}H_{15}NO_4$: C, 73.0; H, 4.3; N, 4.0.

Found: C, 72.8; H, 4.4; N, 4.0%.

α-(N-Acetyloxindolylidene)-γ-(p-chlorophenyl)-$\Delta^{\beta,\gamma}$*-butenolide* (*II*; *R* = *Cl*). The product obtained was crystallized from acetic acid to give glittering dark red crystals, m.p. 226°. Yield 2.4 g (68%).

Anal. *Calcd.* for $C_{20}H_{12}NO_4Cl$: C, 65.6; H, 3.2; N, 3.8; Cl, 9.7.

Found: C, 65.1; H, 3.4; N, 3.8; Cl. 10.0%.

[9] a. Melting points are not corrected; b. Infrared spectra were measured on Infrared Spectrophotometer UNICAM SP 200G.

ACTION OF DILUTE HYDROCHLORIC ACID ON α-(N-ACETYLOXINDOLYLIDENE)-γ-ARYL-$\Delta^{\beta,\gamma}$-BUTENOLIDES

General procedure

The butenolide (II, 1 g) was dissolved in 50 ml acetic acid where a clear solution was obtained ; 10 ml of 6N−HCl were added and the mixture was refluxed for 1 hour. On cooling, reddish black crystals were separated. The product after filtration and washing with water was crystallized from a suitable solvent.

α-Oxindolylidene-γ-phenyl-$\Delta^{\beta,\gamma}$*-butenolide* (*III* ; *R=H*). The product obtained was crystallized from acetic acid as reddish-black needles, decomposed at 287°. Yield 0.82 g (91 %).

Anal. *Calcd.* for $C_{18}H_{11}NO_3$: C, 74.7 ; H, 3.8 ; N, 4.8.

Found : C, 74.0 ; H, 3.6 ; N, 4.8 %.

α-Oxindolylidene-γ-(p-tolyl)-$\Delta^{\beta,\gamma}$*-butenolide* (*III* ; *R=CH*$_3$). The product obtained was crystallized from toluene as reddish-black needles, decomposed at 280°. Yield 0.74 g(84 %).

Anal. *Calcd.* for $C_{19}H_{13}NO_3$: C, 75.2 ; H, 4.25 ; N, 4.6.

Found : C, 75.3 ; H, 4.25 ; N, 4.1 %.

α-Oxindolylidene-γ-(p-chlorophenyl)-$\Delta^{\beta,\gamma}$*-butenolide* (*III* ; *R = Cl*). The product obtained was crystallized from ethanol in reddish black needles, decomposed at 278°. Yield 0.88 g (88 %).

Anal. *Calcd.* for $C_{18}H_{10}NO_3Cl$: C, 66.7 ; H, 3.1 ; N, 4.3 ; Cl ; 10.9.

Found : C, 66.6 ; H, 3.6 ; N, 4.6 ; Cl, 10.6 %.

ACTION OF BENZYLAMINE ON THE BUTENOLIDES (II)

General procedure

A solution of the butenolide (II ; 0.005 mole) in dry benzene (15 ml) and benzylamine (0.6 g, 0.03 mole) was refluxed for 1 hour. On cooling a solid separated out. This was filtered off, washed with petroleum ether (b.p. 60−80°) and crystallized from the suitable solvent.

α-(N-Acetyloxindolylidene)-β-benzoyl-N-benzylpropionamide (*IV, R = H*). The product obtained was crystallized from toluene in yellow powder, m.p. 204°. Yield 2.7 g (69 %).

Anal. *Calcd.* for $C_{27}H_{22}N_2O_4$: C, 74.0 ; H, 5.0 ; N, 6.5.

Found : C, 74.8 ; H, 5.1 ; N, 6.6 %.

α-(N-Acetyloxindolylidene)-β-(p-toluyl)-N-benzylpropionamide (*IV* ; *R = CH*$_3$). The product obtained was crystallized from benzene as yellow powder, m.p. 180−81°C. Yield 1.1 g (50 %).

Satisfactory analytical data could not be obtained as the yellow product changed on standing to a dark violet powder.

α-(N-Acetyloxindolylidene)-β-(p-chlorophenyl)-N-benzylpropionamide (*IV* ; *R = Cl*). The product obtained was a yellow powder, m.p. 198−200°, which on crystallization from benzene changed to dark violet powder. Yield 1.1. g (50 %).

LACTIMIZATION OF α-(N-ACETYLOXINDOLYLIDENE)-β-AROYL-N-BENZYLPROPIONAMIDES (IV)

General procedure

The propionamide derivative (1g) was treated with 6N−HCl (50 ml) and the reaction mixture was refluxed for 1 hour. During heating the yellow colour changed gradually to violet.

The dark violet solid so obtained was washed with water and crystallized from a suitable solvent.

1-Benzyl-3-oxindolylidene-2-oxo-5-phenyl-2,3-dihydropyrrole (*V*, *R* = *H*). The product obtained was crystallized from benzene in dark violet crystals, m.p. 218°. Yield 0.57 g (71 %).

Anal. *Calcd.* for $C_{25}H_{18}N_2O_2$: C, 79.3 ; H, 4.7 ; N, 7.4.

Found : C, 79.6 ; H, 4.8 ; N, 6.7 %.

1-Benzyl-3-oxindolylidene-2-oxo-5-(p-tolyl)-2,3-dihydropyrrole (*V* ; *R* = CH_3). The product. obtained was crystallized from benzene in dark violet crystals, m.p. 250 – 51°. Yield 0.7 g (88 %).

Anal. *Calcd.* for $C_{26}H_{20}N_2O_2$: C, 79.5 ; H, 5.1 ; N, 7.1.

Found : C, 78.8 ; H, 5.1 ; N, 6.9 %.

1-Benzyl-3-oxindolylidene-2-oxo-5-(p-chlorophenyl)-2,3-dihydropyrrole (*V* ; *R* = *Cl*). The product obtained was crystallized from benzene to give dark violet crystals, m.p. 280 – 81°. Yield 0.7 g (88 %).

Anal. *Calcd.* for $C_{25}H_{17}O_2N_2Cl$: C, 72.7 ; H, 4.1 ; N, 6.7 ; Cl. 8.6.

Found : C, 71.82 ; H, 3.8 ; N, 6.8 ; Cl, 9.2 %.

ACTION OF HYDRAZINE HYDRATE ON THE BUTENOLIDES (II)

General procedure

To the butenolide (1 g) in ethanol (20 ml), hydrazine hydrate (1 g) was added. The reaction mixture was shaken at room temperature until its dark red colour changed to pale brown. The solid product obtained was separated and crystallized from a suitable solvent.

Repeating the above experiment with refluxing for 1 hour gave the same product on cooling and diluting with water.

3-Spiro-N-acetyloxindol-4-benzoylmethyl-5-keto-pyrazolidine *VI* ; *R* = *H*). The product obtained was crystallized from ethanol/benzene in a pale brown powder, m.p. 225°. Yield 0.4 g (40 %).

Anal. *Calcd.* for $C_{20}H_{17}O_4N_3$: C, 66.1 ; H, 4.7 ; N, 11.5.

Found : C, 65.3 ; H, 5.3 : N, 11.0 %.

3-Spiro-(N-acetyloxindol)-4-(p-toluylmethyl)-5-ketopyrazolidine (*VI* ; *R* = CH_3). The reaction failed by using ethanol as a solvent on cooling or heating.

Replacing the alcohol by acetic acid (20 ml) gave a solid product which was crystallized from acetic acid as a pale yellow powder, m.p. above 280°. Yield 0.35 g (35 %).

Anal. *Calcd.* for $C_{21}H_{19}O_3N_3$: C, 67.2 ; H, 4.8 ; N, 11.1.

Found : C, 66.4 ; H, 5.4 ; N, 10.4 %.

3-Spiro-(N-acetyloxindol)-4-(p-chlorobenzoylmethyl)-5-ketopyrazolidine (*VI* ; *R* = *Cl*). The product obtained was crystallized from ethanol/benzene in a pale brown powder, m.p. 235 – 6°. Yield 0.4 g (40 %).

Anal. *Calcd.* for $C_{20}H_{16}N_3ClO_4$: C, 63.2 ; H, 4.2 ; N, 10.5 ; Cl, 9.9.

Found : C, 63.0, H, 4.7 ; N, 9.9 ; Cl, 9.3 %.

ACTION OF DILUTE HYDROCHLORIC ACID ON 3-SPIRO-(N-ACETYLOXINDOL)-4-AROYLMETHYL-5-KETOPYRAZOLIDINES (VI)

The pyrazolidine derivative (VI) (1 g) was treated with 6N-HCl (30 ml) and the reaction mixture was refluxed for one hour. The solid obtained was filtered off, washed with water and crystallized from a suitable solvent.

3-Spiro-oxindol-4-benzoylmethyl-5-ketopyrazolidine (*VII*; *R* = *H*). The product obtained was crystallized from ethanol to give a yellow powder, m.p. 270° Yield 0.7 g (79 %).

Anal. *Calcd.* for $C_{18}H_{15}O_3N_3$: C, 67.4 ; H, 4.7 ; N, 13.0.

Found : C, 68.2 ; H, 4.4 ; N, 13.4 %.

3-Spiro-oxindol-4-(p-chlorobenzoylmethyl)-5-ketopyrazolidine (*VII*; *R* = *Cl*). The product obtained was crystallized from ethanol/benzene in a dark brown powder, m.p. 295°. Yield 0.7 g (77 %).

Anal. *Calcd.* for $C_{18}H_{14}N_3ClO_3$: Cl, 9.9, N, 11.8.

Found : Cl, 10.2 : N, 11.0 %.

ACTION OF NITROUS ACID ON THE PYRAZOLIDINES (VI AND VII)

A solution of sodium nitrite (2 moles) in the least amount of ice-cold water was added dropwise with stirring to an ice-cold solution of the pyrazolidines (VI ; R = Cl and H) (1 mole) in glacial acetic acid. The temperature was not allowed to rise above 5°. After the addition was completed, the reaction mixture was left at room temperature for 1/2 an hour, then diluted with water. The solid precipitate was crystallized from ethanol/benzene.

In each case the starting material was recovered unreacted.

Repeating the same experiment on the compounds (VII ; R = H, and Cl) gave back similarly the reactants unaffected.

ALKALINE HYDROLYSIS OF α-(N-ACETYLOXINDOLYLIDINE)-γ-ARYL-$\Delta^{\beta,\gamma}$-BUTENOLIDES (II)

General procedure

A mixture of the butenolide (1 g) and 20 ml of 10 % sodium hydroxide solution was refluxed for 1 hour. The solution after cooling was rendered acidic by dilute hydrochloric acid, then made just alkaline with potassium hydroxide solution and finally acidic with aqueous acetic acid. The precipitate was found to be a mixture of two acids which were separated by fractional crystallization from a suitable solvent.

Benzoic acid. The mixture produced from α-(N-acetyloxindolylidene)-γ-phenyl-$\Delta^{\beta,\gamma}$-butenolide was treated with petroleum ether (b.p. 40—60°). The soluble fraction was recrystallized from the same solvent as colourless crystals, m.p. 120°. Yield 0.3 g. This was proved to be benzoic acid by mixed m.p. experiment.

The insoluble fraction was crystallized from ethanol/benzene as light brown powder (VIII), m.p. above 310°. This compound was found to contain nitrogen (by sodium fusion test), and unaffected by hot 6N-HCl.

p-Toluic acid. The produced mixture from α-(N-acetyloxindolylidene)-γ-(*p*-tolyl)-$\Delta^{\beta,\gamma}$-butenolide was treated with petroleum ether (b.p. 40—60°). The soluble fraction was recrystallized from the same solvent as colourless crystals, m.p. 181°. Yield 0.3 g. This was found to be *p*-toluic acid by mixed m.p. experiment.

The insoluble fraction was found to be compound VIII, the same as in the case of α-(N-acetyloxindolylidene)-γ-phenyl-$\Delta^{\beta,\gamma}$-butenolide.

p-Chlorobenzoic acid. The mixture produced from α-(N-acetyloxindolylidene)-γ-(*p*-chlorophenyl)-$\Delta^{\beta,\gamma}$-butenolide was treated with benzene. The soluble fraction was crystallized from benzene as colourless crystals, m.p. 239—40°. Yield 0.3 g. This was proved to be *p*-chlorobenzoic acid by mixed m.p. experiment.

The insoluble fraction was found to be the same compound VIII.

ALUMINIUM CHLORIDE CATALYZED REACTIONS OF UNSATURATED ACIDS WITH BENZENE. VI[1]

REACTION OF CYCLOPENTYLACRYLIC ACID

ALICE MARIE GLATZ *, VASILE WERTHEIMER* and FLORIN BADEA **

* Institute of Organic Chemistry, Spl. Independenţei 202 B
** Polytechnic Institute, str. Polizu 1, Bucharest

Received September 7, 1973

Aluminium chloride catalyzed reaction of cyclopentylacrylic acid with benzene has been investigated at 40–45°, the reaction products being β-phenyl-β-cyclopentylpropionic (**5**), *trans*-2-phenyl-β-cyclopentylpropionic (**8**), *cis*-3-phenyl-β-cyclopentylpropionic (**10**) acids and the *trans*-2-phenyl-cyclohexylacetic, *cis*-3-phenyl-cyclohexylacetic and *trans*-4-phenyl-cyclohexylacetic acids (**17,19** and **21**) with rearranged skeleton. The isomerization of the reaction products has been investigated in the same conditions with the arylation reaction. Based on the distribution of reaction products and conformational analysis a reaction mechanism has been outlined.

As pointed out in earlier papers, [1–3] two ways are possible in the formation of phenylated acids during the aluminium chloride catalyzed reaction of α, β-unsaturated acids; the direct attack of benzene on the carbocations formed in the reaction and subsequent isomerizations of the finite reaction products.

The first step of the reaction, the trapping of the intermediate carbocations by benzene is a kinetically-controlled reaction and depends only on the relative stabilities of the carbocations originated from the alkylating agent.

The second step, the isomerization of phenylated acids is thermodynamically-controlled and covers to some extent the first step, modifying thus the ratio of the products.

A recent study [2] of the reaction of cyclopentylidene-acetic acid showed that only two main products are formed from the five possible isomers, namely *trans*-2-phenyl-cyclopentylacetic and *cis*-3-phenyl-cyclopentylacetic acids, the third product, *cis*-2-phenyl-cyclopentylacetic acid appearing only in a small amount (3%). The stereoselectivity of the reaction has been explained by a mechanism involving phenonium and lactoide ions, the appearance of lactoide ions in the course of Friedel-Crafts reactions of unsaturated acids being well-known in literature.[4-8]

It has been considered that the investigation of the reaction of cyclopentylacrylic acid (**1**) could give further details regarding the mechanism of these reactions, especially the competition between hydride shift and rearrangement of the five-membered ring.

The aluminium chloride catalyzed reaction of cyclopentylacrylic acid (**1**) with benzene at 40—45° leads with an overall yield of 60% to a mixture of acids (b.p.$_1$ 200°) having the elementary formula $C_{14}H_{18}O_2$. V.p.c.-analysis of the mixture of the corresponding methyl esters showed the presence of seven acids (table 1), which were identified by gas chromatographic comparison with authentical samples.

Table 1

Reaction products of the aluminium chloride catalyzed reaction of cyclopentylacrylic acid (1) with benzene, at 40—45°

Acids*	Moles %

* Identified as methyl esters; the herein given order corresponds to the retention times.

** Amounts determined from the NMR spectrum of the mixture of methyl esters (separated by preparative v.p.c.) using Eu (DPM)$_3$ as paramagnetic shift reagent.

As depicted in table 1, the reaction of cyclopentylacrylic acid (**1**) with benzene leads to phenylated acids with cyclopentane and cyclohexane skeleton.

Only three isomers are formed from the six phenyl-cyclopentylpropionic acids possible, these being the normal reaction products (**5**, **8** and **10**). Although the appearance of the 1-phenyl-1-(β-cyclopentyl-

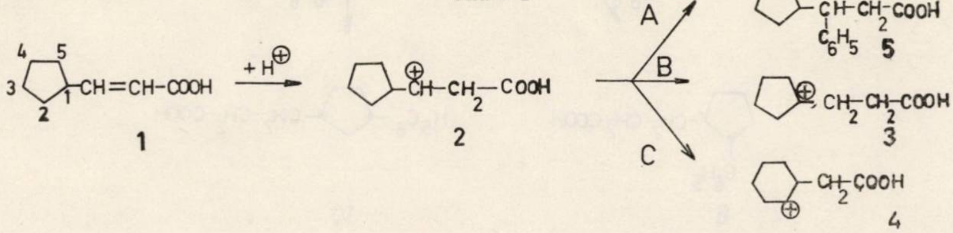
propionic) acid **(12)** in the course of the reaction is highly probable, this acid has not been found among the reaction products.

Unexpectedly, the main products of the reaction are the phenylcyclohexylacetic acids **17**, **19** and **21**, resulted by ring expansion and phenylation of the intermediate carbocations.

As pointed out above, the phenylation of acids takes place by the nucleophilic attack of benzene on the carbocations formed by hydride shift in the initially carbocation (in this case carbocation **2**), each ion undergoing isomerizations.[2,3,9,10]

Protonation of the double bond in acid **1** leads to carbocation **2** which may disappear in three different pathways (Chart 1) : attack of benzene on the primary formed carbocation leading to β-phenyl-β-cyclopentylpropionic acid **(5)** (path A), hydride shift which gives rise to carbocation **3** (path B) and ring enlargement of the five-membered ring to carbocation **4** (path C).

Chart 1



As shown in table 1, the proportion between five- and six-membered ring products is 1 : 6.

Although the data listed in table 1 should indicate an equilibrium between rings, the isomerization experiments of acids **5**, **10** and **12**, on the one hand, and of acids **17**, **19** and **21**, on the other hand, clearly showed that there is no interconversion between rings. Therefore, at least the pathways shown in Chart 1 are kinetically controlled.

Acid **5** is formed in a small amount (less than 4%) indicating that the reaction of carbocation **2** with benzene is much slower than the other two competitive transformations (paths B and C).[11] This is also supported by the failure of acid **5** to undergo isomerization and which, therefore, could be considered certainly as a primary product. The fact that acid **5** does not undergo isomerization is probably due to the imposed sterical hindrance in the formation of a phenonium ion and the vicinity of the destabilizing carboxyl group to the carbocationic center.

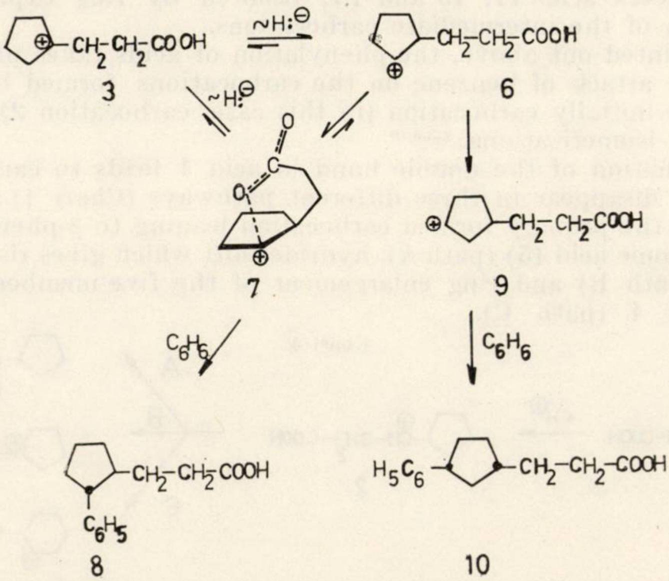
Chart 2 represents the mechanism of the reaction of cyclopentylacrylic acid (**1**) leading to the acids **8** and **10**.

Chart 2



The absence of *cis*-2-phenyl-β-cyclopentylpropionic acid among the reaction products indicates a stereospecific pathway involving an ion species — the lactoide ion **7** [2,4–8] more stable than an open carbocation.

Thus, the hydride shift in **3** and participation of carboxyl group leads to the lactoide ion **7**, which reacts with benzene from the opposite side of the lactoide ring to give *trans*-2-phenyl-β-cyclopentylpropionic acid (**8**). The lactoide ion **7** may also result by carboxyl participation from ion **6**, which partly isomerizes to ion **9**. The attack of benzene on **9** yields *cis*-3-phenyl-β-cyclopentylpropionic acid (**10**).

The proportion between the acids **8** and **10** is 1 : 1.1, indicating that carboxyl participation at the cationic center and hydride shift are comparable in rates, thus confirming earlier observations.[2,9] Acid **10** undergoes isomerization in the conditions of arylation reaction yielding a mixture of acids **8** and **10**, their ratio being 1 : 1.7.

In the case of cyclopentylacrylic acid (**1**) the formation of 1-phenyl-1-(β-cyclopentylpropionic) acid (**12**) may be possible. The tertiary ion **3** is entirely different from his inferior homologue which arises in the Friedel-Crafts reaction of cyclopentylideneacetic acid,[2] the former being able to be stabilized forming the lactoide ion **11**.

However, acid **12** cannot result from the lactoide ion **11** (which is in equilibrium with the open ion **3**), because of the spiran-like structure of **11** which does not allow the attack of benzene.

The absence of acid **12** in the reaction mixture does not invalidate the possibility of his formation, since the acid **12** undergoes easily complete isomerization in the reaction conditions yielding the acids **8** and **10** in a ratio of 1 : 2.6.

Isomerization of 1-phenyl-1-(β-cyclopentylpropionic) acid **(12)** (Chart 3) involves the intermediate phenonium ion **13** resulted by hydride abstraction at carbon C-2. The subsequent attack of a hydride ion on **13** at C-1 leads to *trans*-2-phenyl-β-cyclopentylpropionic acid **(8)**.

Neither in the reaction of cyclopentylacrylic acid **(1)**, nor in the isomerization of 1-phenyl-1-(β-cyclopentylpropionic) acid **(12)**, a *trans* 1,3-disubstituted acid is formed. This is due to the well-known fact that *cis*-1,3-disubstituted cyclopentane derivatives are thermodynamically more stable. [2, 12–15]

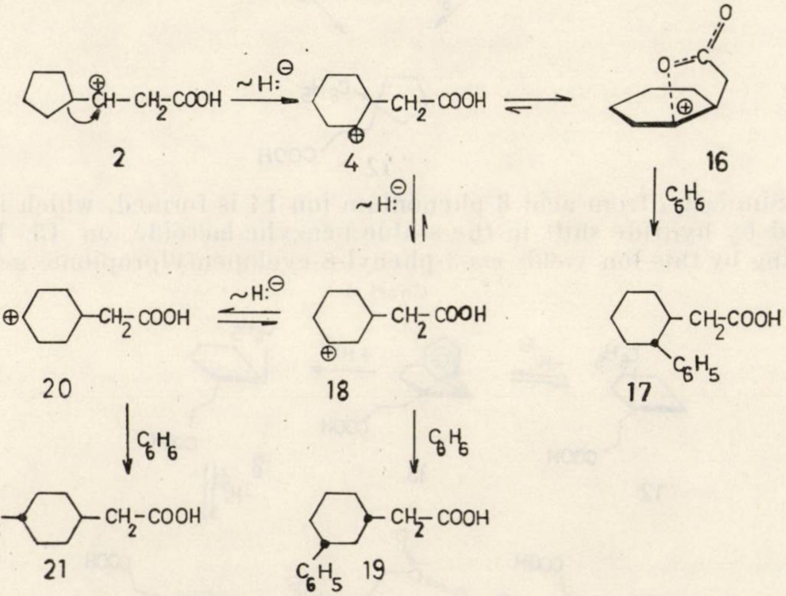
[15] D. Vareck, C. Ouannes and J. Jaques, *Bull. Soc. chim. France*, **1965**, 1662.

Three phenyl-cyclohexylacetic acids are present in the reaction mixture, acids **17**, **19** and **21** (table 1). These acids derive from carbocation **2** by ring enlargement which leads to carbocation **4** (Chart 1, path C). Hydride shift in **4** generates ion **18** which is then converted by another hydride shift to ion **20**.

From carbocation **4** by carboxyl participation the stable lactoide ion **16** results. The attack of benzene on ions **16** and **18** gives rise to *trans*-2-phenyl-cyclohexylacetic acid **(17)** and *cis*-3-phenyl-cyclohexylacetic acid **(19)**, respectively. Similarly, carbocation **20** affords *trans*-4-phenylcyclohexylacetic acid **(21)**.

Chart 4



The greater proportion of six-membered ring products with respect to the five-membered ones (1 : 6) indicates that the breakage of the C—C bond during the rearrangement has a rate comparable with the isomerization of **2** in **3** promoted by hydride shift.

This result becomes explicable considering that the ring enlargement reduces not only the destabilizing effect of carboxyl group in **2**, but the eclipsing strain of the five-membered ring too.

Acid **17** results in a smaller proportion than acids **19** and **21** (1 : 7.2), it showing that the carboxyl group participates in lactoidisation to a less extent in ion **16** than in the foregoing case of ion **7**.

The stereochemistry of the formed phenyl-cyclohexylacetic acids is in agreement with the thermodynamic stabilities of dimethyl[16] — and diphenyl-cyclohexanes[17]; *trans*-1,2, *cis*-1,3 and *trans*-1,4-disubstituted derivatives are the more stable among the six diastereomers possible, the preferred conformation of the three isomers being diequatorial.[16]

[16] Citat 12, p. 214.

[17] A. M. GLATZ, A. C. RĂZUŞ, F. BADEA and C. D. NENITZESCU, *Rev. Roumaine Chim.*, **17**, 1735 (1972).

As shown, phenylated acids undergo isomerizations under the conditions of the arylation reaction.

Accordingly, isomerization of acid **17** yields a mixture of acids **17**, **19** and **21** in a relative proportion of 9.85 : 1.1 : 1. The mixture resulted from the isomerization of **19** contains acids **21** and **19** in a ratio of 1 : 5.25, while the same acids are formed in a ratio of 2.1 : 1 in the isomerization of acid **21**.

The results of isomerization experiments are summarized in table 2.

Table 2

Isomerization products of phenyl-cyclohexylacetic acids

Reagent	Products, moles %		
	17	**19**	**21**
17*	61.7	6.8	6.2
19	—	84	16
21	—	31.8	66.5

* In this reaction some secondary products were formed which were not identified.

A comparison of the proportions of acids **17**, **19** and **21** from tables 1 and 2 clearly shows that the equilibrium has not been attained under the employed conditions.

In the isomerization of disubstituted cyclohexane derivatives, conformational effects of the six-membered ring have to be taken into account.

Thus, *cis*-3-phenyl-cyclohexyl acetic acid **(19)** cannot result by a direct isomerization through phenonium ion from *trans*-2-phenyl-cyclohexylacetic acid **(17)**, since in this way the reaction should proceed with retention of configuration leading to *trans*-3-phenyl-cyclohexylacetic acid **(26)**. Therefore, in the isomerization of **17** to **19** a further step must be involved, which could be : a) either an isomerization 1,3-*trans* → 1,3-*cis*, subsequent to the rearrangement of the phenyl group : b) or a *trans*-1,2⇄ *cis*-1,2 isomerization prior to the formation of the phenonium ion.

The preferred *e, e* conformation of *trans*-2-phenyl-cyclohexylacetic acid **(17)** (one butane-gauche interaction) cannot give rise to a phenonium ion, because of the staggered phenyl group. Hence, the diequatorial conformer must be converted into the diaxial one, the phenyl group being now able to form the phenonium ion **25** (Chart 5). Migration of phenyl group followed by the isomerization of acid **26** should yield acid **19** (case a).

The best criterion for distinguishing between the two possibilities is the comparison of the energy differences involved in both cases.

The energy barrier imposed in the conversion of acid **17** from the *e, e* into the *a, a* conformer exceeds the enthalpy difference between *trans*- and *cis*-2-phenyl-cyclohexylacetic acid (**17** and **23**, respectively) (the energy gap between *e, e* and *a, a* dimethylcyclohexane is 2.7 kcal/

mol, whereas for converting 1,2-dimethylcyclohexane from the *trans* into the *cis* form 1.87 kcal/mol are needed[16]).

These facts show that a reaction pathway involving isomerization of **17** in *cis*-2-phenyl-cyclohexylacetic acid (**23**) and subsequent phenyl migration seems to be more probable (Chart 6, case b).

Noteworthy is that acid **17**, compared with acids **19** and **21**, undergoes isomerization to a less extent (table 2), although the thermodynamic stabilities of disubstituted cyclohexanes decrease in the order *cis* 1.3 > *trans* 1.4 > *trans* 1.2.[16,17] This result can be explained by the fact that the isomerization of acid **17** involves the development of a cationic center, destabilized by the vicinity of carboxyl group, thus increasing the free energy of activation needed for the formation of the intermediate ion **22** (Chart 6).

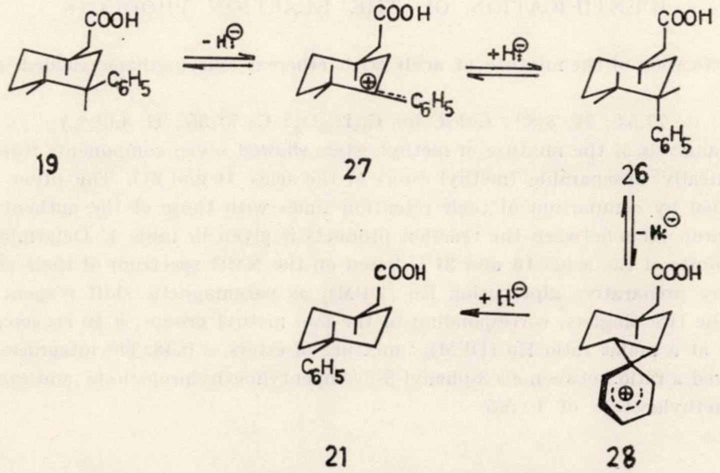
In a similar way, the isomerization of acid **19** in **21** takes place also through a benzylic ion (**27**), followed by the formation of phenonium ion

28 and hydride attack on this, leading to *trans*-4-phenyl-cyclohexylacetic acid (**21**) (Chart 7). In this case the energy needed for converting **19** *e*, *e* in **19** *a*, *a* exceeds also the enthalpy difference between *cis*- and *trans*-3-phenyl-cyclohexyl-acetic acid (**19** and **26**) (the corresponding values for 1,3-dimethylcyclohexane are: 5.4 kcal/mol for converting *e*, *e* into *a*, *a* and 1.8 kcal/mol for the *cis* $\rightleftharpoons$ *trans* isomerization [16]).

Chart 7



The fact that *trans*-4-phenyl-cyclohexylacetic acid (**21**) isomerizes to a larger extent than acid **19** must be due to an effect of entropy of reaction also remarked in the isomerization of the corresponding diphenylcyclohexanes.[17]

EXPERIMENTAL

All melting points are uncorrected. IR spectra were recorded on a double beam UR 20 Carl Zeiss-Jena spectrophotometer. NMR spectra were recorded on a Varian A 60-A spectrometer using TMS as internal standard. Glpc analyses were carried out on a Willy Giede model 18.3 gas chromatograph using a 3 m × 4 mm column packed with 20% ethylene-glycol-succinate on Chromosorb W (60–80 mesh); column temperature: 195°; carrier gas: hydrogen, 80 ml/min.

REACTION OF CYCLOPENTYLACRYLIC ACID (1) WITH BENZENE (ACIDS 5, 8, 10, 17, 19, 21).

A solution of 5 g (35.5 mmoles) cyclopentylacrylic acid (**1**)[18] in 45 ml anhydrous benzene was added dropwise to a stirred suspension of 6.7 g (53 mmoles) of aluminium chloride in 20 ml anhydrous benzene, at 40–45°. Stirring was continued at this temperature for 4 hrs. After quenching in ice-water and extraction of the benzene layer with 10% potassium hydroxide, the alkaline layer was acidified and extracted with ether. Drying over magnesium sulfate and removal of the solvent yielded a pale yellow oil, b.p.$_1$ 200—202°, weighing 4.6 g (60%) which rapidly solidified. (*Found* : C, 77.65 ; H, 7.93 ; *Calcd.* for $C_{14}H_{18}O_2$: C, 77.10 ; H, 8.32%)

---

[18] R. Roth and H. Erlenmeyer, *Helv. Chim. Acta*, **38**, 1278 (1955).

NMR spectrum (CCl_4, δppm) of the mixture of acids shows the following signals : 12.1 (1 carboxylic proton) ; 7.14 (5 aromatic protons, singlet) ; 2.8—0.8 (12 aliphatic protons).

IDENTIFICATION OF THE REACTION PRODUCTS

Esterification of the mixture of acids with ethereal diazomethane yielded an oil. b.p. 1 150—155°.

(*Found* : C, 77.54 ; H, 8.89 ; *Calcd.* for $C_{15}H_{20}O_2$: C, 77.55 ; H, 8.68%)

Glpc-analysis of the mixture of methyl esters showed seven components from which two were analytically unseparable (methyl esters of the acids **10** and **21**). The other components were identified by comparison of their retention times with those of the authentical samples.

The proportion between the reaction products is given in table 1. Determination of the relative amounts of the acids **10** and **21** is based on the NMR spectrum of their ester mixture (separated by preparative glpc, using Eu $(DPM)_3$ as paramagnetic shift reagent.

For the two singlets, corresponding to the two methyl groups, a 10 Hz separation could be obtained at a molar ratio Eu $(DPM)_3$: mixture of esters = 0.48. The integration of the two signals showed a ratio between *cis*-3-phenyl-β-cyclopentylmethylpropionate and *trans*-4-phenylcyclohexylmethylacetate of 1 : 5.5.

REAGENTS. CHROMATOGRAPHIC STANDARDS

β-Phenyl-β-cyclopentylpropionic acid (5) and methyl ester

The acid **5** was obtained by alkaline hydrolysis of methyl ester prepared by Arndt-Eistert synthesis from α-phenyl-α-cyclopentylacetic acid [19] ; m.p. 86—88° (aqueous ethanol).

NMR spectrum (CCl_4, δppm) of methyl ester : 7.15 (5 aromatic protons, singlet) ; 3.6 (esteric-CH_3, 3 protons, singlet) ; 3.15—2.4 (3 protons) ; 2.4—0.8 (9 protons).

trans-2-Phenyl-β-cyclopentylmethylpropionate. The methyl ester of acid **8** has been prepared by Arndt-Eistert reaction of a mixture of phenyl-cyclopentylacetic acids [2] (containing *trans*-and *cis*-2-phenyl-cyclopentylacetic acid and *cis*-3-phenyl-cyclopentylacetic acid) and concentration of the mixture in the *trans* isomer by chromatography over neutral alumina (650 × × 10 mm) eluating with petroleum ether and ethyl ether (10%). By passing repeatedly the mixtures through the column, a 70% enrichment of the mixture in *trans*-2-phenyl-β-cyclopentylpropionate could be reached, the concentration being followed by v.p.c.

cis-3-Phenyl-β-cyclopentylpropionic acid **(10)** *and methyl ester.* The acid **10** was prepared from *cis*-3-phenyl-cyclopentylacetic acid [2] by Arndt-Eistert synthesis followed by alkaline hydrolysis of *cis*-3-phenyl-β-cyclopentylmethylpropionate.

NMR spectrum (CCl_4, δppm) of methyl ester : 7.18 (5 aromatic protons, singlet) ; 3.6 (esteric-CH_3, 3 protons, singlet) ; 3.0 (1 benzylic proton, multiplet centered at δ = 3.0) ; 2.6—1.1 (11 protons).

1-Phenyl-1-(β-cyclopentylpropionic) acid **(12)** *and methyl ester.* The acid 12 has been prepared according to the method described by Arnold *et al.*[20] The methyl ester was obtained by diazomethane esterification.

trans-2-Phenyl-cyclohexylacetic acid (**17**) *and methyl ester*. The synthesis of the acid **17** has been described by Bachmann and Fornfeld.[21] The methyl ester was obtained by esterification with diazomethane.

cis-3-Phenyl-cyclohexylacetic acid (19) and methyl ester

2-Phenyl-6-carbethoxy-cyclohexanone was prepared by the method indicated by Baker, McOmie, *et al.*,[22] with 2-phenylcyclohexanone[23] as starting material.

cis-1-Phenyl-2-oxo-3-cyclohexylacetic acid

To a stirred suspension of 3.8 g (77 mmoles) NaH (50% mineral oil) in 100 ml anhydrous benzene, a solution of 19 g (77 mmoles) 2-phenyl-6-carbethoxy-cyclohexanone in 50 ml anhydrous benzene was added dropwise at 40—45°. Stirring was continued at 60—70° for 1.5 hrs, since no more hydrogen was evolved. A solution of 13 g (77 mmoles) of ethyl-bromoacetate in 30 ml anhydrous benzene was added slowly at 60° and stirring was continued for 45 min. The mixture was then stirred and refluxed for another 3 hrs and after cooling it was poured into ice water and slightly acidified with acetic acid. The separated benzene layer was dried over magnesium sulfate and the solvent removed *in vacuo*. The residual oil (22 g) was refluxed for 16 hrs with 200 ml concentrated hydrochloric acid and 160 ml acetic acid. After removal of solvents *in vacuo* the residual material was dissolved in ether and then extracted with aqueous KOH 7%. The alkaline layer was acidified with hydrochloric acid and deposited a highly viscous material which was crystallized two times from CCl_4 yielding 5 g of a white solid, m.p. 131.5—132.5°. (*Found* : C, 70.88 ; H, 6.78 ; *Calcd.* for $C_{14}H_{16}O_3$: C, 72. 39 ; H, 6.94%).

cis-3-Phenyl-cyclohexylacetic acid (19)

5 g of the ketoacid obtained above were reduced by the method employed by Arnold *et al.*,[20] with hydrazine and potassium hydroxide in diethylene glycol. The mixture worked up as usual yielded, after crystallization from aqueous ethanol (1 :1), 1.3 g of the acid, m.p. 83—86°.

The methyl ester was obtained by diazomethane esterification.

NMR spectrum (CCl_4, δppm) of methyl ester : 7.13 (5 aromatic protons, singlet) ; 3.6 (esteric-CH_3, 3 protons, singlet) ; 2.7 (1 benzylic proton, multiplet centered at $\delta = 2.7$) ; 2.37 (*exo*-cyclic-CH_2-, 2 protons, broadened singlet) ; 2.3—1.2 (9 protons).

trans-4-Phenyl-cyclohexylacetic acid (21) and methyl ester

Reduction of biphenyl-4-carboxylic acid,[24] according to Zimmerman,[25] yielded *trans*-4-phenyl-cyclohexyl-carboxylic acid which by Arndt-Eistert chain lengthening gave the methyl ester of **21**. Alkaline hydrolysis of the methyl ester yielded acid **21**, m.p. 71° (aqueous ethanol).

NMR spectrum (CCl_4, δ ppm) of methyl ester : 7.17 (5 aromatic protons, singlet) ; 3.67 (esteric-CH_3, 3 protons, singlet) ; 2.8—0.9 (12 protons).

ISOMERIZATIONS OF THE ACIDS 5, 10, 17, 19, 21

All isomerization experiments were carried out under identical conditions, in benzene, at 40 – 45°, 4 hrs. The molar ratio employed was : acid $AlCl_3$: benzene = 1.1.5 : 20. The reaction mixtures were worked up as pointed above, esterified with ethereal diazomethane and analysed by v.p.c.

Isomerization of β-phenyl-β-cyclopentylpropionic acid (**5**). Acid 5 failed to undergo isomerization under the conditions employed.

Isomerization of 1-phenyl-1-cyclopentylpropionic acid (**12**). The reaction mixture contained two main components corresponding to the *trans*-2-phenyl-cyclopentylpropionic (**8**) (27.1 %) and *cis*-3-phenyl-cyclopentylpropionic (**10**) (61.2 %) acids, the other components being minor. Acid **12** was completely consumed during the reaction.

Isomerization of cis-3-phenyl-β-cyclopentylpropionic.acid (**10**) yielded (a mixture of *cis*-3-phenyl-β-cyclopentylpropionic acid (**10**) (60.5 %) and *trans*-2-phenyl-β-cyclopentylpropionic acid (**8**) (35.5 %).

Isomerization of phenyl-cyclohexylacetic acids (**17, 19, 21**). The isomerization results of phenyl-cyclohexylacetic acids are summarized in table 2.

QUELQUES REMARQUES SUR LES PROPRIÉTÉS DES BÉTONS AUX RÉSINES SYNTHÉTIQUES SANS LIANTS MINÉRAUX. I

ION IONESCU

Laboratoires des Bétons, Mortiers et Armatures pour Bétons — I.C.M.P.C.—Bucarest, 507, Şoseaua Giurgiului

Reçu le 18 avril 1973

On présente les résultats des recherches sur l'influence des propriétés physiques et chimiques des différents types de résines synthétiques, et des matériaux employés comme liants organiques et agrégats ou filler, ainsi que des facteurs de composition et technologique sur les principales propriétés structurales et physiques-chimiques des bétons à résines synthétiques sans liants minéraux.

1. ASPECTS GÉNÉRAUX. MATÉRIAUX UTILISÉS POUR LES RECHERCHES ET POUR LES EXPÉRIENCES. RÉSULTATS DES RECHERCHES PRÉLIMINAIRES

Les premières études sur les bétons aux résines synthétiques sans liants minéraux ont commencé, dans divers pays, après 1955. Il devenait, en effet, nécessaire de trouver des matériaux à propriétés supérieures à celles des bétons classiques, que ce soit les caractéristiques physiques et mécaniques ou, surtout, la résistance à l'action des agents chimiquement corrosifs. Dès le début, ces études se sont révélées difficiles en raison des grandes différences entre les propriétés de résines synthétiques appartenant aux mêmes groupes de produits, qui varient d'un pays à l'autre et de la nouveauté du sujet. On ignorait le comportement possible, au cours d'une exploitation prolongée, des résines synthétiques utilisées comme liants organiques, soumises à l'action des agents physiques et chimiques, ainsi qu'aux sollicitations mécaniques. Ces raisons, et les méthodologies très différentes, adoptées par les divers chercheurs en fonction du but poursuivi, expliquent la modestie des résultats obtenus jusqu'ici, en regard des perspectives expérimentales ou industrielles qu'ouvre l'étude de ces nouveaux types de bétons. Il n'existe pas encore de critères acceptés par la plupart des chercheurs et applicables à la classification des bétons de résine synthétique aux matériaux et à leurs techniques de confection.

L'une des classifications la plus souvent utilisée pour les bétons aux résines synthétiques sans liants minéraux est celle qui indique le type de la résine utilisée de la manière suivante : [1-3]

— bétons de résines époxydes, bétons de résines furanniques, bétons de résines phéno-formaldéhydes, bétons de résines polyesters, etc.

Pour l'étude des propriétés des bétons aux résines synthétiques, en tenant compte des possibilités qu'elles offrent dans diverses combinaisons avec les matériaux classiques et surtout avec les bétons de ciment, on a considéré que les bétons de résines synthétiques sans liants minéraux devraient remplir approximativement les exigences générales suivantes : aptitude à être confectionnés avec des moyens accessibles aux usines de préfabrication et aux grands chantiers, sans exiger, si possible, un personnel hautement qualifié d'exécution et de surveillance, temps de prise suffisamment prolongé pour le travail et la mise en œuvre et bonne ouvrabilité, durcissement après la mise en œuvre et performances techniques prescriptes atteintes dans un délai relativement bref, afin de permettre un décoffrage et une manutention faciles et la mise en exploitation la plus rapide possible ; ne pas nécessiter des conditions spéciales de protection immédiatement après la mise en œuvre ; faible retrait afin de permettre l'application ou le coulage en couches épaisses ; après le durcissement, bonne résistance à l'action des agents atmosphériques et aux sollicitations dues aux variations de température, au phénomène de gel-dégel, à l'action des rayons solaires et de l'eau, donc durabilité dans différentes conditions d'exploitation ; résistances supérieures à l'action de différents agents chimiquement agressifs ; résistances mécaniques supérieures, surtout résistance à la traction, module d'élasticité voisin de celui du béton de ciment (afin d'éviter de trop fortes concentrations des efforts aux joints ou dans les points de contact des différentes couches) ; fluage peu accusé par rapport à celui du béton ; bonne adhérence au béton de ciment et aux différents types d'armatures, de matériaux de construction, etc. [3] Il convient de considérer, avant même de choisir les résines, quels sont les durcisseurs, le pourcentage et les agrégats convenables, afin de pouvoir satisfaire totalement ou partiellement aux exigences énumérées ci-dessus. Remarquons que certaines des données publiées sur les bétons de résine sont contradictoires, les auteurs consultés expliquent ces contradictions par des différences sensibles entre les propriétés des résines et celles des autres matériaux utilisés. C'est pourquoi nous avons choisi, en vue des études préliminaires, les matériaux suivants, produits en Roumanie :

a) *Résines synthétiques*

1) résines époxydes : résine Dinox 040 A ;

2) résines phénol-formaldéhyde : résine LS. 1 ;

3) résines furanniques : le monomère furfurol-acétone FA ;

4) résines urée-formaldéhydes : les colles Urélit R-UR et Uréfor-U et la colle Urélit E modifiée à la mélamine URM ;

5) résines mélamine-formaldéhydes (triaziniques) : les résines M_1, M_2, M_3, M_4 et MM·

Au total 5 groupes de résines et 11 produits. Comme agrégats, on a utilisé dans cette phase du sable de rivière 0 à 7 mm, provenant de la ballastière Borleşti-Argeş dont la granulation est bonne. Les recherches ont permis de classer les bétons obtenus d'après les critères suivants :

CRITÈRE DES RÉSISTANCES MÉCANIQUES À LA TEMPÉRATURE NORMALE D'ESSAI

Les bétons étudiés sont divisés en trois groupes bien distincts :

1) bétons à fortes résistances mécaniques, $Rc_{28}=500$ à 800 daN/cm^2 et $Rt_{28} = 70$ à 240 daN/cm^2 : les bétons à résine époxyde Dinox 040 A et à résine furannique, monomère FA ;

2) bétons à résistances mécaniques moyennes, $Rc_{28} = 200$ à 350 daN/cm^2 et $Rt_{28} = 20$ à 40 daN/cm^2 : les bétons à résine phénol-formaldéhyde LS.1 ;

3) bétons à faibles résistances mécaniques, Rc_{28} au-dessous de 150 daN/cm^2 : les bétons à résines urée-formaldéhydes et mélamine-formaldéhydes.

CRITÈRE DES RÉSISTANCES MÉCANIQUES APRÈS CONSERVATION PENDANT 72 HEURES À LA TEMPÉRATURE DE 60° SUCCÉDANT À UNE CURE DE 28 JOURS À LA TEMPÉRATURE NORMALE

Les bétons étudiés peuvent être ainsi groupés :

— Comportement très bon, la résistance reste constante ou varie dans les limites de $\pm$ 5% par rapport à Rc_{28} : bétons de résine FA, LS.1, mélamine-formaldéhyde (M_3, M_4, MM) et urée-formaldéhydes modifiées à la mélamine (URM).

— Comportement bon, la résistance diminue tout au plus de 25% comparée au Rc_{28} : bétons de résine urée-formaldéhyde.

— Comportement faible, bétons de résine Dinox 040 A avec lesquels on obtient, après un traitement de 3 jours à 60°, des pertes de résistances de 50 à 80%.

CRITÈRE DE LA CONSERVATION DE LA RÉSISTANCE À L'IMMERSION DANS L'EAU, APRÈS UN DURCISSEMENT À L'AIR DE 28 JOURS, ET DE L'AUGMENTATION DE LA RÉSISTANCE APRÈS UNE CURE MIXTE DE 7 JOURS À L'AIR HUMIDE ET 21 JOURS À L'AIR À HYGROMÉTRIE ET TEMPÉRATURE NORMALES

Les bétons étudiés peuvent être ainsi groupés :

— Comportement très bon : bétons de résine urée-formaldéhydes (UR, U), urée-formaldéhyde modifiée à la mélamine (URM) et mélamine-formaldéhyde (M_3, M_4, MM), qui, conservée en régime mixte et parfois lors de l'immersion dans l'eau, enregistrent des augmentations de résistance, par rapport aux matériaux similaires conservés à l'air dans l'intervalle confection-essai.

— Comportement bon : bétons de résine furannique, monomère FA, et de résine phénol-formaldéhyde LS. 1 qui, après immersion dans l'eau, à 28 jours, ont des résistances pratiquement égales à celles des bétons conservés tout le temps à la température normale avec une humidité relative de l'air de 50 à 65%.

— Comportement assez bon : bétons de résine époxyde Dinox 040A qui, après conservation en régime mixte, enregistrent des résistances de 70 à 90% de celles des éprouvettes conservées 28 jours à l'air à température normale et humidité relative de 50 à 65%.

A partir des données des recherches préliminaires et des données techniques-économiques dont on a disposé alors, il a été possible de classer, en vue des principales applications possibles sous forme de liants organiques, les résines produites et étudiées ;

— Confection de bétons de résines synthétiques sans liants minéraux : la résine furannique, monomère FA, la résine époxyde, Dinox 040 A et la résine phénol-formaldéhyde LS. 1, priorité étant donnée à l'étude du monomère FA et de la résine LS.1.

— Stabilisation des terres : les résines urée-formaldéhydes (UR et U), la résine urée-formaldéhyde modifiée à la mélamine (URM) et les résines mélamine-formaldéhydes (M_3, M_4 et MM).

b) *Agrégats*

Les critères de qualité concernant les conditions que doivent remplir les agrégats destinés aux bétons aux résines synthétiques ont été, initialement, les suivants : les matériaux utilisés comme agrégats ne doivent pas réagir avec la résine utilisée comme liant organique et avec son durcisseur, ce qui aurait pour résultat d'affaiblir la structure du béton. Cette condition impose d'exclure, si l'on emploie des résines qui durcissent sous l'action de certains catalyseurs acides, l'utilisation des matériaux qui renferment des carbonates, car, par leur réaction avec le durcisseur acide, apparaissent à la surface des grains de carbonates, des pellicules ou une couche de matériau altéré qui affaiblit la structure du béton.[4]

Une autre cause d'affaiblissement peut être la réaction avec les carbonates d'une partie du durcisseur acide de la résine, car il est possible que le durcisseur restant ne suffise pas à assurer les réactions de polymérisation à la température ambiante et à durcir complètement la résine.

Pour obtenir une bonne adhérence, il est nécessaire d'utiliser un agrégat minéral à teneur minimale d'impuretés, car celles-ci peuvent affecter les propriétés finales du béton. Ainsi, l'argile adhérant aux agrégats empêche la formation d'une forte liaison directe entre la résine et la surface des granules par interposition d'une couche de faible résistance. De plus, quelques-uns des composants de l'argile peuvent réagir avec le durcisseur de la résine, ce qui est une autre cause de mauvais résultats. Une pellicule d'eau à la surface des agrégats rend, elle aussi, dans une certaine mesure, l'adhérence incertaine, la plupart des résines synthétiques étant insolubles dans l'eau. [1-4]

Des résistances mécaniques supérieures pour une faible consommation de résine ne peuvent être obtenues qu'aux conditions supplémentaires suivantes :

— Les agrégats proviendront de roches à résistance très élevée.

— On utilisera un agrégat à granulométrie continue et à densité maximale, avec un volume minimal de vides.

---

[4] S. Solacolu, «Chimia fizică a silicaţilor tehnici», Ed. tehnică, Bucarest, 1968.

— Le travail et le compactage du matériau frais seront effectués avec soin afin d'éviter la ségrégation des composants du mélange, la résine utilisée comme liant ayant une faible viscosité. Cette condition a été vérifiée tant par le calcul que par l'expérience et la conclusion est qu'on ne peut utiliser sans discernement les compositions d'agrégats établies et recommandées comme optimales pour la préparation des bétons de ciment. En effet, dans les bétons de ciment, le volume de vides de l'agrégat est en bonne partie compensé par le liant minéral lui-même pour lequel les normes en vigueur admettent une finesse de broyage qui inclut 85 à 90% de micro-granulats au diamètre inférieur à 0,088 mm, puisqu'on sait que les grains de ciment de diamètre supérieur à 30 μ ne sont jamais complètement hydratés et qu'ils remplissent dans le béton le rôle de micro-agrégats, raison pour laquelle le ciment durci porte encore le nom de «micro-béton». Les calculs et les expériences effectués ont prouvé la nécessité d'introduire dans le mélange d'agrégats une quantité de matériau très fin (qui doit remplir, en première approximation, les mêmes conditions de qualité que le gros agrégat) et qui, dans les bétons aux résines synthétiques, a un rôle similaire au filler calcaire utilisé dans la préparation des mélanges asphaltiques : c'est pour cette raison que, dans le présent ouvrage, le matériau fin ajouté à l'agrégat destiné aux bétons a été appelé filler. En ce qui concerne le rôle du filler dans l'agrégat destiné aux bétons de résines synthétiques, les recherches ont permis de déterminer que celui-ci répond aux considérations techniques et économiques suivantes :

— L'addition de filler en quantité optimale contribue à une bonne répartition du liant organique qui se dépose en pellicules à la surface de l'agrégat, formant avec celui-ci — qui lui donne sa rigidité — un système spatial unifié grâce aux forces d'adhésion qui se développent à la prise et au durcissement (fig. 1 *a* et *b*). On est ainsi sûr d'obtenir un matériau homogène, aux propriétés relativement uniformes au niveau de la macrostructure. Judicieusement dosé, le filler contribue à remplir les vides se trouvant entre les éléments des gros granulats et, matériau moins cher et d'obtention plus facile, il remplace partiellement la résine. Ainsi le filler contribue à la confection d'un matériau plus dense, à faible perméabilité et à résistances mécaniques élevées, avec une quantité réduite de résine (fig. 1 *a* et *b*). Il contribue encore à éviter la ségrégation des composants du mélange frais et à améliorer l'ouvrabilité du béton, lorsqu'on utilise certaines résines synthétiques à basse viscosité, tels que le monomère FA et la résine LS. 1. Un excès de filler dans le mélange d'agrégats donne des résultats négatifs, tels que : une augmentation non justifiée du dosage en résine (en raison de la grande surface spécifique du filler), une diminution du poids spécifique du béton et l'obtention d'un matériau à résistances mécaniques plus faibles (fig. 1 *c*). [1-4]

— Les conditions économiques et les possibilités de fourniture des agrégats pour les bétons de résines synthétiques exigent que ceux-ci soient les plus communs possibles. Il en résulte, en première approximation, qu'on peut utiliser les matériaux suivants : les agrégats siliceux de rivière, exempts de carbonates, les agrégats quartzeux de carrière, riches en SiO_2, les sables quartzeux fins utilisés dans la verrerie, les agrégats de concassage provenant des roches dures à caractère acide ou neutre, ainsi que le granite, l'andésite basaltique de Malnaş, etc., les agrégats spéciaux : carbure de silicium, corindon, coke de haut fourneau, etc.

— La composition granulométrique des agrégats destinés aux bétons de résines synthétiques peut être déterminée par les essais à partir des agrégats à compositions optimales pour les bétons de ciment, à granulométrie 0 à 3, 0 à 7 et 0 à 15, auxquels on ajoute la quantité nécessaire de filler (matériau finement broyé à granulométrie inférieure à 0,15 mm) jusqu'à ce qu'on obtienne le volume minimal de vides dans le mélange d'agrégat et de filler.

Afin de vérifier expérimentalement les critères de qualité établis, les recherches ont porté sur les matériaux suivants :

— A_1 : agrégat minéral siliceux de la ballastière de Borleşti, rivière d'Argeş, classes 0 à 7 et 7 à 15 mm, à 86 % de SiO_2 (environ 60 % de quartz et 30 % de feldspath) ;

— A_2 : agrégat minéral quartzeux, sable et gravier lavé de l'exploitation Glatna, Timiş, classes 0 à 1, 1 à 4, 4 à 8 et 8 à 15 mm, renfermant 98,5 % de SiO_2 (environ 95 % à 98 % de quartz), qui a été à nouveau trié au laboratoire.

— A_3 : agrégat minéral quartzeux, sable et gravier lavé de l'exploitation Făgetul Ieri — Cluj, classes 1 à 3, 3 à 7 et 7 à 15 mm à 98 % minimum de SiO_2 (environ 95 à 97 % de quartz).

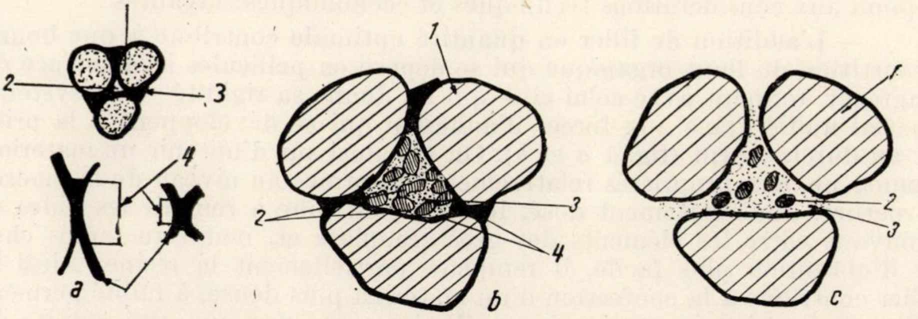

Fig. 1. — Formation de la structure du béton de résine synthétique ;

a) lorsqu'on emploie un agrégat à volume important de vides (monogranulaire). *1.* granules de gros sable ou de gravier. *2*, vide ou pore. *3* et *4*, joints de résine formés entre les particules.

b) lorsqu'il s'agit d'un agrégat à composition granulométrique judicieusement choisie, avec la quantité strictement nécessaire de matériau de remplissage. *1*, grains de gros sable ou de gravier. *2*, matériau fin de remplissage. *3*, grains de sable fin. *4*, liant organique ;

c) dans le cas d'une quantité exagérée de matériau de remplissage. *1*, grains de gros sable ou de gravier. *2* , grains de sable fin. *3*, matériau de remplissage très fin.

— A_4 : criblure d'andésité basaltique de Malnaş livrée couramment pour les travaux routiers, classes 1 à 3, 3 à 8, et 8 à 15 mm, lavée et tamisée à nouveau au laboratoire.

— A_5 : granite concassé (provenant de l'exploitation Turcoaia, Tulcea), classes 1 à 4, 4 à 8 et 8 à 15 mm, lavé et trié à nouveau au laboratoire.

— A_6 : agrégat A_1, où l'on a remplacé par du calcaire concassé (environ 93 % de CaO) les éléments de diamètre 1 à 7 dans la proportion de 15 et de 30 % de la classe correspondante de sable siliceux.

— Fc, limaille de fer (ou têtes de clou), de fuseau granulométrique 0,7—4,00 mm, déchet industriel provenant de l'industrie des Fils Métalliques, Cîmpia Turzii.

— CS, carbure de silicium, de fuseau granulométrique 0,16 à 2,00 mm.

— C, corindon, de fuseau granulométrique 0,06 à 1,6 mm.

— F_1, filler de sable quartzeux lavé, utilisé dans la verrerie, à fuseau granulométrique limite 0,04 à 0,20 mm, à 97 % de SiO_2 au minimum (environ 96 % de quartz) ;

— F_2, filler de farine de quartz, obtenu en broyant l'agrégat A_2, à granulométrie inférieure à 0,50 mm, dont environ 90 % dans le fuseau 0,04 à 0,15 mm ;

— F_3, filler d'andésite basaltique broyée (A_4) à granulométrie approximativement dans le même fuseau que F_2 ;

— F_4, filler spécial, coke de haut fourneau broyé à la même finesse que F_2.

Pour systématiser les recherches et pour mettre en ordre les nombreux paramètres étudiés, on a procédé de la manière suivante :

1) étude et sélection de l'agrégat ou des agrégats aptes à fournir les meilleurs résultats, parmi les 6 types communs — A_1—A_6 ;

2) sélection du filler ou des fillers aptes à fournir les meilleurs résultats, parmi les 4 types étudiés ;

3) détermination des taux optimaux de filler pour différentes compositions d'agrégats dans le domaine 0 à 15 mm et étude des agrégats spéciaux F_c, C_s et C, etc., pour la préparation des bétons de résine furannique — monomère FA.

Les principaux résultats des recherches à ce stade, avec les agrégats habituels A_1—A_6 et donc le filler F_1 (voir tableau 1), ont permis les conclusions suivantes : l'addition de filler influence sensiblement, de façon positive, les résistances mécaniques pour toutes les compositions d'agrégats étudiées avec conservation constante du dosage en résine, durcisseur et diluant, et procure une meilleure ouvrabilité du matériau frais, contribuant à éviter la ségrégation des composants du mélange et à fournir des résultats plus homogènes ($\pm$ 8 % au maximum par rapport à la moyenne), alors que les résultats obtenus avec les éprouvettes confectionnées sans addition de filler montrent une plus grande dispersion ($\pm$ 12 % pour les essais à 28 jours et $\pm$ 16 % pour les essais à 3 et 7 jours), ce qui confirme par voie expérimentale les critères établis.

Le rapport entre la résistance à la compression et la résistance à la traction par flexion des bétons à monomère FA étudiés varie alors entre 4,5 et 6,2. Les valeurs minimales du rapport $R_c/R_{ti} = 4{,}5-5{,}2$ sont généralement obtenues pour des compositions d'agrégats avec une addition de filler qui s'avère donc favoriser un accroissement sensible de la résistance à la traction par flexion des bétons de résine FA.

— L'agrégat A_1 = sable et gravier de la rivière d'Argeş, ballastière de Borleşti (les plus facilement disponibles) — peut être utilisé dans la préparation des bétons à monomère FA avec des résultats assez bons, s'il est bien lavé et bien séché, et si la fraction inférieure à 0,2 mm (qui contient le taux maximal d'impuretés) est complètement remplacée par du filler F_1.

— Des deux types d'agrégats quartzeux lavés étudiés, A_2 et A_3, celui qui donne les meilleurs résultats est l'agrégat A_2, le plus pur. Il est à remarquer qu'en utilisant A_2 et A_3 on obtient des résultats supérieurs à ceux obtenus avec l'agrégat de rivière A_1.

— L'agrégat de concassage A_4, andésite basaltique, donne des résultats supérieurs, comparés à ceux des agrégats de carrière A_2 et A_3 et à ceux de l'agrégat de rivière A_1, pour des dosages égaux de résine, de durcisseur et de diluant.

— Les recherches avec l'agrégat A_6 prouvent que les résistances mécaniques des éprouvettes diminuent sensiblement avec l'augmentation du taux de calcaire dans l'agrégat A_1, et confirment, toujours par voie expérimentale, les résultats théoriques.

Il résulte donc de ces études qu'il est préférable d'utiliser les agrégats suivants : A_2, agrégat quartzeux de carrière, lavé, provenant de l'exploitation Glatna-Timiş ; A_4, agrégat de concassage, criblure d'andésite basaltique provenant de la carrière de Malnaş ; A_1, agrégat de ballastière provenant de la ballastière de Borleşti de la rivière d'Argeş, comme agrégat supplémentaire et seulement pour certaines déterminations comparatives.

Les principales conclusions des recherches effectuées pour le choix du filler ou des fillers sont les suivantes : avec les bétons fins à dosage élevé (21% de résine) et approximativement dans les mêmes conditions de travail (tassement au cône normalisé = 6,2 à 7 cm), les meilleurs résultats sont obtenus en utilisant comme filler le coke de haut fourneau broyé F_4 (fig. 2*a*), ensuite, dans l'ordre, le filler d'andésite basaltique broyé F_3 et le filler de quartz broyé F_2, les résultats les plus modestes étant obtenus avec le sable fin quartzeux lavé F_1 utilisé dans les verreries. Cette constatation est confirmée par les recherches sur les bétons avec agrégats de carrière A_2 et avec agrégats de concassage A_4. Il est à remarquer que les écarts des résistances des bétons, si l'on utilise différents fillers, sont beaucoup plus faibles que ceux indiqués par l'étude des seuls fillers ; la raison en est la diminution du poids du filler dans la masse de l'agrégat (fig. 2*b* et *c*). Ainsi, par rapport au filler F_1, on obtient des différences de plus de 5 à 18% de la résistance à la compression à 28 jours des différents bétons dont la préparation comprenait des fillers F_2, F_3 et F_4. Les différences entre les résultats obtenus avec différents fillers ont incité à poursuivre les examens microscopiques afin d'élucider les points suivants : rugosité des différents fillers et agrégats utilisés et forme de leurs éléments ; adhérence dans le système filler-liant organique et agrégat-liant organique. Il en résulte que :

— Les agrégats A_2 et les 2 types de filler F_1 et F_2 ont, généralement, des éléments arrondis, rapport b/a de plus de 0,7 et rapport c/b supérieur à la valeur 0,45 à 0,50 pour la plupart des grains avec une bonne concordance en ce qui concerne la forme.

La rugosité des surfaces augmente avec la diminution du diamètre des grains. Ainsi les grains de diamètre compris entre 7 et 15 mm ont des surfaces très lisses, ceux de diamètre 3 à 7 mm également, une rugosité plus accentuée apparaissant pour les grains de diamètre 1 à 3 mm et s'accentuant de plus en plus pour les grains de diamètre inférieur à 1,00 mm. La surface la plus rugueuse a été observée pour les grains de diamètre 0,08 à 0,20 mm du filler F_1 (qui ont pu être convenablement observés au microscope (fig. 3*a*)). Dans le filler F_2 (grains de diamètre 0,08 à 0,20 mm) on observe assez aisément la rugosité accrue des surfaces (par rapport au filler F_1), les surfaces ont des striures proéminentes, des arêtes et des coins, etc., semblables à ceux qui sont observés sur l'agrégat de concassage A_4 (fig. 3*b*). Les résistances mécaniques supérieures obtenues avec le filler F_2, par rapport au filler F_1 (les deux fillers ayant la même composition minéralogique : plus de 95 % de quartz) trouvent ainsi une première explication, en ce sens que la rugosité accrue des surfaces des grains du filler F_2, obtenu par broyage, contribue à assurer une meilleure adhérence dans le système filler liant organique.

Les observations effectuées sur la forme des grains de l'agrégat A_4 et des fillers F_3 et F_4 ont montré pratiquement les mêmes rapports b/a de plus de 0,7 et c/b de plus de 0,45 à 0,50. On a remarqué que les grains de l'agrégat de concassage A_4 (andésite basaltique) et des fillers broyés F_3 et F_4 ont des formes anguleuses, à arêtes vives et des faces rugueuses, ce qui conduit à une première explication des résistances obtenues avec ces matériaux. Mais une autre question se pose : pourquoi, en utilisant le coke de haut fourneau broyé comme filler F_4, obtient-on des résistances supérieures à celles fournies par l'andésite basaltique broyée F_3 et par le quartz broyé F_2? Les observations effectuées au microscope ont prouvé qu'il y a certaines différences entre l'andésite basaltique et le quartz, dues probablement à la dureté, à la fragilité, ainsi qu'à la perfection ou à l'imperfection des plans de clivage, de sorte que lors du broyage du quartz on observe des grains présentant des arêtes vives, une cassure concoïdale à surface relativement lisse et quelques-unes peuvent même être considérées comme telles dans une certaine mesure, ce qui indique que les points d'ancrage dans la pellicule de résine seront donc moins nombreux. A la surface de plusieurs grains similaires d'andésite, on remarque des cassures à nerf à nombreuses petites proéminences qui représentent autant de points d'ancrage dans la pellicule de résine, déterminant ainsi une meilleure adhé-

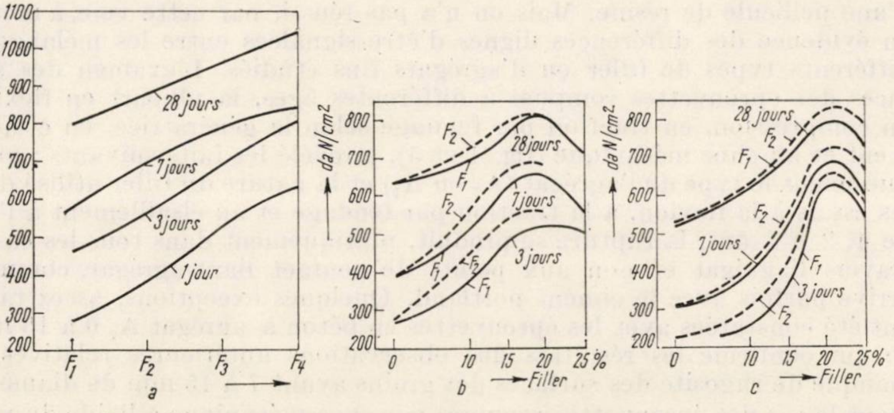

Fig. 2. — Variation de la résistance à la compression, à différents âges d'essai, en fonction du type et du pourcentage de filler.
a) pour des bétons fins FA, filler F_1, F_2, F_3 et F_4; b) pour des bétons fins FA, agrégats de carrière 0 à 7 mm ; c) pour des bétons fins FA, agrégats de carrière 0 à 15 mm.

rence dans le système filler-résine, ce qui explique, dans une certaine mesure, les différences de résistance obtenues en utilisant les fillers F_3 et F_2. Il faut mentionner qu'on n'a pas décelé au microscope de différences de ce genre, lors de l'examen parallèle des fillers F_2 et F_4 , en faveur de ce dernier, ce qui incite à limiter les conclusions relatives à l'effet de la rugosité des surfaces aux fillers de provenance minérale F_1, F_2 et F_3. Le filler F_4 (coke de haut fourneau broyé) étant un matériau qui appartient à la chimie du carbone, il est possible dans ce cas que l'augmentation de résistance du système filler-liant organique soit favorisée, tant par des phénomènes physiques que par certaines réactions chimiques de surface qui ont lieu entre le liant organique et le filler.

L'étude au microscope électronique de l'adhérence dans le système liant organique-filler et liant organique-agrégat dans un mélange frais très fluide d'agrégat fin ou de filler-liant organique (fig. 3*c*) a mis en évidence une bonne interaction dans la zone de contact filler (agrégat fin)-liant organique pour n'importe quel type d'agrégat ou de filler utilisé, la surface des grains du filler ou de l'agrégat fin étant parfaitement recouverte d'une pellicule de résine. Mais on n'a pas réussi, par cette voie, à mettre en évidence des différences dignes d'être signalées entre les mélanges à différents types de filler ou d'agrégats fins étudiés. L'examen des surfaces des éprouvettes rompues à différentes âges, la plupart en flexion, en compression, en traction par fendage selon la génératrice, en cisaillement et au choc mécanique (fig. 4 et 5), a révélé les faits suivants : quels que soient le type de l'agrégat (A_2 ou A_4) et la nature du filler utilisé dans les essais à la flexion, à la traction par fendage et au cisaillement à l'âge de 1, 2 à 3 ans, la rupture se produit, pratiquement dans tous les cas, à travers l'agrégat et non aux points de contact liant-agrégat, comme il arrive parfois avec le ciment portland. Quelques exceptions, assez rares, ont été constatées avec les éprouvettes en béton à agrégat A_2 0 à 15 mm, ce qui confirme les résultats des observations antérieures relatives au manque de rugosité des surfaces des grains ayant 7 à 15 mm de diamètre. Dans le cas des éprouvettes rompues par choc mécanique à l'aide du marteau Föpl, à l'âge de 1 à 2 ans, la rupture se produit toujours par les grains de l'agrégat et par la masse de mastic noir formée par le filler et le liant organique, pour les bétons préparés avec l'agrégat de concassage A_4, andésite basaltique, quel que soit le type du filler utilisé, ce qui procure à ce type de bétons des résistances au choc plus importantes.

Soumises de 3 à 5 fois, en compression, à des charges équivalant à 0,5—0,6 de la charge de rupture, à l'âge de 2 à 3 ans, les différentes compositions de bétons à agrégats A_2 et A_4, retenues comme objet optimal d'étude, n'ont pas montré de discontinuités ou de décollements à l'interface liant-agrégat. Le mastic de couleur noir ou marron foncé (dans le cas du liant mixte FA + LS. 1), formé d'un mélange de filler et de liant organique, se présente comme une masse compacte fortement adhérente aux éléments les plus gros de l'agrégat (fig. 5). Outre l'influence de la forme des grains, de la rugosité, de la surface du filler et des agrégats sur l'accroissement des résistances mécaniques des bétons à monomère FA, l'utilisation du filler F_2 (quartz broyé) tend à déterminer des résis-

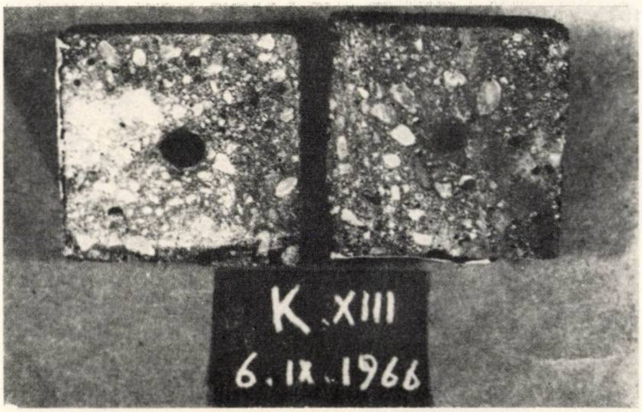

Fig. 4. — Eprouvettes en béton fin à agrégats quartzeux A2, filler Fl, monomère FA, sollicitées à 0,55 R_c rupture, permettant de vérifier l'adhérence du liant à l'agrégat après deux ans environ.

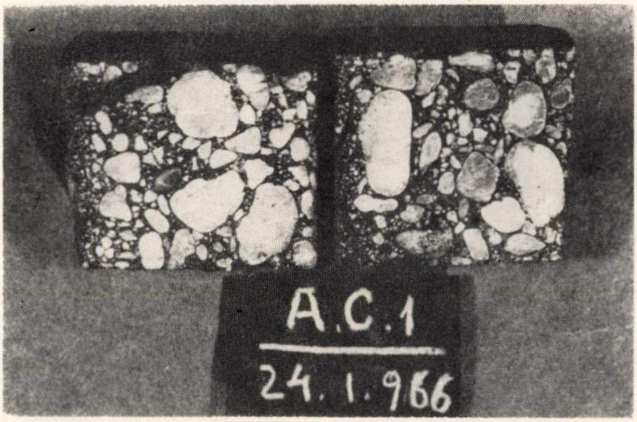

Fig. 5. — Eprouvettes sollicitées à 0,06 R_c rupture, afin de vérifier l'adhérence du liant à l'agrégat après deux ans environ (béton à agrégats quartzeux A2, filler F2 + F4, à monomère FA).

tances plus faibles, par rapport à celles obtenues avec F_3 (andésite basaltique broyée), ce qui peut être dû à l'hydrophilie plus accentuée du quartz (problème qui ne constitue pas l'objet du présent ouvrage).

Des recherches de sélection des fillers ont prouvé que les meilleurs résultats sont obtenus en utilisant des agrégats à granulométrie continue qui compactés ont un volume de vides de 20% au maximum. Avec l'agrégat utilisé les taux moyens suivants de filler ont fourni les résultats optimaux : pour l'agrégat 0 à 3 mm = 12% (10 à 15%) ; pour l'agrégat 0 à 7 mm = 15% (10 à 20 %) ; pour l'agrégat 0 à 15 mm = 20 % (15 à 25 %). Ainsi, les compositions granulométriques obtenues pour les bétons à monomère FA diffèrent de celles recommandées pour les bétons de ciment, par le fait que pour les nouveaux types de bétons un plus gros pourcentage d'agrégat fin est nécessaire, sans compter la présence du filler.

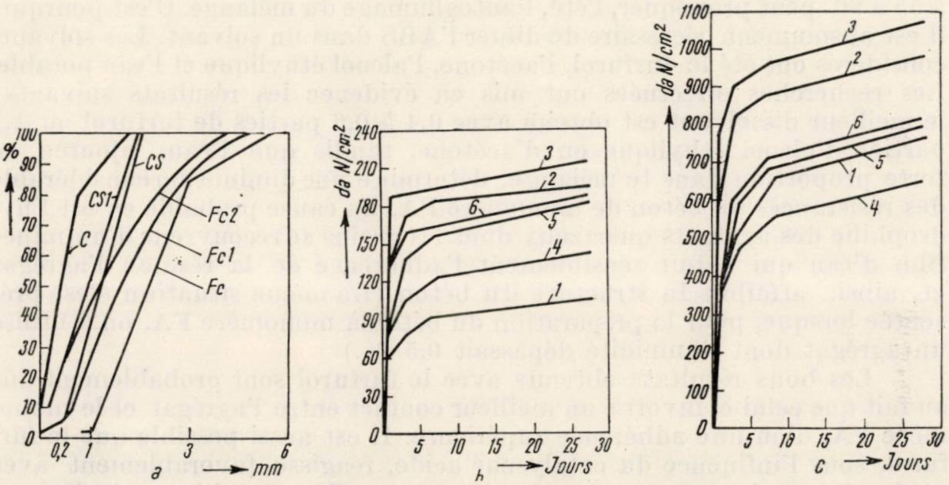

Fig. 6. — a) Compositions granulométriques pour les agrégats spéciaux utilisés dans l'étude : Fc — agrégat spécial non corrigé ; Fcl — agrégat corrigé par l'addition de 37% de sable quartzeux A2 et 16% de filler de quartz broyé F2 ; Fc2 — agrégat corrigé par l'addition de 20 % de sable quartzeux A2 et 20 % de filler de quartz broyé F2 ; Cs — agrégat spécial non corrigé ; CS1 — agrégat corrigé par l'addition de 38% de filler de quartz broyé F2 ; C — agrégat spécial non corrigé.

b) Variation de la résistance à la traction par flexion dans le temps.

c) Variation de la résistance à la compression dans le temps pour les bétons à monomère FA et agrégats spéciaux :

1, agrégat FC + 10,0% FA ; *2*, agrégat FCl + 12,0% FA ; *3*, agrégat FC2 + 9,6% FA ; *4*, agrégat CS + 16% FA ; *5*, agrégat CS + 16% FA ; *6*, agrégat C + 18% FA.

Les études sur les agrégats spéciaux Fc, Cs et C ont conduit à choisir les compositions optimales d'agrégats : Fc à correction de sable et de filler (Fc_2, Fc_1), carbure de silicium à correction (CS. 1) et corindon (C) (voir fig. 6*a*) qui ont donné les résultats maximaux (fig. 6 *b* et *c*). Il a été prouvé que les meilleurs résultats sont obtenus avec l'agrégat Fc à correction (Fc_1, Fc_2) et, dans l'ordre, les agrégats C et CS_1 (carbure de silicium à correction).

c) *Les agents durcisseurs et leurs diluants*

Le monomère FA se polymérise sous l'action de certains agents durcisseurs (catalyseurs acides) tels que les acides benzène sulfonique, toluène sulfonique, sulfurique et chlorhydrique. Des recherches comparatives ont prouvé que les meilleurs résultats sont obtenus avec l'acide benzène sulfonique et l'acide sulfurique. L'emploi de l'acide sulfurique comme durcisseur du béton à monomère FA présente toute une série de difficultés dans l'industrie et même au laboratoire et, pour cette raison, on y a renoncé ; par la suite, seul l'acide benzène sulfonique a été utilisé.

L'acide benzène sulfonique (ABS) est solide à la température de 15 à 20° et liquide à la température de 55 à 60° ; pour être utilisé comme durcisseur il doit être soit dilué dans de faibles quantités de solvant, soit réchauffé à la température de 55 à 60°. L'emploi de l'acide réchauffé à 55 à 60° peut provoquer, l'été, l'autoallumage du mélange. C'est pourquoi il est absolument nécessaire de diluer l'ABS dans un solvant. Les solvants considérés ont été le furfurol, l'acétone, l'alcool éthylique et l'eau potable. Les recherches effectuées ont mis en évidence les résultats suivants : le meilleur dissolvant est obtenu avec 0,4 à 0,6 parties de furfurol ou 1,1 parties d'alcool éthylique ou d'acétone, tandis que l'eau, ajoutée en forte proportion dans le mélange, détermine une diminution considérable des résistances du béton de monomère FA. La cause probable en est l'hydrophilie des agrégats quartzeux dont les grains se recouvrent d'un mince film d'eau qui réduit sensiblement l'adhérence de la résine à l'agrégat et, ainsi, affaiblit la structure du béton. (La même situation s'est présentée lorsque, pour la préparation du béton à monomère FA, on a utilisé un agrégat dont l'humidité dépassait 0,5 %.)

Les bons résultats obtenus avec le furfurol sont probablement dus au fait que celui-ci favorise un meilleur contact entre l'agrégat et le monomère FA, d'où une adhérence supérieure. Il est aussi possible que le furfurol, sous l'influence du catalyseur acide, réagisse favorablement avec quelques-uns des composants du monomère FA et qu'il en résulte une amélioration des propriétés du béton.

Les recherches pour établir le taux optimal de durcisseur (ABS) des bétons de monomère FA préparés par une méthode similaire et durcis à la température normale de leur conservation, avec le rapport furfurol/ABS = 0,60 et en faisant varier la quantité d'ABS utilisé, ont prouvé que lorsqu'on utilise le furfurol, ce taux optimal est de l'ordre de 20 à 25% du poids du monomère FA.

d) *Influence de certaines additions de résine phénol-formaldéhyde LS.1 sur les propriétés des bétons de monomère FA*

La recherche sur les possibilités de confectionner des bétons à base de deux résines synthétiques, furannique (monomère FA) et phénol-formaldéhyde (LS. 1), repose sur le fait que les résines de furfurol sont compatibles avec les résines phénol-formaldéhydes, et que les unes et les autres durcissent à froid ordinairement avec les mêmes durcisseurs, dans le cas présent l'acide benzène sulfonique. Quelques-uns des résultats obtenus sont représentés graphiquement par les figures 7 *a*, *b*, *c* et *d* et il en ressort que :

— Le poids apparent des bétons de monomère FA et de résine LS. 1 diminue légèrement avec le taux de LS. 1. Ceci est dû à la diminution de l'ouvrabilité du mélange en raison de la viscosité plus élevée de la résine LS. 1.

— Les résistances à la traction par flexion et à la compression, ainsi que les retraits, diminuent aussi avec l'augmentation du taux de LS. 1. La diminution des résistances est explicable, compte tenu des propriétés physico-mécaniques des résines phénolformaldéhydes et leurs plus faibles résistances mécaniques, ainsi que de leur moindre compacité (fig. 7*a*). Les retraits plus faibles sont dus eux aussi aux propriétés des résines LS.1. Il a été prouvé qu'il est possible d'utiliser les bétons de résine FA et LS.1

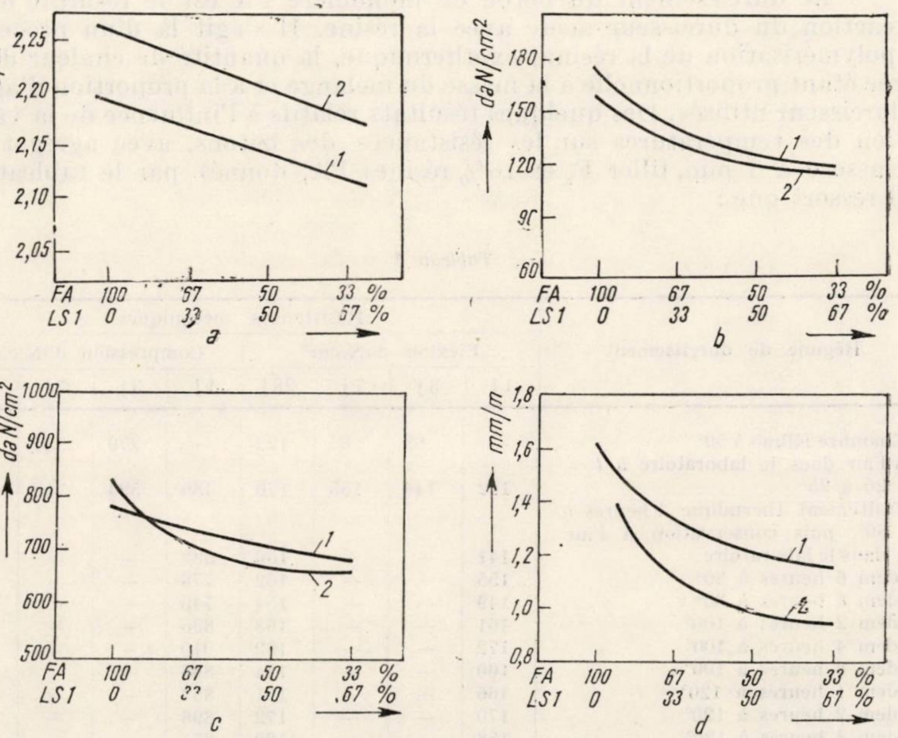

Fig. 7. — a) Variation du poids apparent des bétons à monomère FA et résine LS. 1 en fonction du pourcentage de résine LS 1. b) Variation de la résistance à la traction par flexion des bétons à monomère FA et résine LS. 1 en fonction du pourcentage de résine L.S. 1, essais effectués à 28 jours d'âge.
c) Variation des résistances à la compression des bétons à monomère FA et résine LS. 1 en fonction du pourcentage de résine LS. 1, essais effectués à 28 jours d'âge. d) Variation des contractions des bétons à monomère FA et résine LS. 1 en fonction du pourcentage de résine LS. 1, mesures effectuées à 28 jours d'âge.

1, béton à agrégats quartzeux A2 0 à 3 mm et 12% filler F2 ; *2*, béton à agrégats quartzeux A2 0 à 15 mm et 20% filler F2.

dans le rapport 1/1 lorsqu'il n'est pas nécessaire d'obtenir des résistances mécaniques supérieures à 700 daN/cm² à 28 jours et d'améliorer sensiblement les propriétés des bétons de résines phénol-formaldéhydes dont les résistances à 28 jours sont en général inférieures à 400 daN/cm².

e) *Influence de la température, de l'humidité, de la technologie de préparation et de la mise en œuvre sur les propriétés du béton de résines synthétiques sans liants minéraux*

Le durcissement du béton de monomère FA est le résultat de la réaction du durcisseur acide avec la résine. Il s'agit là d'un processus (polymérisation de la résine) exothermique, la quantité de chaleur dégagée étant proportionnelle à la masse du mélange et à la proportion d'agent durcisseur utilisée. Des quelques résultats relatifs à l'influence de la variation des températures sur les résistances des bétons, avec agrégat A_2, classe 0 à 3 mm, filler F_2 et 16% résines FA, donnés par le tableau 1 ; il ressort que :

Tableau 1

Régime de durcissement	Résistances mécaniques							
	Flexion daN/cm²				Compression daN/cm²			
	1 j	3 j	7 j	28 j	1 j	3 j	7 j	28 j

Idem 2 heures à 120°	170	—	—	172	896	—	—	901
Idem 4 heures à 120°	158	—	—	160	874	—	—	831
Idem 6 heures à 120°	164	—	—	146	828	—	—	802

Remarques : Pour les éprouvettes traitées thermiquement, la température a été élevée progressivement pendant une heure ; elles ont été ensuite maintenues à la température établie durant 1 à 8 heures, conformément au programme. Le refroidissement des éprouvettes s'est effectué lentement, après arrêt de l'étuve jusqu'au lendemain matin.

— Le traitement thermique à sec des éprouvettes en béton fin de monomère FA contribue à leur durcissement rapide : en 2 heures environ à 100°, on obtient des résistances pratiquement égales aux résistances des éprouvettes durcies 28 jours dans les conditions de laboratoire. Ceci s'explique probablement par une polymérisation plus avancée du monomère FA sous l'action du traitement thermique. Des 10 régimes de traitement thermique utilisés, celui qui donne les meilleurs résultats consiste à soumettre les éprouvettes durant 2 heures à 100°, 1 à 2 heures à 120° ou à 80°.

— Les températures basses ont un effet défavorable sur les résistances du béton de monomère FA, probablement parce que les réactions entre l'agent durcisseur et la résine sont alors empêchées, et qu'il se produit une polymérisation partielle de la résine dans l'intervalle où l'on effectue les essais ;

— L'eau, en grande quantité, introduite dans le mélange de béton de monomère FA, comme solvant du durcisseur, ou l'humidité des agrégats si elle dépasse 0,5% de leur poids ont aussi un effet sensiblement défavorable sur les résistances mécaniques du béton, tant en raison de l'absorption d'eau des agrégats qui se recouvrent d'une mince pellicule d'eau, ce qui conduit à une diminution de l'adhérence dans le système agrégat minéral-liant organique, qu'en raison des pores capillaires et des vides sous les agrégats que peut causer la présence d'eau, ce qui affaiblit la structure du béton. Avec conservation des éprouvettes les 24 premières heures à l'ambiance du laboratoire, et immersion ultérieure dans l'eau jusqu'à l'âge d'essai (7, 28 jours, etc.), on obtient pour les résistances des valeurs qui représentent 35 à 60 % de celles des éprouvettes témoin conservées tout le temps à l'ambiance du laboratoire, ce qui prouve que l'eau modifie défavorablement les propriétés des bétons de monomère FA aux jeunes âges, en affectant le processus de polymérisation, et la formation de sa structure. L'humidité de l'air, dans l'intervalle décoffrage-essai, contribue aussi à réduire les résistances du béton, selon le temps qu'il se trouve exposé à l'action de l'air humide.

Les recherches effectuées ont prouvé que la technologie de préparation et de mise en œuvre influence tant la consommation de résine que les propriétés mécaniques, dans une proportion allant jusqu'à ± 30%. Ainsi, les bétons à consistance dure préparés en malaxeur forcé, mis en œuvre soigneusement et compactés par vibration, ont, pour des dosages de résine plus faibles, d'environ 10%, les mêmes propriétés physico-mécaniques. Il est à remarquer que pour les bétons à consistance dure, aussi bien que pour ceux à consistance plastique, le compactage doit être effectué très attentivement, afin d'éviter la ségrégation avec toutes les conséquences qui en découlent.

Une humidité de l'air de maximum de 65% et une température minimale de 15° sont indiquées pendant la préparation, la mise en œuvre et les 10 premiers jours après la coulée.

COPOLYMERE KONJUGIERTER DIENE MIT MONOESTERN DER MALEINSAÜRE. VII[1]

ANDERE ASPEKTE DER REAKTIONSKINETIK DER RADIKALISCHEN COPOLYMERISATION VON ISOPREN MIT MONOESTERN DER MALEINSÄURE

I. NANU* und C. ANDREI **

* Laboratorium für Makromolekulare Chemie, Polytechnisches Institut Timişoara, Romania

** Forschungslaboratorium, Ploieşti, Petrochemische Industriegruppe Brazi, Romania

Eingegangen am 3. März 1973

Im weiteren Verlauf der Untersuchung der radikalischen Copolymerisationsreaktion von Isopren mit Monoestern der Maleinsäure wird der Einfluß der Art der Monoester, der Initiatoren und der Lösungsmittel auf die Reaktion aufgezeigt. Das Anwachsen der Copolymerisationsgeschwindigkeit der Monoester der Maleinsäure mit wachsender Länge der Alkylkette erklärt sich aus der Tatsache, daß die Abbruchreaktion vom Diffusionsvorgang kontrolliert wird. Die Ergebnisse der Untersuchung des Einflußes der Verdünnung auf den Umsatz und die Zusammensetzung der Polymeren als auch der Einfluß der Art des Lösungsmittels bringt die Auffassung nahe, daß an der Copolymerisationsreaktion ein Donor-Acceptor Komplex teilnimmt, der sich zwischen den Monomeren bildet, während die Tatsache, daß die Änderung der Viskositätszahl der Copolymeren in Abhängigkeit vom Umsatz eine Konstante ist, einen typisch monoradikalischen Mechanismus anzeigt.

EINLEITUNG

In vorhergehenden Arbeiten wurden die kinetischen Aspekte der Copolymerisationsreaktion von Isopren mit verschiedenen Monoestern der Maleinsäure untersucht, besonders bei niedrigem Umsatz (unter 5%). Es wurde hervorgehoben, in welcher Weise diese Systeme den klassischen Copolymerisationsgleichungen entsprechen und welchen Einfluß die sterischen, polaren u.a. Faktoren auf die Reaktion ausüben.[1-4]

[4] I. Nanu und C. Andrei, *Rev. Roumaine Chim.*, **17**, 741 (1972).

In der vorliegenden Arbeit untersuchten wir andere Aspekte der radikalischen Copolymerisationsreaktion dieser Systeme (den Einfluß der Art der Monoester, der Initiatoren und der Lösungsmittel auf die Reaktion, die Wirkung der Verdünnung auf den Umsatz und die Zusammensetzung der Copolymeren als auch die Änderung der Viskositätszahl der Copolymeren in Abhängigkeit vom Umsatz) die ebenfalls Argumente in der Wahl und Unterstützung des Reaktionsmechanismus bilden werden.

EXPERIMENTELLER TEIL

Die verwendeten Monomeren (Isopren und Monoester der Maleinsäure) wiesen dieselben Merkmale mit denen der vorhergehenden Arbeiten auf.[2,5]

Der Lösungs-Copolymerisationsprozeß wurde in Glasampullen unter Stickstoff, in Gegenwart freier Radikale, ausgeführt.

Die Trennung und Reinigung der Copolymeren erfolgte durch Lösen des Reaktionsgemisches in Äthyläther und Aufsfällen mit Petroläther, ein Vorgang der 2—3 mal wiederholt wurde.

Die Copolymeren wurden bei einer Temperatur von 40—50° getrocknet und der Umsatz nach der erhaltenen Menge berechnet.

Die Analyse der Copolymeren erfolgte mittels der Elementarmikroanalyse.

ERGEBNISSE UND DISKUSSIONEN

DER EINFLUSS DER ART DES MONOESTERS AUF DIE REAKTION

Die Änderung des Umsatzes in Abhängigkeit von der Zeit für die radikalische Copolymerisation des Isoprens mit Monobutylmaleat, Monoheptylmaleat und Monocetylmaleat ist in Abb. 1 wiedergegeben.

Die Reaktionen wurden in homogenem Medium (Cyclohexanon) bei einem Molverhältnis Isopren : Monoester von 1 : 1 und bei gleicher Molkonzentration in allen drei untersuchten Systemen ausgeführt. Aus dieser Darstellung geht hervor, daß die Copolymerisationsgeschwindigkeit mit steigender Länge des n-Alkylradikals des Monoesters wächst, eine Tatsache, die auch für Umsätze unter 5% zutrifft. [1]

Die steigende Reaktivität des Monoesters der Maleinsäure mit wachsender Länge der Alkylkette erklärt sich aus der Tatsache, daß die Abbruchreaktion von Diffusionsvorgängen bestimmt wird, ähnlich der von Otsu und Mitarb. [6] gefundenen Beziehung für die Polymerisation der Alkylmethakrylate.

Demnach ist die Differenzierung der Geschwindigkeiten der Abbruchreaktionen nicht auf die Reaktionsfreudigkeit der Makroradikale zurückzuführen, sondern sie ergibt sich aus den Diffusionsvorgängen, durch die die Makromoleküle in eine für die Reaktion günstige Stellung

[6] T. Otsu, I. Ito und M. Imoto, *J. Polymer Sci. Part A*, **2**, 2901 (1964).

gelangen. Der Einfluß der Diffusion auf die bimolekulare Abbruchreaktion kann wie ein Dreistufenvorgang behandelt werden :

— die erste Stufe ist die Diffusion der zwei Makroradikale aus der Lösung in eine solche Nähe, daß bestimmte Segmente als in Berührung stehend angesehen werden können ;

— die zweite Stufe ist die Neuordnung der Ketten, so daß die reaktionsfreudigen Atome in eine für die chemische Reaktion günstige Stellung gelangen ;

— die letzte Stufe stellt die chemische Reaktion dar.

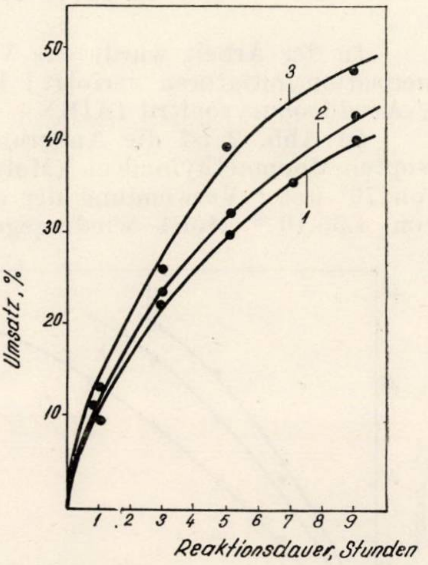

Abb. 1. — Änderung des Umsatzes mit der Copolymerisationsdauer in Cyclohexanon bei 70° ;

1, Isopren-Monobutylmaleat ; 2, Isopren-Monoheptylmaleat ; 3, Isopren-Monocetylmaleat. Molverhältnis[M_1^0] : [M_2^0]$=1 : 1$(und die gleiche Molkonzentration). Initiator : [AIBN] $\times 10^2 = 4{,}55$ Mol/l.

North und Reed [7,8] stützten sich auf die Annahme, daß die Makroradikale die statistische Konfiguration eines Knäuels aufweisen, in dessen Innerem das aktive Ende mit größerer Wahrscheinlichkeit auftritt als außerhalb und gelangten zur Schlußfolgerung, daß die die Abbruchgeschwindigkeit bestimmende Stufe die Diffusion des aktiven Endes aus dem Inneren des Knäuels in eine für die Reaktion geeignete Region ist.

In dem Maße wie die Konzentration des Polymeren wächst, hängt die Autodiffusion des aktiven Endes aus dem Molekülknäuel von der „Mikroviskosität" der dem Radikal benachbarten Regionen ab.

Die infolge des Diffusionsvorganges fallende Abbruchgeschwindigkeit führt zu einem Anwachsen der Copolymerisationsgeschwindgkeit.

Hervorzuheben ist, daß in den untersuchten Systemen dieses Anwachsen der Reaktionsgeschwindigkeit nicht von der Größe einer unter dem Namen „Geleffekt" bekannten Beschleunigung ist.

[7] A. M. North und G. A. Reed, *Trans. Faraday Soc.*, **57**, 859 (1961).

[8] A. M. North und G. A. Reed, *J. Polymer Sci. Part A*, **1**, 1311 (1963).

Es ist wichtig hervorzuheben, daß nicht nur die Viskosität der Monoester der Maleinsäure (mit der Anzahl der Atome aus der Alkylgruppe steigende Funktion) die Reaktionsgeschwindigkeit der Copolymerisationsreaktion beeinflußt, sondern auch die viel größere Viskosität des Diels-Alder Adduktes, das sich im System zwischen Dien und Monoester in einer Parallelreaktion bildet, von Bedeutung ist.

Aber dieser letzte Aspekt wird in einer anderen Arbeit ausführlicher behandelt werden.

DER EINFLUSS DER ART DER INITIATOREN

In der Arbeit wurde das Verhalten von drei verschiedenen Polymerisationsinitiatoren verfolgt: Benzoylperoxid, Lauroylperoxid und α, α'-Azodiizobutyronitril (AIBN).

In Abb. 2 ist die Änderung des Umsatzes der Copolymerisation Isopren-Monomethylmaleat (Molverhältnis 1 : 1) bei einer Temperatur von 70° unter Verwendung der drei Initiatoren in einer Konzentration von $4.55.10^{-2}$ Mol/l wiedergegeben.

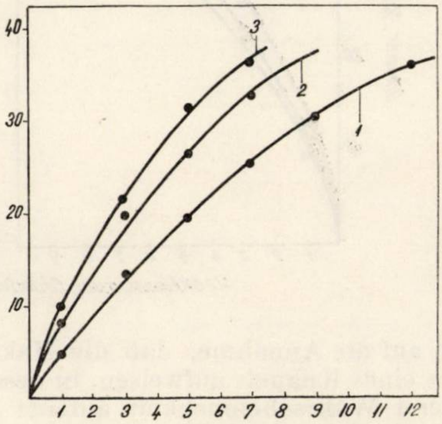

Abb. 2. – Einfluß der Art des Initiators auf die Copolymerisationsreaktion Isopren-Monomethylmaleat (Molverhältnis 1 : 1).

1, Benzoylperoxid; *2*, Lauroylperoxid; *3*, α, α'-Azodiisobutyronitril (AIBN). Initiatorkonzentration $4{,}55 \cdot 10^{-2}$ Mol/1; Temperatur 70°, Lösungsmittel: Cyclohexanon.

Die verschiedenen Ergebnisse, die mit den drei Initiatoren erhalten wurden, stimmen mit den Daten aus der Literatur überein, die die Halbwertszeit der Initiatoren betreffen, die in der Reihenfolge: Benzoylperoxid $>$ Lauroylperoxid $>$ AIBN fällt.[9]

DER EINFLUSS DER VERDÜNNUNG AUF DEN UMSATZ UND DIE ZUSAMMENSETZUNG DER COPOLYMEREN

Im Jahre 1946 schlugen Bartlett und Nozaki[10] vor, daß an der alternierenden Copolymerisation von Styrol mit Maleinsäureanhydrid ein Molekularkomplex teilnimmt, der sich zwischen den beiden Monomeren bildet. Mayo und Walling [11,12] widersetzten sich aber dieser Hypothese indem sie sich auf folgende experimentelle Beobachtungen stützten:

---

[9] * * * Polymerisation Initiators, Prospect Firma Noury Van der Lande, Olanda.
[10] P. D. Bartlett und K. Nozaki, *J. Amer. Chem. Soc.*, **68**, 1495 (1946).

— das physikalische Außerachtbleiben einer Assoziation zwischen den Monomeren in allen Fällen, die eine hohe Alternanz in der Copolymerisationsreaktion aufweisen:

— die Copolymerisationskonstanten ändern sich nicht mit der Verdünnung der Monomeren und

— die Kinetik der alternierenden Copolymerisationssysteme ist unklar.

Trotzdem hat man in den letzten Jahren mit Bestimmtheit die Bildung eines Komplexes durch Ladungsaustausch zwischen den Monomeren hervorgehoben und hat bei der Untersuchung mehrerer alternierender Systeme angenommen, daß er an der Copolymerisationsreaktion teilnimmt.[13–18]

Ebenso finden sich auch Untersuchungen über die Änderung der Copolymerisationskonstanten in radikalischen Reaktionen erwähnt,[19,20] aber die Untersuchungen über den Einfluβ der Verdünnung auf die alternierende Copolymerisation sind relativ begrenzt und wurden erst in letzter Zeit vorgelegt. [21,22]

Verfolgen wir die Copolymerisation des Isoprens mit Monomethylmaleat und Monobutylmaleat in Abhängigkeit von der Lösungsmittelmenge (für dieselbe Monomerenladung im Molverhältnis 1 : 1), so können wir ein bemerkenswertes Sinken des Umsatzes zum Polymeren feststellen (Abb. 3).

Gleichzeitig mit dem fallenden Umsatz zum Copolymeren bemerkt man auch ein Sinken des Monoestergehaltes im Copolymeren, demzufolge ein Anwachsen des Isoprengehaltes und demnach ein Entfernen von der Alternanz (Abb. 4).

Im Falle der Bildung eines Komplexes durch Ladungsaustausch zwischen den Monomeren, könnte die Änderung des Umsatzes und der Zusammensetzung des Copolymeren in Abhängigkeit von der Lösungsmittelmenge, durch das beträchtliche Zurückgehen der Konzentration des Donor-Acceptor-Komplexes mit der Verdünnung erklärt werden. Dies letztere ist für die erhöhte Reaktionsfreudigkeit und für die erhöhte Alternanz in der Copolymerisationsreaktion verantwortlich.

Eine derartige Erklärung wurde von Iwatsuki und Yamashita[21] gegeben, die die Copolymerisation von zwei ternären Systemen untersuchten: 2-Chloräthylvinyläther-Maleinsäureanhydrid-Akrylonitril, und p-Dioxen-Maleinsäureanhydrid-Akrylonitril. Die beiden sahen diese ternären Systeme als die Copolymerisation eines bi-nären Systems (zwischen Akrylonitril und dem Donor-Acceptor Komplex, der sich zwischen den anderen beiden Monomeren bildet) an.

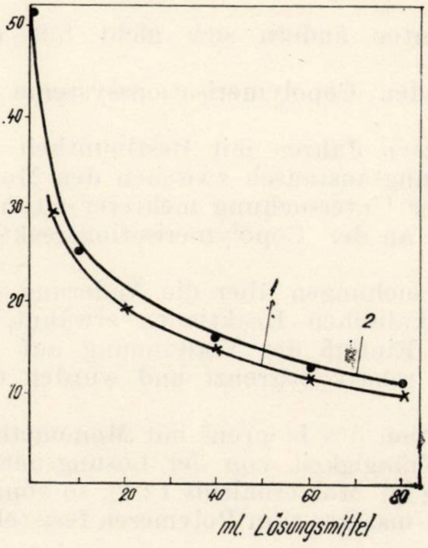

Abb.3

Abb. 3. – Änderung des Umsatzes mit der Lösungsmittelmenge (Cyclohexanon) für die gleiche Menge Monomeren (Molverhältnis 1 : 1).

1, Isopren-Monomethylmaleat; 2, Isopren-Monobutylmaleat; AIBN-Konzentration 4,55.10^{-2} Mol/l; Temperatur 70°, Copolymerisationsdauer 3 Stunden.

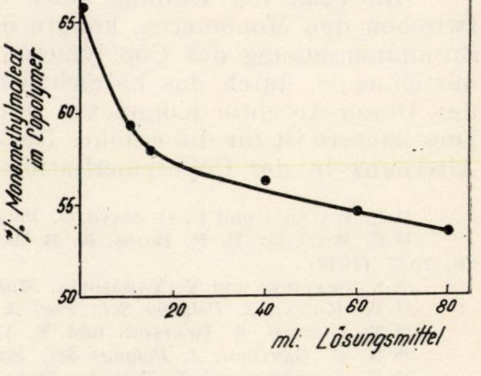

Abb. 4. – Einfluß der Verdünnung auf die Zusammensetzung der Copolymeren Isopren-Monomethylmaleat (Lösungsmittel: Cyclohexanon) Copolymerisationsbedingungen wie in Abb.3.

Wenn sich zwischen Isopren und den Monoestern der Maleinsäure kein Komplex durch Ladungsaustausch bildet, so könnte das in Abb. 3 und 4 aufgezeigte Verhalten aufgrund einer Kettenübertragungsreaktion mit dem Lösungsmittel erklärt werden (die bestätigt wird durch die viel kleinere Molekularmasse der in Lösung erhaltenen Copolymeren, im Vergleich zu denen, die in Masse erhalten werden).

Es ist klar, daβ bei diesen Copolymeren mit kleiner Molekularmasse, bei denen der Endgruppeneffekt bemerkenswert ist, auch die Zusammensetzung des Copolymeren eine andere als die alternierende ist.

Trotzdem kann man die zu groβe Änderung des Umsatzes und der Zusammensetzung der Copolymeren mit der Verdünnung eher dem Sinken der Konzentration des Komplexes durch Ladungsaustausch zwischen den Monomeren zuschreiben (gemäβ der ersten Erklärung).

DER EINFLUSS DER ART DES LÖSUNGSMITTELS

Der Gesamteffekt des Einflusses der Art des Lösungsmittels in der Copolymerisationsreaktion des Isoprens mit Monobutylmaleat (Molverhältnis 1 : 1) ist in Tab. 1 wiedergegeben.

Tabelle 1

Einfluß der Art des Lösungsmittels auf die Copolymerisation von Isopren mit Monobutylmaleat (Molverhältnis 1 : 1)

Lfd. Zahl	Lösungsmittel	Dielektrizitätskonstante [23] bei 20°	Umsatz %
1	Dioxan	2,30*	12,90
2	Tetrahydrofuran	7,70	14,35
3	Cyclohexanon	18,30	19,75
4	Methyläthylketon	18,50	19,75
5	Dimethylformamid	37,70	5,00
6	Dimethylsulfoxid	48,00	4,20
7	Benzol	2,28	32,50
8	Toluol	2,38*	32,20
9	*p*-Xylol	2,27	32,10
10	Isopropylbenzol	2,38	32,00
11	Monochlorbenzol	5,70	33,50
12	Trichloräthylen	3,42**	32,10
13	Tetrachlorkohlenstoff	2,23	32,40
14	Chloroform	4,80	32,60

* Dielektrizitätskonstante bei 25°; ** bei 16°,
– Copolymerisationstemperatur 70°;
– Reaktionszeit zwei Stunden;
– Initiatorkonzentration (AIBN) $4{,}30 \cdot 10^{-2}$ Mol/l.

Aus der Tabelle ist ersichtlich, daβ man zwischen dem Umsatz zum Copolymer und der Dielektrizitätskonstanten der Lösungsmittel keine klar umrissene Beziehung herstellen kann. Diese Tatsache ergibt sich daraus, daβ beim Untersuchen des Einflusses der Art des Lösungsmittels mehrere Faktoren berücksichtigt werden müssen:

— der Einfluβ des Lösungsmittels auf die Beschleunigung der Zersetzung des radikalischen Initiators;

— die Interaktion mit den der Copolymerisation unterworfenen Monomeren;

— die Schaffung eines homogenen oder heterogenen Mittels bei der Copolymerisation.

Infolge der Untersuchung der Copolymerisationsreaktion des Isoprens mit Monobutylmaleat in 14 Lösungsmitteln wurde festgestellt, daβ die Lösungsmittel von 1—6 bei der Copolymerisation ein homogenes System schaffen, während das gebildete Copolymer in den Lösungsmitteln 7—14 unlöslich ist (heterogenes Medium).

Unter diesen Bedingungen ist ein allgemeiner Vergleich zwischen den untersuchten Lösungsmitteln nicht möglich.

Aus Tabelle 1 geht hervor, daβ Lösungsmittel wie: Dioxan, Tetrahydrofuran und besonders Dimethylformamid und Dimethylsulfoxid die Copolymerisationsreaktion in groβem Maβe beeinflussen.

Der kleine Umsatz, der in diesen Fällen erzielt wird, beweist die Wechselwirkung zwischen Lösungsmittel und Monoester und auf diese Weise wird das Comonomere der Copolymerisationsreaktion entzogen (die Wechselwirkungen können von der Art der Wasserstoffbrücken sein). Solche Einflüsse der elektronenabgebenden Lösungsmittel sind auch in der alternierenden Copolymerisation einiger Systeme aufgezeigt worden, bei denen man die Rolle der Komplexe durch Ladungsübertragung zwischen den Monomeren in betracht gezogen hat.[21,24-27]

Novicov und Mitarb.[25] stellten bei der Untersuchung der Copolymerisation von Maleinsäureanhydrid mit Vinylbutyläther in Dimethylformamid und Dimethylsulfoxid fest, daβ man in diesen Fällen im UV-Spektrum keinen Komplex durch Ladungsübertragung zwischen den Monomeren beobachten kann, es bilden sich aber auch keine Copolymeren. Aus diesen Feststellungen schlossen die Autoren, daβ die Bildung der Komplexe zwischen den Monomeren in direktem Verhältnis zur Bildung der Copolymeren steht. In solchen Fällen wird die Abhängigkeit der Copolymerisationsgeschwindigkeit vom Charakter des Mediums durch den Einfluβ des Lösungsmittels auf die Komplexierung der Monomeren bestimmt.

Wenn wir nun diese Erwägungen in betracht ziehen, wie auch den groβen Einfluβ der erwähnten Lösungsmittel auf die Copolymerisation des Isoprens mit Monoestern der Maleinsäure, so könnten wir auch in diesem Falle voraussetzen, daβ die Reaktion unter Beteiligung eines Donor-Acceptor Komplexes zwischen den Monomeren verläuft.

Erwähnenswert ist das Verhalten der Lösungsmittel, die während der Copolymerisation ein heterogenes Medium bilden (die Lösungsmittel mit den Ordnungszahlen 7—14 aus Tab. 1). Die Verwendung dieser Lösungsmittelgruppe führt praktisch zum gleichen Umsatz an Copolymeren, der aber viel gröβer ist als im Falle der Verwendung der ersten Gruppe.

[27] A. V. Ryabov, Yu D. Semchikov und N. N. Slavnitskaya, *Vysokomol. Soedineniya A*, **12**, 553 (1970).

Hervorzuheben ist die Unabhängigkeit des Umsatzes von der Dielektrizitätskonstanten des Lösungsmittels in dieser Reihe, eine Beziehung, die man auch bis jetzt in der Copolymerisation anderer Monomeren kannte.

DIE ÄNDERUNG DER VISKOSITÄTSZAHL DER COPOLYMEREN IN ABHÄNGIGKEIT VOM UMSATZ

Die Beziehung zwischen dem Molekulargewicht und dem Umsatz, bei dem die Polymeren erhalten wurden, liefert wertvolle Hinweise über den Polymerisationsmechanismus.

Es wurde festgestellt, daβ im Falle der konventionellen Polymerisation mit freiem Radikalen (monoradikalischer Mechanismus) das Molekulargewicht konstant bleibt, wenn der Umsatz mit der Zeit wächst. Im Falle eines biradikalischen Mechanismus wächst das Molekulargewicht mit dem Umsatz.[28]

Die Beziehung zwischen Viskositätszahl ($\eta_{sp/c}$) und Umsatz für das Copolymer Isopren-Monomethylmaleat, kann in Abbb. 5 verfolgt werden.

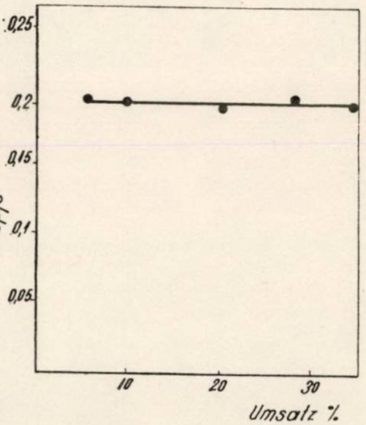

Abb. 5. — Änderung der Viskositätszahl des alternierenden Copolymeren Isopren-Monomethylmaleat mit dem Umsatz.

Die Tatsache, daβ die Viskositätszahl in Abhängigkeit vom Umsatz konstant ist, weist auf einen typisch monoradikalischen Mechanismus hin. Auch andere Arbeiten, betreffend die alternierende Copolymerisation verschiedener Systeme wie: Styrol-Maleinsäureanhydrid, [17] p-Dioxen-Maleinsäureanhydrid,[15] in denen die Beteiligung eines Komplexes durch Ladunsgsübertragung zwischen den Monomeren suggeriert wurde, haben dieselbe Unabhängigkeit der Viskositätszahl der Copolymeren vom Umsatz hervorgehoben, was eine Reaktion durch Biradikale ausschlieβt.

[28] N. L. Zutty, C. W. Wilson, G. H. Patter, D. C. Priest und C. J. Whitworth, *J. Polymer Sci., Part A*, **3**, 2781 (1965).

Trotzdem haben Zutty und Mitarb.[28] bei der Untersuchung der alternierenden Copolymerisation von Bicyclo-2, 2, 1-hepten-2 mit SO_2 aufgrund der steigenden Viskositätszahl mit dem Umsatz, einen Mechanismus vorgeschlagen, der anfänglich die Bildung eines Komplexes zwischen den Reaktionsteilnehmern einschließt, der eine Neuordnung dieses Komplexes zu Biradikalen und ihre Weiterreaktion zur Bildung der Copolymeren folgt.

Anders wurde die spontane alternierende Copolymerisation von 1-Methyl-Cyclopropen mit SO_2 erklärt, obwohl auch in diesem Falle das Molekulargewicht mit dem Umsatz wächst.[29] Das Verhalten in dieser letzten Reaktion wurde der Bildung eines langlebigen Radikals zugeschrieben.

COPOLYMERIZATION OF EPICHLORHYDRIN AND PROPYLENE OXIDE WITH THE $AlEt_3-H_2O$ CATALYTIC SYSTEM

VICTORIA DIMONIE, D. DONESCU and I. GAVĂT

Institute of Macromolecular Chemistry "P. Poni", "Polymerization Processes" Department
Bucharest, Str. Dumbrava Roşie, 18, Romania

Received July 27, 1973

The kinetics of the epichlorhydrine (ECH) and propylene oxide (PO) copolymerization was studied with the $AlEt_3 - H_2O$ system in benzene medium. The dependence of the composition of the formed copolymers upon the composition of the initial mixture of comonomers was established, as well as the variation of the composition of the copolymer with time, the yield in copolymer after 24 hours of reaction and the evolution of the molecular weights with time. It was found that during copolymerization in the presence of $AlEt_3 - H_2O$, PO was the more active monomer.

1. INTRODUCTION

The study of the cationic copolymerization of cyclic monomers forms a much investigated problem in literature.[1]

Unlike the radical copolymerization of vinyl monomers,[2] the phenomena appearing in the ionic copolymerization of cyclic monomers are much more complex, this fact explaining the difficulty of applying the Mayo — Lewis theory to the latter case. In the cationic polymerization and copolymerization of cyclic monomers, in most cases the going on of the reactions has a non-steady character, the comonomer reactivities depend upon the nature of the catalyst and solvent used,[3-6] and even from the beginning of the monomer consumption, secondary reactions are taking place: formation of low-molecular secondary products,[7-11] depolymerization,[12] and chain transfer.[13-16]

[6] K. Burg, N. Schlaf and H. Cherdron, *Makromol. Chem.*, **145**, 247 (1971).

For this reason, we consider that for the study of the copolymerization of cyclic monomers, the reactivity ratios do not represent kinetic constants significant for the characterization of the respective systems.

Since for the cationic copolymerization of cyclic monomers, the determinant factors of their reactivity are their basicity and the ring strain,[3,17] we attempted to study a system of comonomers ECH and PO, having very near ring strains, but different basicities. The copolymerization of these two monomers has already been studied with different catalytic systems: $FeCl_3-PO$,[18] $AlEt_3 - TiCl_3$,[19] $AlEt_3 - H_2O$,[20] $Al(tC_4H_9O)_3$ and $Al\ (tC_4H_9O)_3 - ZnCl_2$.[21]

The study carried out by Kropachev *et al.*[20] consists in the determination of the reactivity ratios for different comonomers using catalysts of the cationic type. In the case of the copolymerization of ECH and PO with the $AlEt_3-H_2O$ system, the following values of the constants of reactivity were found: $r_{ECH} = 0.09$ and $r_{PO} = 4.65$.

In the present work, we study the kinetics of the copolymerization of ECH and PO with the $AlEt_3-H_2O$ system, the dependence of the instantaneous composition and of the composition with time of the copolymers formed upon the composition of the comonomer mixture, as well as the evolution of the molecular weight of the copolymers with time, in order to obtain supplemental data about this system.

redistilled in purified argon atmosphere, was measured in glass phials dried at 200° and vacuum of 10^{-3} mm Hg and then sealed by flame.

Propylene oxide — commercial product was conditioned in the same way as ECH.

Benzene — Reactivul, Bucharest, product — was rectified, deoxygenated and finally dried on 4 Å molecular sieves. The solvent was measured from the reservoir under argon pressure through a glass G_3 filter into a flask with magnetic cock.

Toluene — Reactivul, Bucharest, product—was conditioned as benzene. The measuring was performed with an automated microburette under argon atmosphere.

The purity of all the reagents was checked by chromatography.

Triethyl aluminium — Schering A. G. product — was used in benzene solution measured into glass bulbs with thin walls. The determination of the $AlEt_3$ solution concentration was performed by complexometry.

2.2. POLYMERIZATION

The polymerizations were carried out in purified argon medium in an apparatus previously dried for 2 hours to 10^{-2} mm Hg.

Benzene, toluene, the monomers and water (measured with the microsyringe in equimolecular amounts with $AlEt_3$), were successively introduced into the reaction flask under magnetic stirring.

The reaction mixture was homogenized, thermostated and the catalyst bulb introduced by striking. The degree of the conversion with time was followed by vapour phase chromatography determination of the unreacted monomers.

The chromatographic determination was performed on the reaction mixture precipitated at 0° in CH_3OH containing isooctane applying the internal standard method. In the present case the internal standard was toluene. A PERKIN — ELMER 452 chromatograph was used, the column being filled with 20% Carbowax 20 M on Chromosorb P 60/80 mesh support as stationary phase. The eluent gas was H_2 with a rate of flow of 100 ml/min and the column temperature 60°.

All the polymerizations have been carried out under the following conditions: overall concentration of monomers 2 moles/l, catalyst $4 \cdot 10^{-2}$ moles/l, toluene 0.524 moles/l and temperature 30°.

2.3. ANALYSIS OF THE COPOLYMERS

The copolymers composition was established by the determination of chlorine.

The composition determinations are in good concordance with the data obtained by chromatography.

The intrinsic viscosity of the copolymers has been determined in dioxan solutions at 25° with the Ubbelohde viscosimeter.

The NMR spectra have been performed in benzonitrile solutions with a JNM—C—60 HL spectrometer at 60 Mz and 70°.

3. RESULTS AND DISCUSSION

We followed the kinetics of homopolymerization of the two monomers and that of copolymerization at different molar ratios of the initial mixture of monomers.

It can be seen in figure 1 that the homopolymerization of ECH and of PO occurs in a similar manner, in two stages : a rapid stage at the beginning of the process, followed by a slow period. The initial polymerization rate (R_0) of PO is a little lower than that of ECH.

In the case of copolymerization (figure 2), the high basicity of propylene oxide ($pKb = 6.94$) as against that of ECH ($pKb = 8.84$)[3] has a determinant role, this resulting in consumption rate of PO higher than that of ECH. The consumption curves of each comonomer have the same characteristic as in the homopolymerization.

The dependence of the consumption rate of each comonomer upon its molar fraction in the feed is different (figure 3). While the consumption rate of PO substantially increases with the increase of its concentration in the initial monomer mixture, in the case of ECH only a slight increase of the reaction rate is observed. Even at high values of the ECH molar fraction, the consumption rates are with about one order of magnitude lower than the homopolymerization rate. This fact is owed to the higher basicity of PO which is preponderantly consumed. The same phenomenon is noticed in the case of co-catalytic addition of PO in the homopolymerization of ECH. [22]

The higher reaction rate of PO with respect to that of ECH causes an enrichment in PO of the copolymer formed with respect to the initial composition of the reaction mixture (figure 4).

During the process development, the molar fraction of the PO units in the copolymer is decreasing owing to the diminishing of the PO molar fraction in the mixture of unreacted comonomers. This causes the variation with time of the copolymer composition (figure 5).

The molar fraction of each monomer consumed at a certain moment is directly proportional to its instantaneous molar fraction in the mixture during the whole process, (figure 6).

The maintaining constant reactivity of the two monomers with respect to the active species, during the whole copolymerization time, shows that, regardless of the polymerization stage, the nature of the active centres is not changing. In the case of the catalytic system $AlEt_3-H_2O$, the greater reactivity of the monomer with higher basicity, PO, confirm once more the cationic character of the active species.

The yield in copolymer, after 24 hours of reaction, is strongly affected by the composition of the initial monomer mixture (figure 7). It is highest in the case of homopolymers and decreases, reaching a minimum, in the range of the PO molar fraction of 0.3 to 0.5.

In figure 7 is shown the variation of the intrinsic viscosity with conversion increase. As it occurs in many cationic polymerization of cyclic monomers, in the case of copolymerization of ECH with PO, the variation of the molecular weights with time is characterized by a curve with a maximum. The diminishing of the molecular weights is owed to the appearing of strong transfer reactions [23] with the polymer or oligomers.

We tried to settle the copolymer structures by NMR, but we had no positive result.

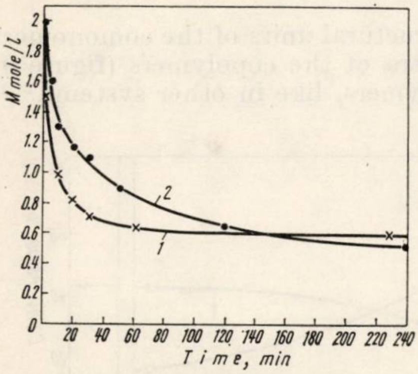

Fig. 1. — Variation of the monomer concentration in the homopolymerization of : ECH (*1*) and PO (*2*).

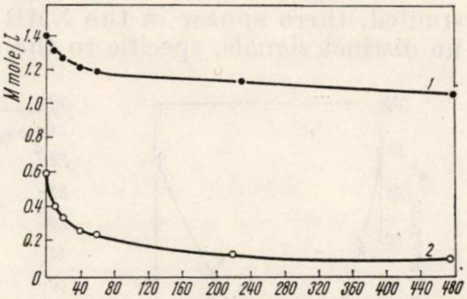

Fig. 2. — Variation of the monomers concentration in the copolymerization of PO and ECH; initial molar ratios 0.7 : 0.3 = ECH (*1*) : PO (*2*).

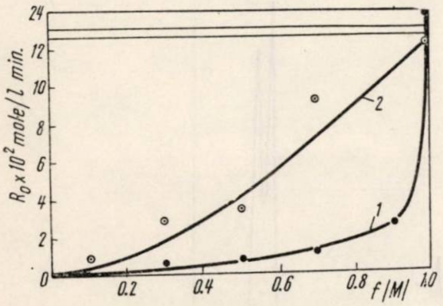

Fig. 3. — Dependence of monomer disappearance rates on the initial molar ratio of comonomers ; ECH (*1*) and PO (*2*).

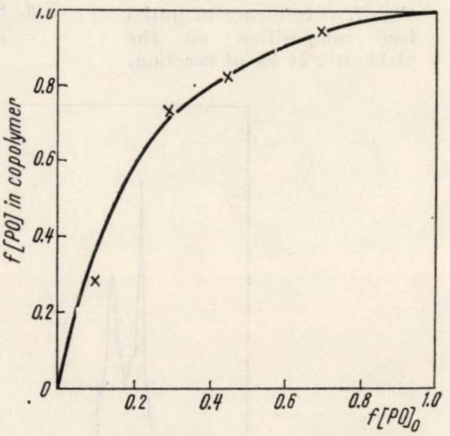

Fig. 4. — Composition diagram of copolymers as function of feed composition.

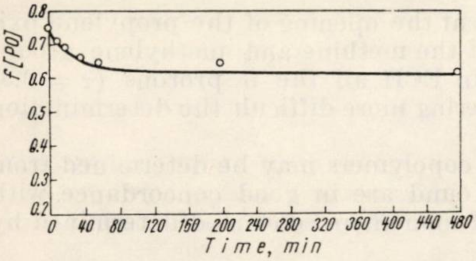

Fig. 5. — Variation of the molar fraction of PO consumed *versus* time. $|PO_0| : |ECH|_0 = 0.3 : 0.7$.

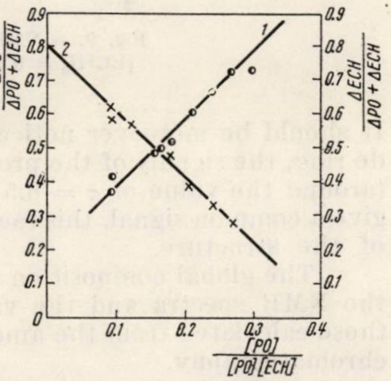

Fig. 6. — Dependence of the molar fraction of consumed monomers on the PO molar fraction in the mixture of unreacted monomers.

Owing to the resemblance of the structural units of the comonomers studied, there appear in the NMR spectra of the copolymers (figure 9) no distinct signals, specific to the copolymers, like in other systems.[24,25]

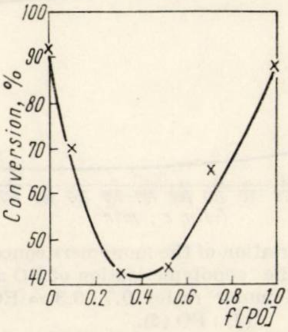

Fig. 7. — Influence of initial feed composition on the yield after 24 hs of reaction.

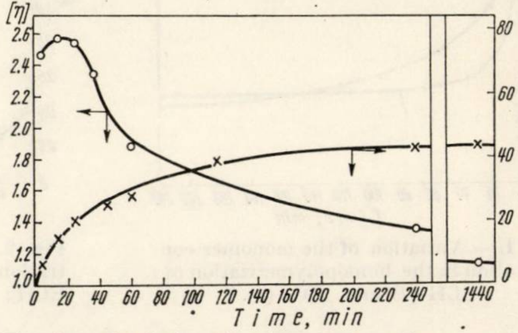

Fig. 8. — Intrinsic viscosities and copolymer conversion *versus* time; $[PO]_0 : [ECH]_0 = 1 : 1$.

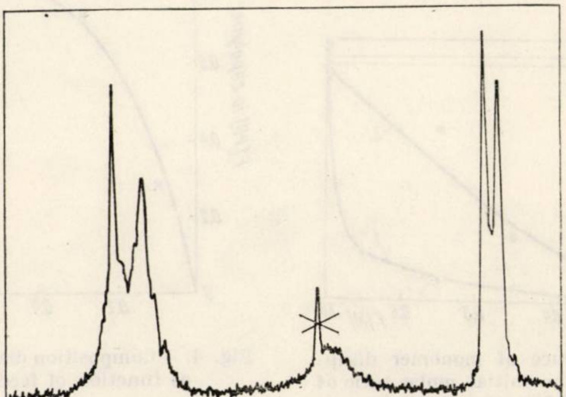

Fig. 9. — NMR spectra of copolymer; $[PO]_0$: $[ECH]_0 = 0.3 : 0.7$ time reaction : 12 min.

It should be moreover noticed that at the opening of the propylene oxide ring, the signals of the protons of the methine and methylene groups (around the value of $\tau = 6.5$) and in ECH all the 5 protons ($\tau = 6.3$) give a common signal, this fact rendering more difficult the determination of the structure.

The global composition of the copolymers may be determined from the NMR spectra and the values found are in good concordance with those calculated from the amount of monomers consumed determined by chromatography.

THE INFLUENCE OF CROSS-LINKAGE OF ANION EXCHANGERS ON THE DISTRIBUTION COEFFICIENT OF SAMARIUM IN MIXED SYSTEMS OF ORGANIC SOLVENT AND MINERAL ACID

ŞTEFANIA SPIRIDON and CARMEN GRIGORESCU-SABĂU

Institute of Atomic Physics, Bucharest, P.O. Box, 35, Romania

Received April 4, 1973

The distribution coefficients have been determined for Sm^{3+} ions between mixed solutions of alcohol and nitric acid and Dowex-1 resin with various cross-linkage degrees. With the aid of these values and the specific volumes determined by the picnometric method, the charge of the complex ions formed in these solutions has been calculated.

It is well known that the physical properties of the ion exchanger resins are strongly influenced by their cross-linkage, namely by the divinylbenzene content. On this content depends the size of the pores of the exchanger and its swelling capacity. Thus, the low cross-linked resins present a greater volume change in water and, inversely, the strong cross-linked resins will swell less, but they present a greater selectivity, a smaller porosity and exchange capacity.

A phenomenon connected with the changes in the water content of the resin is the dehydration of the strongly hydrated ions. It has been observed that the volume of the hydrated layer is proportional with the relative content of water in a resin. Based on this observation, the ionic radii of the hydrated and dehydrated ions can be calculated and the variations in the distribution coefficients of different ions [1–4] can be explained.

In the mixed systems of organic solvents and water with a small concentration of organic component, the content of absorbed ions differs slightly from that of water. This means that the resins in organic aqueous solutions absorb water preferentially, which leads to the supposition that the ions in the resin will become hydrated to the same degree as in water [5] and the equilibrium will be determined by variation of the properties of

the solution ; consequently, the equilibrium will be displaced in the direction of intensifying the less hydrated ions.

The study of the variation of distribution coefficients in aqueous media on anion exchanger has shown that the more they increase the greater is the cross-linkage.[4, 6,7] The same is true in alcohols—nitric acid mixtures.[8-10]

The present work has studied systematically the variation of the distribution coefficients of samarium on anion exchanger of different cross-linkage in mixed media of organic solvent and nitric acid. It was also tried to establish the charge of the complexes formed.

EXPERIMENTAL

The distribution coefficients (K_d) of samarium ions have been determined as it was mentioned in a previous publication in the case of praseodymium ions.[11, 12] The Sm ions concentration was held to 2.3×10^{-5} equiv/ml and $^{153}_{62}$Sm ($T_{1/2} = 46.2$ h) was used as tracer.

The anion exchanger Dowex-1 (NO_3^-) with different cross-linkage (X2, X4, X8, X10) and the organic solvents (methyl, ethyl, *n*-propyl and isopropyl alcohol) were used in nitric acid of concentrations which varied as follows : for 70% solvent — 0.06 N, 0.15 N, 0.24 N, 0.30 N, 0.60 N, 0.90 N, 1.20 N and 1.80 N acid ; for 80% solvent : 0.04 N, 0.10 N, 0.16 N, 0.20 N, 0.40 N, 0.60 N,0.80 N and 1.20 N acid and for 90% solvent : 0.05 N, 0.08 N, 0.10 N, 0.20 N, 0.30 N, 0.40 N and 0.60 N acid.

For favouring a better separation of strong adsorbed ions in the case of great alcohol and acid concentrations, Dowex-1 (100—200 mesh) was used.

Owing to the study of the distribution coefficients of ions on ion exchange resins with different cross-linkage degree, the estimate of the charge of the adsorbed ions was possible. [13] This calculation requires the determination of the distribution coefficients of the studied ions on two kinds of resins in identical conditions.

With that end in view, the K_d-values for Sm^{3+} ions on Dowex-1X4 (NO_3^-) (20—50 mesh) for methyl alcohol (concentrations of 70%, 80%, 90%) and nitric acid (concentrations of 0.30, 0.60, 1.20 and 1.80 N) were determined. The values are given in table 1.

Table 1

The variation of K_d with the concentration of CH_3OH and HNO_3 for Dowex 1 × 4 (20—50 mesh)

Concentration of CH_3OH	Conc. HNO_3	K_d	Conc. CH_3OH	Conc. HNO_3	K_d	Conc. CH_3OH	Conc. HNO_3	K_d
70%	0.3N	3.27	80%	—	—	90%	0.3N	76.56
	0.6N	4.157		0.6N	27.83		0.6N	146.56
	1.2N	9.535		1.2N	43.52	—	—	—

The specific volume of the swollen resins has been determined through the picnometric method.[14] The values are given in table 2.

Table 2

$1/V$-values for the resins Dowex 1 × 4 (20–50 mesh) and Dowex 1 × 4 (100–200 mesh) determined by the picnometric method

Resin	Conc. CH_3OH	Conc. NO_3H	$1/V$	Conc. CH_3OH	Conc. HNO_3	$1/V$	Conc. CH_3OH	Conc. HNO_3	$1/V$
Dowex 1 × 4 (20–50 mesh)	70%	0.3N	1.027	80%	—	—	90%	0.3N	0.882
		0.6N	0.885		0.6N	0.878		0.6N	0.886
		1.2N	0.875		1.2N	0.881		—	—
Dowex 1 × 4 (100–200 mesh)	70%	0.3N	0.917	80%	—	—	90%	0.3N	0.919
		0.6N	0.914		0.6N	0.859		0.6N	0.927
		1.2N	0.866		1.2N	0.831		—	—

Knowing the K_d-value for Dowex-1X4 (NO_3^-) (20–50 mesh) and Dowex-1X4 (NO_3^-) (100–200 mesh), the dried resins densities and the specific volumes, the charge of the ions may be determined, with the help of the relation:

$$Z = \frac{\log K_{d_1}/K_{d_2}}{\log V_2/V_1} + 1$$

where Z = the charge of ions in the mixtures used

K_{d_1} and K_{d_2} = the distribution coefficient values for the Sm^{3+} ions on Dowex 1X4 (NO_3^-) (20–50 mesh) and Dowex 1X4 (NO_3^-) (100–200 mesh), respectively.

V_1 and V_2 = the specific volumes of the two resins determined through the picnometric method $\left(V = \frac{1}{\rho}, \text{ where } \rho \text{ is the density of dry resin} \right)$.

RESULTS AND DISCUSSION

In the present work, alcohols were preferred because they are miscible with water and are polar substances, which permit the use of metal ions as simple combinations, any addition of strange salts being unnecessary. The alcohols used have a much less dielectric constant than water, so that in mixture with it, they will diminish considerably the dielectric constant of the mixture and will increase the electrostatic forces. That means that the formation of ion pairs and their association in complex species without charge, which have less mobility because of their greater radius, will be facilitated. On the other hand, the presence of the organic solvent favours the dehydration of the metal ions, consequently the formation of complexes with negative charge, which will be preferably adsorbed by the anion exchanger, resulting the increase of K_d with the growing of organic solvent concentration (fig. 1).

[14] J. Inczedy, "Analytical Applications of Ion Exchangers", Akademiai Kiado Budapesta, 1966, p. 116.

The plot of log K_d as a function of the nitric acid concentration for the different cross-linkage of the resin shows an increasing distribution of the K_d values for the same solvent concentration (fig. 1). The shape of the curves is maintained for all four cross-linkage degrees used (fig. 2). In the solvent absence, the K_d values would grow with the cross-linkage. But in the presence of organic solvent these values decrease, so that the greatest distribution coefficients will be in the resin having 2% divinylbenzene and the smallest distribution coefficients in the resin having 10% divinylbenzene. Because the resins with a great content of divinylbenzene are less swelling and less sensible to the variation of the ionic strength of the solution, the diffusion processes are slower. Thus, the more convenient for work are those resins which contain 4–5% divinylbenzene and the most data in literature are given for these kinds of resins.[15,16]

Fig. 3 shows the variation of log K_d as a function of the concentration of the organic solvent. In contrast to figs. 1 and 2, the curves become concave, but keeping the same growing order of the K_d values both for the concentration of the alcohol and of the nitric acid used.

Fig. 4 represents the variation of log K_d *versus* the cross-linkage grade for different solvent concentrations. On passing from 70% to 90% solvent, the shape of the curves changes. It is interesting that in this case the curves tend to group together in pairs as follows: for 70% solvent the two similar pairs are methyl alcohol, *n*-propyl alcohol and ethyl alcohol, *iso*propyl alcohol, for 80% solvent the resemblance is made between ethyl alcohol, *n*-propyl alcohol and *iso*propyl alcohol, for 90% solvent the groups include methyl alcohol, isopropyl alcohol and ethyl alcohol, *n*-propyl alcohol.

The great similarity of physical and chemical properties of lanthanides, conferred by the electrons accomodated in the 4f shell, has made their separation very difficult. For this reason their separation was very much studied by different methods, among others also the ion exchange method.

Thus, it was shown that in nitric acid 5–6 N, the K_d of light rare earths are included between 5 and 7, while through the increasing of acidity the values become smaller.[17] Replacing a part of the aqueous phase of the acid solution by an organic solvent miscible with water, the adsorption of the lanthanides on strong basic anionites,[18-21] for example Dowex 1, increases.

The increasing of the concentration of organic solvent, as shown by Edge,[15] leads to the adsorption of rare earths. This fact was demon-

strated by Sm, where the greater values of the distribution coefficient were obtained for 90% alcohol (fig. 1). By comparing the K_d-values for the different cross-linkage degrees which were used, it was observed that these are decreasing (fig. 2) in the order 4% divinylbenzene-8% divinylbenzene; at 10% divinylbenzene they grow very little to 80% for methyl, ethyl and isopropyl alcohol and to 90% for methyl alcohol.

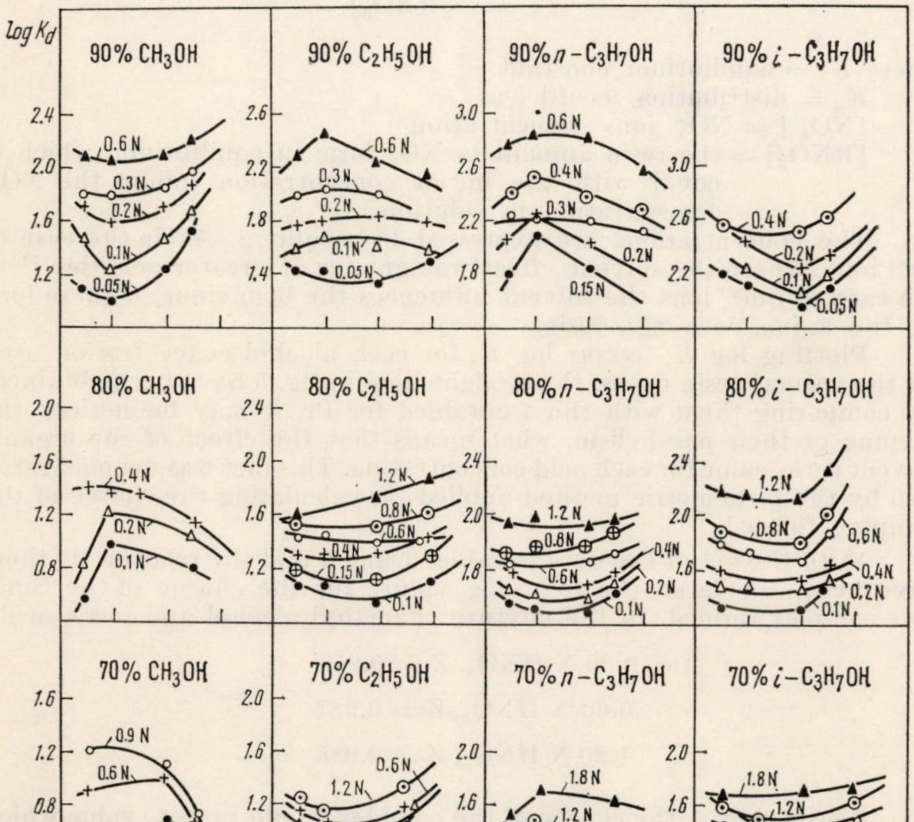

Fig. 4. — The variation of log K_d as a function of the cross-linkage degree. N is the same as in fig. 3.

The experimental data have confirmed that the reaction with Sm^{3+} ions in acid solution is influenced by the presence of an organic solvent. Assuming that in the presence of nitric acid a complexation of Sm^{3+}

ions takes place and applying the law of action in the reaction of equilibrium, the equilibrium constant may be calculated:

$$K_e = K_d \frac{[NO_3^-]}{[RNO_3]} \tag{2}$$

where K_e = equilibrium constant
K_d = distribution coefficient
$[NO_3^-]$ = NO_3^- ions concentration
$[RNO_3]$ = the resin amount in NO_3^- form in equilibrium, which is equal with the initial concentration minus the NO_3^- concentration in solution.

The concentrations are expressed in mequiv/g. As in the case of Pr^{3+} ions, where the solvent effect was greater at greater acidities, [11] in the case of Sm^{3+} ions the solvent influences the behaviour of these ions on the anion exchange resin.

Plotting log K_e *versus* log K_d for each alcohol concentration used for the various resin types, the straight lines in fig. 5 have been obtained. By comparing them with those obtained for Pr, it may be noticed the keeping of their parallelism, what means that the effect of the organic solvent is the same for each acid concentration. This fact was demonstrated also by the picnometric method applied for calculating the charge of the complex formed.

With the aid of the data in tables 1 and 2 and the relation (1) there have been calculated the following values for the charge of the Sm^{3+} ions complex-formed in the mixture of methyl alcohol and nitric acid:

for 0.30 N HNO_3, $Z = 0.959$
0.60 N HNO_3, $Z = 0.981$
1.20 N HNO_3, $Z = 0.986$

Consequently, the charge of the complex would be +1, value which explains why the K_d values are small in the mixtures used, indicating that the utilization of some great alcohol and acid concentrations could lead to negative complexes, more strongly adsorbed on the anionite.

If we use the logarithms in relation (2), we obtain:

$$\log K_e = \log K_d + \log \frac{[NO_3^-]}{[RNO_3]} \tag{3}$$

This means that for every acid concentration used, the corresponding values for the different organic solvent concentrations will give a straight line, which was on the other hand confirmed by fig. 5 and the charge determined for the complex ion.

The strength and stability of the connection metal-ligand in a complex combination depend on the nature of the central ion and of the ligand and firstly on their electronegativity. The OH^- and NH_2^-

ligands lead to the formation of a π bond,[22, 23] which decreases the charge of the central metallic ion, determining a decrease of the separation energy. As, generally, a central ion having a high valency determines the donor properties of the ligands and a small one will determine the acceptor ones, it could be shown that in the case of La^{3+} and Ce^{3+} ions the complexes obtained are stable. It might be possible that in the presence of alcohols, hence of the OH^- radical, compounds should be formed in which, by analogy with the other ions of rare earths, the complex ions of Sm^{3+} lower their valency. The present data confirm this hypothesis.

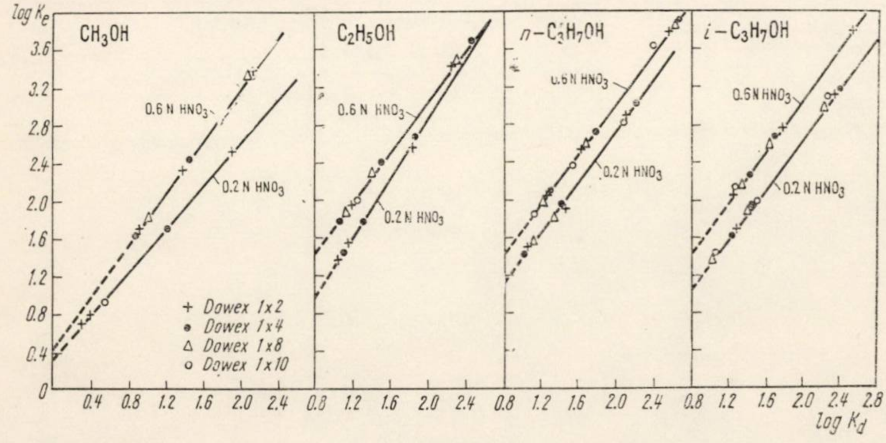

Fig. 5. — The variation of log K_d as a function of log K_e for various acid and solvent concentrations.

The results obtained in the case of the study of the behaviour of the Sm^{3+} ions on ion exchangers in mixed media of organic solvent and mineral acid are a part of a set of works carried out in view of establishing the optimum conditions for an individual separation of the elements of rare earths.

DIE AMPEROMETRISCHE TITRIERUNG DES QUECKSILBERS (II) IN STARK ALKALISCHEM MEDIUM MIT THIOACETAMID

GHEORGHE FACSKO und MARIA NEMEŞ
Polytechnisches Institut Timişoara, Laboratorium für Elektrochemie, Bocşa-Str. 6

Eingegangen am 26. Feb. 1973

In vorliegender Arbeit wird die amperometrische Bestimmung des Hg^{2+}-Ions in einer das Natriumsalz der 4-Sulfonamidobenzoesäure und Natriumhydroxyd enthaltenden Grundlösung untersucht. Die amperometrische Titrierung wurde bei 0,7 V (im Vergleich zur G.K.E.) vorgenommen, wobei für Hg^{2+}-Konzentrationen von $10^{-3}-10^{-4}$ Äquiv. gr/1, die Bestimmungsfehler bis zu−4 % betrugen.

Sowie wir in einer früheren Arbeit [1] zeigten, präzipitiert das Hg^{2+}-Ion in neutralem Medium mit dem Natriumsalz der 4-Sulfonamidobenzoesäure (4−Sb−Na). Der gebildete weiβ-käsige Niederschlag löst sich in Natriumhydroxyd unter Bildung einer komplexen Verbindung, anscheinend gemäβ der Gleichung:

$$H_2N - SO_2 - C_6H_4 - COO^- + Hg^{2+} + 2OH^- \rightleftarrows HgN - SO_2 - C_6H_4 - COO^- + 2H_2O \quad (1)$$

Da wir feststellen konnten,[2] daβ das Hg (II) in einer NaOH-4-SB-Na-Grundlösung eine gutausgebildete polarographische Treppe aufweist, haben wir das Unternehmen einiger Untersuchungen betreffs der amperometrischen Bestimmungsmöglichkeiten des Quecksilbers aus diesem Medium als zweckgemäβ erachtet.

Als Reagenz wählten wir Thioacetamid, das zur amperometrischen Bestimmung des Quecksilbers (II) in saurem Medium von Kalinka und Petri [3] mit entsprechenden Ergebnissen angewandt wurde.

Das von uns verwendete alkalische Medium weist aber unbestreitbare Vorteile im Vergleich zum sauren Medium auf, da das Quecksilber (II) mittels des Natriumsalzes der 4-Sulfonamidobenzoesäure in Lösung gehalten wird, während die meisten übrigen Ionen präzipitieren. Dies ermöglicht eine schnelle und bequeme Trennung des Quecksilbers von den meisten übrigen Ionen.

ARBEITSWEISE

Die Polarogrammen wurden mittels eines Polarographen LP 60 aufgenommen. Als Anode wurde eine gesättigte Kalomelelektrode verwendet, die über eine Salzbrücke, bestehend aus einer durch Agar-Agar immobilisierten KNO_3-Lösung, mit der zu untersuchenden Lösung in Verbindung gebracht wurde.

Die amperometrischen Titrierungen wurden mittels desselben Polarographen LP 60 durchgeführt. Der Diffusionsgrenzstrom wurde an der Skala des Registrierpotentiometers abgelesen.

Die Titrationszelle bestand aus einem 100 ml — Glasbecher; die zu untersuchende Lösung wurde mittels einer Salzbrücke, bestehend aus einer durch Agar-Agar immobilisierten KNO_3-Lösung, mit einer großflächigen Kalomelelektrode in leitende Vervindung gebracht.

Die zu polarographierenden Lösungen wurden wie folgt vorbereitet: In einem 25 cm^3 -Meßkolben wurden 5 ml einer 0,5 N NaOH - 5 ml einer 0,5 M 4-SB-Na-, 1 ml einer gesättigten Na_2SO_3-Lösung, sowie aliquote Volumen einer $Hg(NO_3)_2$-Lösung bekannter Konzentration hinzugefügt. Nach der Zugabe von bidistilliertem Wasser bis zur Marke, wurde 10 Minuten zwecks Entfernung des gelösten Sauerstoffes gewartet, wonach bei einer Tropfzeit von 3 Sekunden, im Bereich 0—2 V polarographiert wurde. Zwecks Aufzeichnung der Eichkurven wurden die Lösungen bei +25° thermostatiert.

Die der amperometrischen Bestimmung unterworfenen Lösungen wurden wie folgt vorbereitet: im 100 ml-Titrierungsbecher wurde 10 ml einer 0,5 N $NaOH^-$, 10 ml einer 0,5 M 4-SB-Na-, 2 ml einer gesättigten Na_2SO_3 - Lösung sowie 4 ml einer 10^{-2}N Hg $(NO_3)_2$ - Lösung bekannter Konzentration hinzugefügt, wonach das Volumen zu 50 ml aufgefüllt wurde.

Die 4-Sulfonamidobenzoesäure wurde aus Chloramin T synthetisiert und zweimal aus Alkohol rekristallisiert. Die 0,5 N 4-SB-Na-Lösung wurde durch Abwägen der 4-Sulfonamidobenzoesäure, Hinzugabe von NaOH in stöchiometrischer Menge und darauffolgender Komplettierung mit bidistilliertem Wasser bis zum entsprechenden Volumen präpariert.

Die 10^{-2}N $Hg(NO_3)_2$-Lösung wurde durch Auflösen von genau abgewogenem Quecksilberoxyd (II) p.a. in Salpetersäure p.a. in einem Meßkolben und darauffolgender Komplettierung bis zur Marke präpariert. Das Quecksilberoxyd (II) wurde als Titrosubstanz angesehen.

Die 10^{-2}N Thioacetamid-Lösung wurde durch genaues Abwägen eines rekristalisierten Thioacetamids präpariert.

Die übrigen Reagenzen waren p.a.

EXPERIMENTELLE ERGEBNISSE

Gemäß dem in vorangehender Arbeit[2] Dargestelltem, weist das Quecksilber (II) in einer 0,1N NaOH- und 0,1 M 4-SB-Na-Grundlösung eine gutausgebildete polarographische Treppe auf, deren Höhe vom Reststrom entsprechend der Grundlösung gemessen wird. Im Konzentrationsbereich 10^{-5} bis. $2{,}4.10^{-3}$ N Hg(II) ist die polarographische Treppenhöhe der Quecksilber (II)-Konzentration genau proportional. Mit dem Anstieg der Quecksilberkonzentration verschiebt sich das Halbstufenpotential um cca 30 mV bei einer zehnfachen Vergrößerung der Hg (II)-Konzentration.

Hinsichtlich des Einflusses der Natriumhydroxyd-Konzentration im Bereich 8.10^{-3} bis 10^{-1} N wurde keine Änderung der Treppenhöhe, verzeichnet, wobei sich das Halbstufenpotential um nur 15 mV zu positiveren Werten verschob.

Im gleichen Konzentrationsbereich (8.10^{-3}—10^{-1} N) des 4SB—Na wurde eine 12%-ige Abnahme des Diffusionsgrenzstromes und keine Änderung des Halbstufenpotentials verzeichnet.

Die amperometrische Titrierungen wurden bei −0,7 V (im Vergleich zur G.K.E.) durchgeführt, da unsere Untersuchungen angaben, daß das Hg (II) in der von uns angewandten Grundlösung einen klaren Diffusionsgrenzstrom zwischen 0,3 und 1,1 V aufweist.

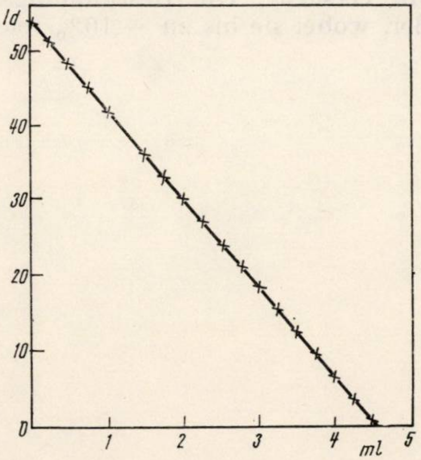

Abb. 1

Die 10^{-2} Thioacetamid-Reagenzlösung wurde aus einer geeichten 10-ml Bürette zu 0,25 ml der zu bestimmenden Lösung hinzugefügt.

Der Diffusionsgrenzstrom wurde dem Reststrom und der Volumenänderung entsprechend korrigiert.

Die graphische Darstellung des Diffusionsgrenzstromes in Abhängigkeit vom zugefügten Reagenzvolumen ergibt Titrationskurven, die jener in Abbildung 1 wiedergegebenen ähnlich sind. Der Äquivalenzpunkt erfolgt aus dem Schnittpunkt der erhaltenen Geraden mit der Abszisse.

Tabelle 1 wiedergibt einige typische Ergebnisse.

Tabelle 1

Die amperometrische Bestimmung des Hg (II) mit Thioacetamid

Nr. der Bestimmung	ml einer 10^{-2}N $Hg(NO_3)_2$—Lösung F = 0,9320	Hg in der Probe mg	Hg gefunden mg	Differenz mg	Differenz %
1	5,08	4,752	4,563	−0,189	−3,9
2	5,08	4,752	4,568	−0,184	−3,8
3	5,08	4,752	4,613	−0,139	−2,9
4	5,08	4,752	4,563	−0,189	−3,9
5	5,08	4,752	4,582	−0,170	−3,5
6	5,13	4,799	4,613	−0,186	−3,8
7	5,13	4,799	4,824	−0,025	+0,5
8	5,13	4,799	4,673	−0,126	−2,6

Wie aus der Tabelle ersichtlich, betragen die Bestimmungsfehler bis zu —4%. Trotzdem erachten wir die Ergebnisse der Methode, angesichts des bequemen Trennungsvermögens, den das genannte Medium aufweist, als zufriedenstellend.

Auch die umgekehrte Titrierung, des Thioacetamids mit dem Quecksilberkomplex, wurde versucht. Die Bestimmungsfehler sind aber für diesen Fall viel gröβer, wobei sie bis zu — 10% reichen können.

STUDIES ON THE ELECTROANALYTICAL BEHAVIOUR OF MEMBRANE-ELECTRODES UNDER CURRENT. V*

THE *E*-pH ELECTRODE FUNCTION AND THE USE OF THE PVC + TRICRESYLPHOSPHATE MEMBRANE IN THE ACID-BASE POTENTIOMETRIC TITRATION AT CONSTANT DIRECT CURRENT

ELENA HOPÎRTEAN and C. LITEANU

Chair of Analytical Chemistry, "Babeş-Bolyai" University, Str. Arany Janos 11, Cluj, Romania

Received February 12, 1973

The paper studies the electrode pH function of the PVC+ tricresylphosphate membrane in "foil" as well as in "bubble" form, under a current having an intensity between 0.1 and 0.8 μA, compared to the one obtained at zero current. We ascertain that a substantial extension of the electrode function linearity field, as well as an increase of its slope takes place under current. As a consequence of this change of the electrode function, the titrations carried out under current offer a much higher variation of the potential around the equivalence point than for zero current. The membrane-potential-current curves are also given and the behaviour mechanism under current of the PVC-tricresylphosphate membrane-electrode is discussed.

In the literature we find only two papers dealing with the analytical turning to account of membrane-electrodes under current. [1,2] The attempts to use membranes as indicator resistances in conductometric titrations on a high conductive medium [3–5] have given interesting results. Studies on the current-potential curves of the $BaSO_4$ — cellophane [6,7] or $BaSO_4$ — parchment paper [8] membrane obtained in the rectifying field, meant to bring some contributions to the understanding of the electrical transportation through the membrane, have also been published.

The present paper studies the pH electrode function of the PVC + tricresylphosphate membrane ("bubble" and "foil") under current, as

compared to the one obtained at zero current. The results obtained with the PVC + tricresylphosphate membrane-electrode under current in the potentiometric titration of HCl with KOH are given. The membrane potential-current curves as well as the behaviour mechanism under current of the membrane-electrode are also given.

EXPERIMENTAL

1. *Experimental device.* The PVC + tricresylphosphate membrane-electrode [9,10] was used in "foil" as well as in "bubble" form. The draft of the working device used for the "foil" membrane, in titrations as well as to obtain the membrane-current potential curves is shown in figure 1.

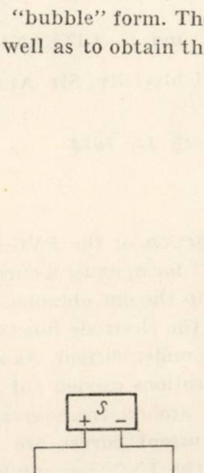

Fig. 1. — Diagram of the working device.

1, SCE with Luggin capillaries; 2, platinated Pt-electrodes; 3, membrane; *C*—cell; *S*—direct current source; *R* — resistor (330 kΩ); *P*—electronic potentiometer.

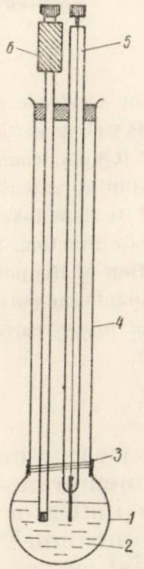

Fig. 2. — "Bubble" membrane-electrode.

1, membrane; 2, internal solution; 3, fastening system; 4, glass tube; 5, wire Pt-electrode; 6, SCE.

The working cell (*C*) [11] made of two compartments is provided with two saturated calomel electrodes with Luggin (*1*) capillaries, and with two Pt-platinized electrodes (1 cm^2 surface). The latter are used to apply a current of required intensity of the direct current source *S*, on the membrane (*3*) attached to the partition of the cell. The reference compartment contains HCl 10^{-4} N. The reference compartment can evidently be polarized anodically or cathodically. In the measurements carried out under current, the sign of the potential coincided with the polarizing sign of the reference compartment. The membrane potential was measured in stirring conditions at 25 ± 0.1° C by means of a MV-11 pH-meter (P), with a ± 1 mV precision.

In the case of the membrane used in "bubble" form (figure 2), the reference solution (10^{-4} N HCl) is inside the bubble. Lucie platinum wire electrodes were used for conduction.

[9] C. Liteanu and E. Hopîrtean, *Rev. Roumaine Chim.*, **15**, 749 (1970).

[10] C. Liteanu and E. Hopîrtean, *Talanta*, **17**, 1067 (1970).

[11] C. Liteanu, I. C. Popescu and M. Preda, *Rev. Roumaine Chim.*, **18**, 1819 (1973).

For the "foil" membrane-electrode, as well as for the "bubble" membrane-electrode, the potential was determined by measuring the e.m.f. of the following cell:

SCE ‖ 10^{-4} M HCl |Membrane| Solution to be studied ‖ SCE

2. EXPERIMENTAL RESULTS

2.1. THE pH ELECTRODE FUNCTION

The pH of the solutions used to determine the electrode functions was measured by means of a glass electrode. The pH electrode functions obtained for the "bubble" form membrane are given in figure 3.

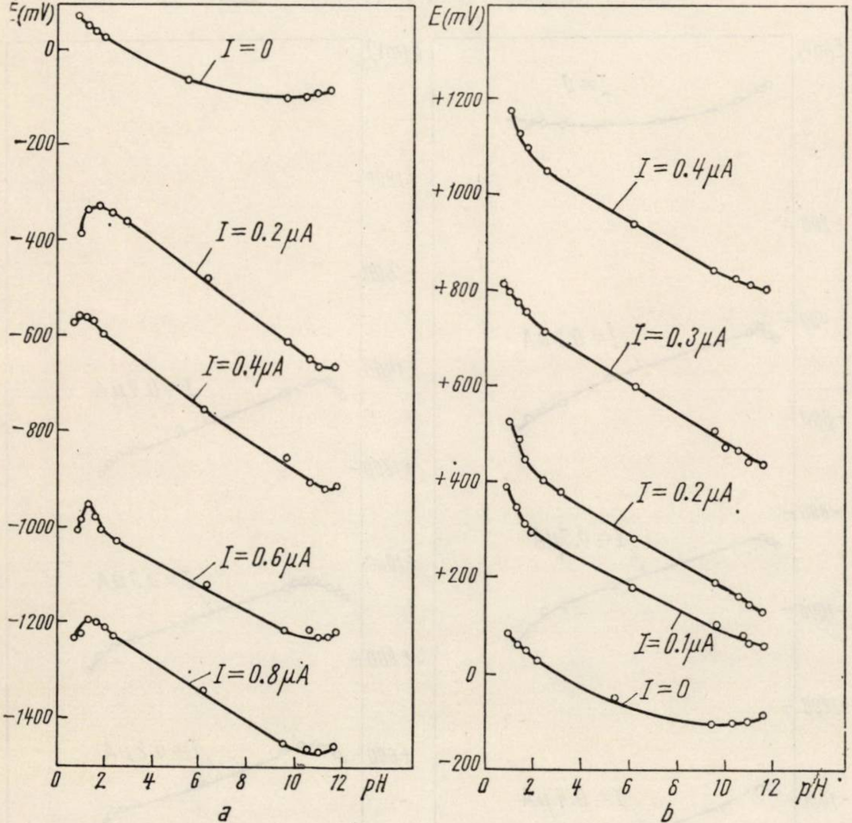

Fig. 3. — E — pH electrode function for membrane-electrode in "bubble" form. *a*, cathodic polarization; *b*, anodic polarization.

The improvement of the electrode function under current, i.e. the extending of the linearity field, as well as the increase of the average slope of the electrode function is concretized by the data in table 1.

Table 1

Influence of the applied current ("bubble" membrane) upon the slope of the electrode function

I (μA)	Polarization	pH range	Average slope (mV)
0	—	2– 9.5	17.0

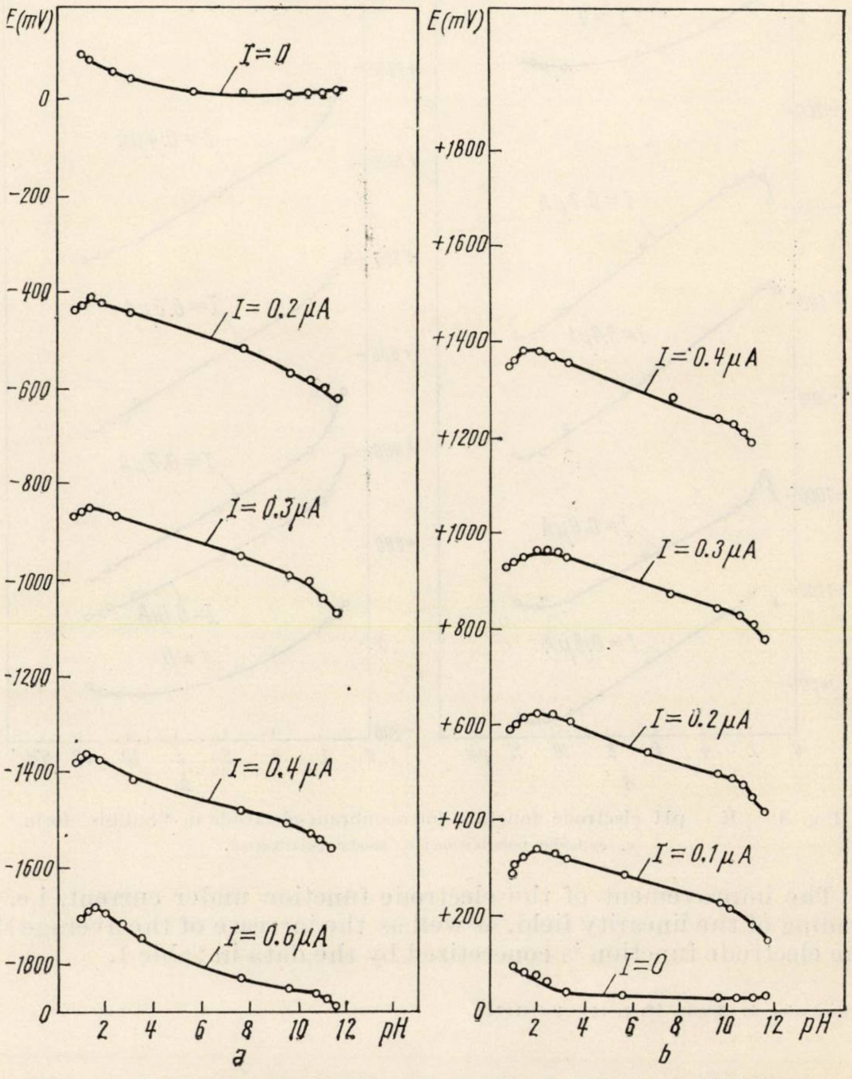

Fig. 4. — E-pH electrode function for membrane-electrode in "foil" form.
a, cathodic polarization; b, anodic polarization.

Figure 4 gives the electrode functions obtained for the "foil" membrane. It is worth pointing out that for this membrane, having initially a lower sensitivity towards the H^+ ions,[10] the turning on of the current results in a more marked improvement of the electrode function, as is seen from table 2.

Table 2

Influence of the applied current ("foil" membrane) upon the slope of the electrode function

I (μA)	Polarization	pH range	Average slope (mV)

2.2. ACID-BASE POTENTIOMETRIC TITRATIONS

We have carried out potentiometric titrations of 10^{-1} M HCl with $5 \cdot 10^{-1}$ M KOH at zero current and at net current, for anodic, as well as for cathodic polarization of the reference compartment.

Figure 5 gives the titration curves obtained with "bubble" membrane-electrode at $I = 0.2$ μA and $I = 0$, and in figure 6 are given the titration curves obtained with the "foil" membrane electrode at $I = 0.2$ μ A and $I = 0$. The titrations carried out with a membrane under current are characterized by a much higher potential variation around the equivalence point than those carried out at zero current, as it was indeed to be expected by studying the electrode functions under current. The titration curves obtained under current of other intensities have a similar form, being only placed in other potential fields. The improvement of the detection of the equivalence point was characterized by the jump index, respectively by the ratio $(\Delta E_{\pm 1\%})_{I \neq 0}/(\Delta E_{\pm 1\%})_{I=0}$. The accuracy of the titrations under current was expressed by the errors affecting the equivalence volumes calculated according to the Hahn-Weiler[12] method *versus* the equivalence volume calculated according to the same method, for the titration carried out in the presence of the glass electrode.

The data referring to the jump index and the accuracy of the 10^{-1} M HCl with $5 \cdot 10^{-1}$M KOH titration according to the intensity of the applied current and the sign of the reference compartment polarization for the "bubble" membrane-electrode are given in table 3, and for the "foil" membrane-electrode in table 4.

---

[12] F. L. HAHN and G. WEILER, *Z. analyt. Chem.*, **64**, 417 (1926).

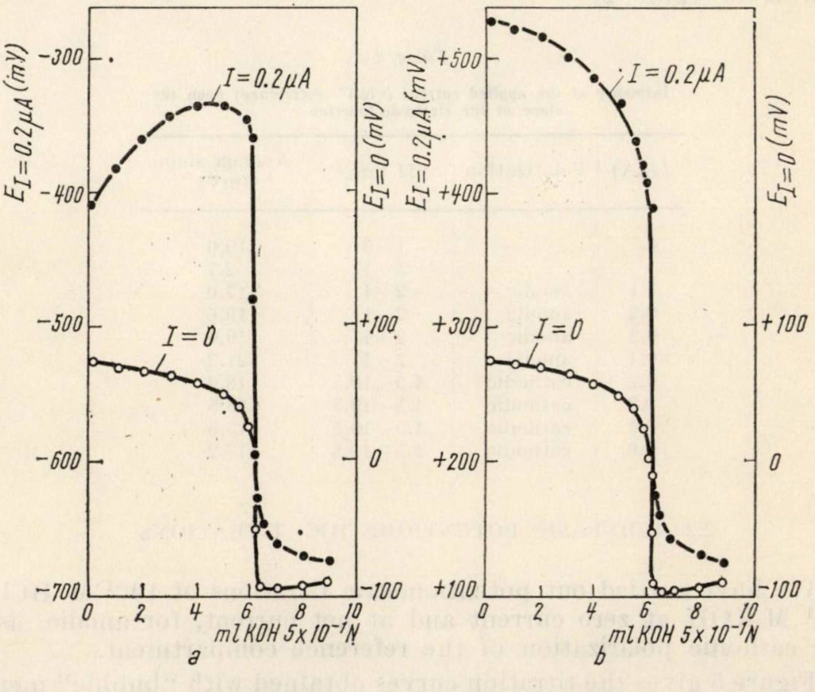

Fig. 5. — Titration of 10^{-1} M HCl with 5×10^{-1} M KOH using "bubble" membrane electrode.

a, cathodic polarization; *b*, anodic polarization.

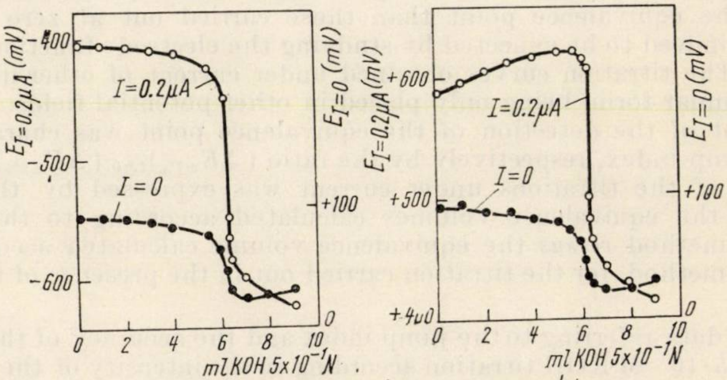

Fig. 6. — Titration of 10^{-1} HCl with 5×10^{-1} M KOH using "foil" membrane electrode.

a, cathodic polarization; *b*, anodic polarization.

The data of tables 3 and 4 show that the titrations under current have high accuracy. Excepting just one case, the recorded errors are under $\pm 0.15\%$. The variation of the potential around the equivalence point is much increased, the jump index having values between 2 and 3 for the "bubble" membrane-electrode, and between 5.4 and 6.8 for the "foil" membrane-electrode.

Table 3

Influence of current intensity upon precision and accuracy of 10^{-1} M HCl with 5×10^{-1} M KOH titration; "bubble" membrane electrode. For glass electrode $V_e = 6.22$ ml

I (μA)	Polarization	V_e(ml)	e(%)	$(\Delta E)_{\pm 1\%}$ (mV)	$\frac{(\Delta E_{\pm 1\%})_{I\neq 0}}{(\Delta E_{\pm 1\%})_{I=0}}$
0	anodic	6.23	+0.14	70	—
0.1	anodic	6.22	0.00	152	2.1
0.2	anodic	6.25	+0.46	172	2.4
0.3	anodic	6.21	−0.15	168	2.4
0.4	anodic	6.22	0.00	145	2.0
0.2	cathodic	6.22	0.00	212	3.0
0.4	cathodic	6.21	−0.15	195	2.8
0.6	cathodic	6.21	−0.15	181	2.6
0.8	cathodic	6.22	0.00	165	2.3

Table 4

Influence of current intensity upon precision and accuracy of 10^{-1} M HCl with 5×10^{-1} M KOH titration, "foil" membrane electrode. For glass electrode $V_e = 6.27$ ml

I(μA)	Polarization	V_e(ml)	e(%)	$\Delta E_{\pm 1\%}$(mV)	$\frac{(\Delta E_{\pm 1\%})_{I\neq 0}}{(\Delta E_{\pm 1\%})_{I=0}}$
0	—	6.28	+0.15	15	—
0.1	anodic	6.27	0.00	95	6.3
0.2	anodic	6.28	+0.15	102	6.8
0.3	anodic	6.28	+0.15	99	6.6
0.4	anodic	6.28	+0.15	98	6.5
0.6	anodic	6.28	+0.15	82	5.4
0.2	cathodic	6.28	+0.15	102	6.8
0.3	cathodic	6.28	+0.15	100	6.6
0.4	cathodic	6.27	0.00	95	6.3
0.6	cathodic	6.27	0.00	89	6.0

We have then studied the influence of the concentration on the magnitude of the potential jump around the equivalence point at the HCl with KOH titration under current, compared to the one at zero current. The titration curves obtained using the "foil" membrane-electrode are given in figure 7.

Table 5 gives the data of the equivalence volumes obtained at zero current and under current, as well as the data referring to the jump index for the respective titrations.

The results obtained while titrating at different concentrations using the "bubble" membrane-electrode were similar. From the titration curves in figure 7, as well as from the data in table 5, it results that by applyng

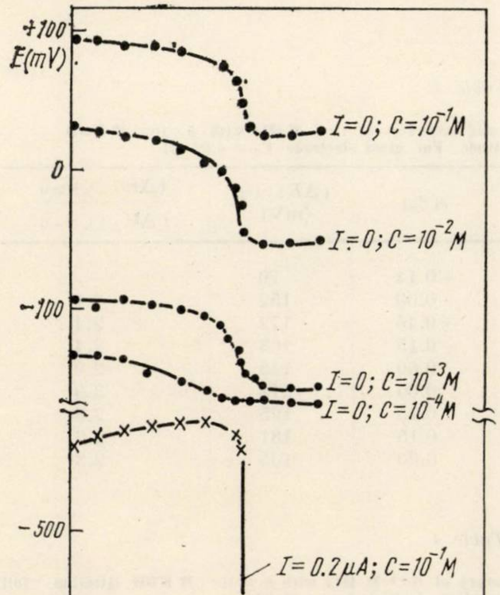

Fig. 7. — Influence of the applied current upon the HCl with KOH titration at different concentrations using "foil" membrane-electrode; cathodic polarization.

a 0.2 μA current to the membrane, the sensitivity of the latter towards the H^+ ions increases in such way as to allow a successful titration of the HCl even at a 10^{-4} M concentration.

Table 5

Results of HCl with KOH titration at different concentrations : "foil" membrane-electrode ; cathodic polarization

* error calculated towards V_e at $I = 0$

2.3. MEMBRANE-POTENTIAL-CURRENT STATIC CURVES

The membrane-potential-current static curves obtained for the "bubble" membrane-electrode using both polarization directions are given in figure 8.

The figure shows that in this case the following relationship stands for both test solutions :

$$E_m = a + bI$$

respectively :

$$\eta = a' + bI, \text{ where}: \eta = |E_{I \neq 0} - E_{I=0}|$$

We have also proceeded in the same way for the "foil" membrane-electrode. Also making use of both polarization directions and test solutions we have obtained the curves in figure 9. When 10^{-1} M KOH was used as test solution (figure 9, curve *2*), the $E_m - I$ curve took a linear form using a semi-logarithmical rendering : $\eta - \lg I$, hence being valid a relationship of the type:

$$\eta = A + B \lg I$$

3. DISCUSSION

By examining the current-membrane potential static curves for the studied membranes (figures 8 and 9) it results that, excepting the foil-membrane system, cathodically polarized and test solution KOH, all other systems behave as ohmic resistances in the whole studied potential filed. We can thus calculate the resistance of the system from the slopes of the respective curves obtained. The obtained results are given in table 6.

We notice that while the membrane resistance, measured in alternating[9] current is of approximately 2.17 × $10^5\ \Omega$, in direct current the

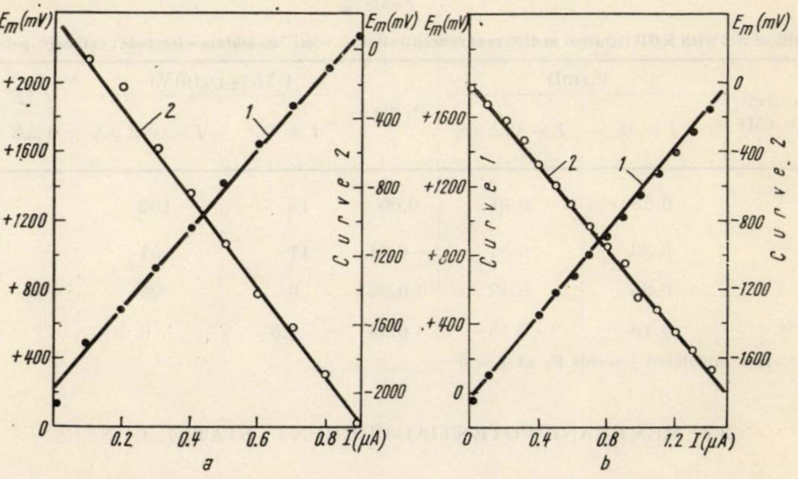

Fig. 8. — Membrane potential-current static curves for "bubble" membrane-electrode

a, test solution 10^{-1} M HCl; *1*, anodic polarization; *2*, cathodic polarization; *b*, test solution 10^{-1} M KOH; *1*, anodic polarization; *2*, cathodic polarization.

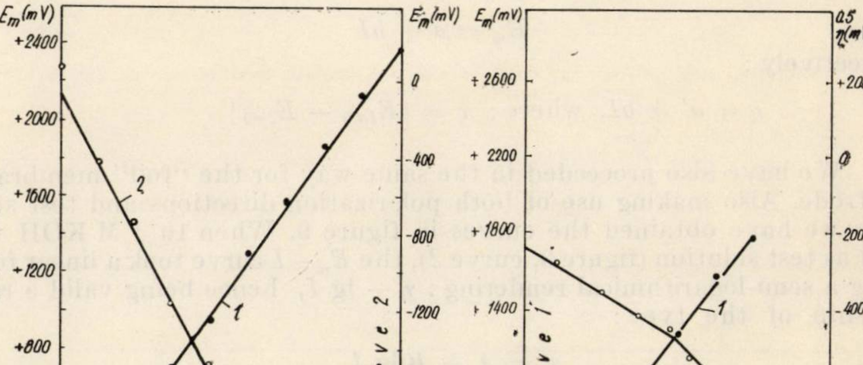

Fig. 9. — *a*) Membrane potential-current static curves for "foil" membrane-electrode. Test solution 10^{-1} M HCl.

1, anodic polarization; 2, cathodic polarization.

b) Membrane potential-current (*1*) and overvoltage — log *I*(*2*) curves for "foil" membrane-electrode. Test solution 10^{-1} M KOH.

1, anodic polarization; 2, cathodic polarization.

resistance of the system is approximately 10 times higher. The supplementary resistance appearing in these conditions is certainly due to a concentration polarization appearing in the layer of adjacent solutions on the two faces of the membrane. We meanwhile note that the resistances for the two polarization senses are not identical, as the solutions on the two faces of the membrane are not identical, either regarding the electrolyte or regarding the concentration.

Table 6

Electrical resistance of PVC + tricresylphosphate membrane calculated from the data of membrane potential-current curves

Membrane	Polarization	Test solution	Electrical resistance (Ω)
"Bubble" form	cathodic	HCl 10^{-1}M	2.64×10^6
	cathodic	KOH 10^{-1} M	1.24×10^6
	anodic	HCl 10^{-1}M	2.34×10^6
	anodic	KOH 10^{-1}M	1.21×10^6
"Foil" form	cathodic	HCl 10^{-1}M	3.60×10^6
	anodic	HCl 10^{-1}M	2.88×10^6
	anodic	KOH 10^{-1} M	2.61×10^6

For the "foil" membrane and the 10^{-1} M KOH test solution, in the case of cathodic polarization (figure 9, curve *2*), as shown, the relationship $\eta = A + B \lg I$; ($\eta > 0.1$V) is valid, which shows the installation in the working conditions of a concentration polarization.[11] In the working conditions, as $[OH^-]/[H^+] = 10^{13} = [Na^+]/[H^+]$, only a Na^+ transport through the membrane must practically take place. As in the $\eta - \lg I$ representation we obtain two curves with different slopes, we can suppose that the Na^+ ion transport takes place by two different mechanisms: directly, through the solution soaking the pores of the membrane, and by jumps, respectively by successive chelatization with the active component of the membrane (tricresylphosphate). This latter mechanism is in agreement with the fact that the membrane is also sensitive for the Na^+ ions[13] as well as with the decrease of the electrical resistance of the system with the increase of the pH (table 6).

By examining the electrode functions (figures 2 and 3) we notice that the behaviour of the membrane improves very much under current by extending its linearity field with the marked increase of the slope (tables 1 and 2). Meanwhile, a shifting of the standard potential of the electrode takes place. This is easily understood, taking into account, as shown above, that the system works as an electrical resistance, the passing of the current being meanwhile accompanied by a partial concentration polarization, which has as consequence the increase of the $(a_{H^+})_{ext}/(a_{H^+})_{int}$ ratio. Thus, for instance, in the case of a "bubble" membrane, at the anodic polarization with 10^{-1} M HCl test solution (figure 8, curve *1*), $R = 2.3$.

---

[13] C. LITEANU and E. HOPÎRTEAN, *Rev. Roumaine Chim.*, **16**, 559 (1971).

$\cdot 10^6\,\Omega$, so that for instance, for $I=0.1$ μA, there results through the ohmic effect $E = 230$ mV, respectively: $E_{I-0.1\mu\text{A}} = (E_{I=0} + 230)$ mV $= 304$ mV. Having obtained experimentally $E = 390$ mV, we assign the difference to the above mentioned concentration polarization effect, i.e.:

$$[(a_{\text{H}^+})_{\text{ext}}/(a_{\text{H}^+})_{\text{int}}]_{I\neq 0} > [(a_{\text{H}^+})_{\text{ext}}/(a_{\text{H}^+})_{\text{int}}]_{I=0}$$

The fact that electrode functions are improved under current, extending the pH field in which the slope of the electrode functions is markedly increased as compared to that at zero current (tables 1 and 2) suggests that the current has a favourable effect on the reversibility of the interface processes. Thus, the stability between the H^+ ion and tricresylphosphate being high enough, and, on the other hand, the tortuosity degree of the PVC matrix being also high, an intensitivity of the electrode towards high pH is reached by a blocking effect of the interface. The activity of the H^+ ions in the membrane thus remains superior to the one at equilibrium, so that the electrode function at zero current flattens out in an alkaline field. In the case of the membrane being under current, the H^+ ions being implied in the transport of the current through the membrane, their accumulation in the membrane phase will be prevented, having as consequence the extension of the linearity field of the electrode function.

This is confirmed by the memory effect noticed when interrupting the polarization current: the electrode potential does only slowly return to the value preceeding the polarization.

As the behaviour under current of the membrane is due to the two phenomena (ohmic effect and concentration polarization), the change of sign of the electrode function slope in the initial portion is the result of a competition between the two mentioned phenomena.

CONCLUSIONS

The application of a continuous and constant polarization current on the PVC-tricresylphosphate membrane-electrode has lead to the following important results:

— the E-pH electrode function in the case of the "bubble" electrode and especially in the case of the "foil" electrode was deeply changed by the broadening of the linearity field, the increase of the slope and the shifting of the standard potential, so that the electrode can also be used in direct potentiometry:

— the deep changes of the electrode functions under current, respectively the improvement of the electrode behaviour can be explained by the contribution of an ohmic effect as well as by the polarization concentration process at the membrane-solution interface;

— the potentiometric acid-base titrations carried out under current are characterized by a very good accuracy if compared to the glass electrode and by a substantial increase of the potential jump at the equivalence point, compared to the titration at zero current.

SPEKTROPHOTOMETRISCHE DOSIERUNG DES BENZIDINS UND *o*-TOLIDINS MIT NATRIUMHYPOCHLORIT

I. FLOREA

Technische Hochschule „Traian Vuia“, Timişoara.
Laboratorium für Allgemeine Chemie, Str. Remus 14.

Eingegangen am 31. Januar 1973

Es wird eine neue spektrophotometrische Methode für die Dosierung des Benzidins und *o*-Tolidins mit Natriumhypochlorit vorgeschlagen. Die gebildeten Verbindungen sind gelb-orange und weisen je ein Absorbtionsmaximum bei $\lambda =$ $= 429$ nm und $\lambda = 440$ nm auf. Die durchgeführten Bestimmungen zeigen, daß die Methode die Dosierung des Benzidins und des *o*-Tolidins mit Natriumhypochlorit zwischen den Grenzwerten 1—100 μg und 2—100 μg ermöglicht. Die Dosierung des Benzidins und *o*-Tolidins mit Natriumhypochlorit kann man in Gegenwart von *o, m, p*-Toluidin und β-Naphthylamin durchführen, während die Dosierung des Benzidins auch in Gegenwart von α-Naphthylamin möglich ist. Die Ergebnisse sind gut, die Empfindlichkeit der Methode ist bemerkenswert.

In zwei vorhergehenden Arbeiten [1,2] haben wir uns mit der spektrophotometrischen Dosierung des Benzidins und *o*-Tolidins mit Natriumhypochlorit beschäftigt. Die entstandenen gelb-orange Verbindungen wurden mit Chloroform extrahiert und es wurden die Extinktionen bei $\lambda = 443$ nm und $\lambda = 454$ nm gemessen. In der vorliegenden Arbeit bedienen wir und desselben Reagenzes bei der Dosierung des Benzidins und *o*-Tolidins in wäßrigem Medium.

In dieser Arbeit verfolgt man eine neue spektrophotometrische Methode für die Dosierung des Benzidins und *o*-Tolidins, wobei als Reagenz eine schwefelsaure Natriumhypochloritlösung verwendet wird. Der Methode liegt die Bildung gelb-orangefarbener Chinondiimine [3–7]

zugrunde, die man infolge der oxydierenden Wirkung des Natriumhypochlorits auf die Benzidin- und *o*-Tolidinlösungen erhält. Die entstandenen Verbindungen erlauben die Dosierung des Benzidins und *o*-Tolidins bei $\lambda = 429$ nm und $\lambda = 440$ nm. Die Methode empfiehlt sich für Benzidin- und *o*-Tolidinmengen zwischen 1—100 µg und 2—100 µg.

Benzidin und *o*-Tolidin können—in oben angeführten Quantitäten—mit Natriumhypochlorit in : a) Wässern, b) in Gegenwart von *o*-, *m*- und- *p*-Toluidin bis zu 40µg und c) in Gegenwart von bis zu 20 µg β-Naphthylamin dosiert werden. Benzidin kann auch in Gegenwart von bis zu 20 µg α-Naphthylamin dosiert werden. Benzidin und *o*-Tolidin können aber weder einer in Gegenwart des anderen, noch in Gegenwart von *o*-Dianisidin dosiert werden.

EXPERIMENTELLES

Gerätschaft

Besteht aus der in der vorhergehenden Arbeit verwendeten. [1,2]

Reagenzien

a) Die Benzidinlösung. — In einem 100 ml Meßkolben löst man 0,0100 g reines Benzidin in 10 ml Eisessig auf und füllt mit Wasser bis zur Marke nach. 1 ml Lösung enthält 0,1 mg Benzidin.

b) Die *o*-Tolidinlösung stellt man auf dieselbe Weise — wie die Benzidinlösung—her.

c) Die Benzidin- und *o*-Tolidinlösungen der Konzentration 0,01 mg/ml werden durch Verdünnen bis zu 200 ml von 20 ml a - bzw. b-Lösung mit 10%-ger Essigsäure zubereitet.

d) Die 0,01 %-ge *o*-, *m*- und *p*-Toluidinlösungen sowie die α- und β-Naphthylaminlösungen wurden aus abgewogenen reinen Substanzen präpariert. 1 ml Lösung enthält 0,1 mg Substanz. In den der Analyse unterworfenen Proben wurden mit Volumen zwischen 0,1—0,4 ml im Falle des *o*-, *m*- und *p*-Toluidins, und zwischen 0,1—0,2 ml im Falle des α- und β-Naphthylamin, gearbeitet. [1,2]

e) Die Natriumhypochloritlösung wird auf derselben Weise, wie in den vorhergehenden Arbeiten, hergestellt.[1,2]

ARBEITSWEISE

Mit einer Mikrobürette werden 0,1—1,0 ml a-Lösung bzw. 0,1—1,0 ml c-Lösung, welche zwischen 1—100 µg Benzidin enthalten, und 0,1—1,0 ml b-Lösung bzw., 0.2—1,0 ml c-Lösung, welche zwischen 2—100 µg *o*-Tolidin enthalten, abgemessen und in einen 25 ml Meßkolben eingeführt. Man gibt je 10 molare Schwefelsäure und 2 ml Natriumhypochloritlösung für Benzidin bzw. 2,5 ml für *o*-Tolidin dazu, schüttelt durch und ergänzt mit 10 molarer Schwefelsäure bis zu 25 ml. Nach 10 Minuten mißt man die Extinktion für Benzidin und *o*-Tolidin, bei $\lambda = 429$ nm und $\lambda = 400$ nm.Als Blindpiobe diente Wasser.

ERGEBNISSE UND DISKUSSIONEN

DAS ABSORBTIONSPEKTRUM

Die Absorbtionskurven der durch Vermengen der Benzidin bzw. *o*-Tolidinlösungen mit der Natriumhypochloritlösung entstandenen Verbindungen sind in Abb. 1 dargestellt und weisen je ein Absorbtionsmaximum für Benzidin und *o*-Tolidin auf, bei λ = 429 nm und λ = 440 nm. Die gebildeten Verbindungen eignen sich zur spektrophotometrischen Dosierung des Benzidins und *o*-Tolidins. Die Dosierung ist vorzugsweise für Dosierungen aus Amingemischen empfohlen, da Benzidin und *o*-Tolidin in Gegenwart von *o*-, *m*-, *p*-Toluidin und β-Naphthylamin und Benzidin auch in Gegenwart von α-Naphthylamin in den oben angegebenen Quantitäten- dosiert werden können.

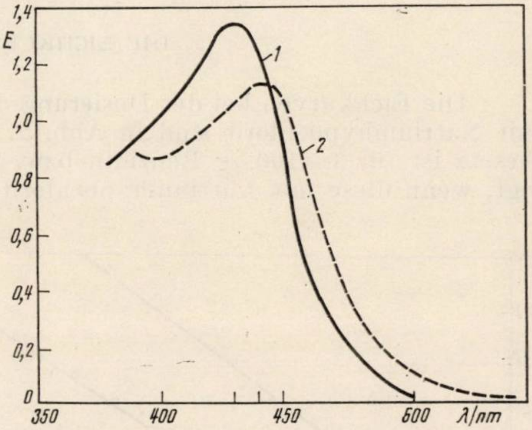

Abb. 1. — Das Absorbtionsspektrum der gebildeten Verbindungen, bei Benützung der 1 cm-Küvette.

1. 1 ml Benzidinlösung a + 10 ml molare Schwefelsäure + 2 ml Natriumhypochloritlösung e + 10 molare Schwefelsäure bis zu 25 ml Volumen. *2,* 1 ml *o*-Tolindinlösung b 10 ml 10 molare Schwefelsäure + 2,5 ml Natriumhypochloritlösung e + 10 molare Schwefelsäure bis zu 25 ml Volumen.

EINFLUSS DER ZEIT

Die Farbenbeständigkeit der sich infolge der Oxydation des Benzidins und des *o*-Tolidins durch die saure Natriumhypochloritlösung bildenden Verbindungen wurde binnen 60 Minuten verfolgt, wobei die Extinktionen bei λ = 429 nm und bei λ = 440 abgelesen wurden. Aus den erhaltenen Ergebnissen ist folgendes feststellbar: die Farbenbeständigkeit wird für beide Substanzen in 5—10 Minuten erreicht. Die aus Benzidin und Natriumhypochlorit bestehende Verbindung ist 40—50 Minuten lang beständig, während jene aus *o*-Tolidin und Natriumhypochlorit 25—30 Minuten lang beständig ist.

EINFLUSS DER REAGENZIENKONZENTRATION

Die optimalen, für die Dosierung der oben angegebenen Benzidin- und *o*-Tolidinquantitäten erforderliche Natriumhypochloritmengen sind 2—2,5 ml bzw. 2,5—3 ml. Innerhalb dieser Intervalle verhalten sich die

Extinktionswerte der entstehenden Verbindungen konstant, angenommen man geht von derselben Benzidin- bzw. *o*-Tolidinmenge aus.

EINFLUSS DER SCHWEFELSÄUREKONZENTRATION

Die Konzentration der Schwefelsäure spielt eine sehr wichtige Rolle bei der Farbenbeständigkeit der Verbindungen, die infolge der Reaktion zwischen Benzidin und *o*-Tolidin und Natriumphypochlorit entstanden sind. Aus den Extinktionsmessungen dieser Verbindungen—bei verschiedenen Molaritäten der Schwefelsäurekonzentration—geht hervor, daß die Beständigkeit der Farbe dieser Verbindungen aus Benzidin und *o*-Tolidin ihre Höchstwerte in 10 molarer Schwefelsäure erreicht.

DIE EICHKURVEN

Die Eichkurven bei der Dosierung des Benzidins und des *o*-Tolidins mit Natriumhypochlorit sind in Abb. 2. veranschaulicht. Das Beer'sche Gesetz ist für 1—100 μg Benzidin bzw. 2—100 μg *o*-Tolidin berücksichtigt, wenn diese mit Natriumhypochlorit versetzt werden.

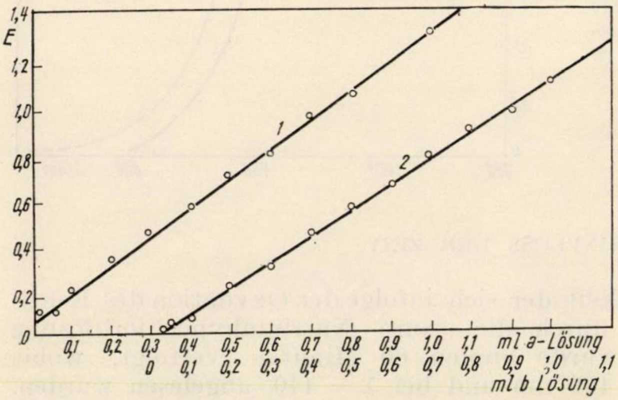

Abb. 2. — Die Absorbtionskurven.

1. Die Benzidinproben, jeweils mit 2 ml Natriumhypochlorit in 10 molarem schwefelsaurem Medium behandelt. *2.* Die *o*-Tolidinproben; jeweils mit 2,5 ml Natriumhypochlorit in 10 molarem schwefelsaurem Medium behandelt.

Die experimentellen Ergebnisse sind in den Tabellen 1 und 2 zusammengefaßt.

Die in den Tabellen 1 und 2 verzeichneten Ergebnisse bezeugen, daß Benzidin und *o*-Tolidin in Gegenwart von *o*-, *m*- und *p*-Toluidin bis zu 40 μg und β-Naphthylamin bis zu 20 μg dosiert werden können; Benzidin sogar in Gegenwart von bis zu 20 μg α-Naphthylamin.

Im Vergleich zur Chloramin T-Methode, die meist gebräuchliche Dosierungsmethode des Benzidins aus den Abwässern, welch letztere man—wegen der Farbenunbeständigkeit bei Licht— in so kurzer Zeit als nur möglich bei schwachem, diffusen Licht durchführen muß oder man vergleicht die aus Chloroform extrahierte Probe mit einer Kalium-

bichromat-Standardlösung, bietet die neue Methode nachstehend angeführte Vorteile:

a) die bequeme, bei gewöhnlichem Licht durchgeführte Dosierung des Benzidins mit Natriumhypochlorit, dank der verhältnismäßig großen Farbenbeständigkeit der entstanden Verbindungen, ohne die oben angeführten Vorsichtsmaßnahmen berücksichtigen zu müssen:

b) Beseitigung der Chloroformextraktion der gebildeten Verbindung;

c) die in einem größeren Maßstab zu erfolgende direkte Dosierung des Benzidin, u. zw. zwischen 1—100 µg, gegenüber 1—50 µg im Falle der Chloramin T-Methode.

Zusätzlich bietet die Arbeit eine neue sehr empfindliche spektrophotometrische Dosierungsmethode des *o*-Tolidins. *o*-Dianisidin kann auf diesem Weg nicht dosiert werden.

NOTE POUR LES AUTEURS

La *Revue Roumaine de Chimie* publie des articles en anglais, français, russe, allemand ou espagnol. Les auteurs sont priés d'envoyer des articles, notes, communications et comptes rendus inédits.

Les manuscrits seront dactylographiés à deux intervalles. Les tableaux seront dactylographiés sur feuilles séparées, de même que la légende des figures. Les diagrammes seront tracés à l'encre de Chine sur papier calque. Les tableaux et les figures seront numérotés par des chiffres arabes, en nombre strictement nécessaire. Prière de ne pas inscrire les mêmes données dans les tableaux et les figures. Les formules chimiques seront incluses dans le texte ; en outre, elles seront transcrites sur des feuilles séparées. Les auteurs sont priés d'indiquer les caractères italiques (en soulignant les lettres au crayon), ainsi que tout autre caractère spécial. L'ordre des références bibliographiques sera celui de leur mention dans le texte ; le nom de l'auteur sera précédé de l'initiale du prénom ; les publications périodiques seront présentées suivant les prescriptions internationales. Les références seront ajoutées à la fin de l'article ; elles paraîtront comme des notes, au bas de la page. Le texte sera précédé d'un résumé, comprenant 15 lignes au maximum.

L'entière responsabilité du contenu des articles appartient aux auteurs. On publie des articles dus aux collaborateurs roumains ou étrangers. Les auteurs recevront 50 tirés à part.

SPECTROGRAPHIC DETERMINATION OF TRACES OF COPPER, LEAD, CHROMIUM, NICKEL, MOLYBDENUM AND COBALT IN NATURAL WATERS

V. EM. SAHINI, MARGARETA CRAIU and EUGENIA IVANA
Centre of Physical Chemistry, str. Galaţi 31, Bucharest, Romania

Received September 28, 1973

The traces of copper, lead, chromium, nickel, molybdenum and cobalt were determined spectrographically by the carrier distillation method in natural waters. Natrium chloride, cesium chloride and a mixture of natrium chloride and silver fluoride were utilized as carriers.

The trace elements play an important role in life systems and are the constituents of natural waters that vary to a large extent. The concentration variations of trace elements reflect the interactions taking place in water. Many elements are taken in by plants or animals and after their death and decomposition they return in the water circuit.

In the selection of analysis technique[1] there are some limitations; some elements that must be quantitatively determined are very hardly examined because of their unknown distribution. The amounts of sample available are small. The elements exist in a complex matrix that varies as a function of the major and trace elements present. The sample must be accurately prepared owing to the inhomogeneous nature of the materials. These facts favour the choice of the spectral method for the determination of elements in water in a d.c. arc, by the carrier distillation method.[2]

The literature referring to spectrographic and spectrophotometric analysis of natural waters is not too rich. Thompson[3] utilized the spectrographic method for the determination of trace and major elements in ocean or sea water and in marine sediments. Most of the papers refer to the spectrographic and spectrophotometric determination in soils and extracts of soils, sediments, plants and extracts of plants.[4–9]

Some papers are related to the study of the influence of various carriers on trace elements evaporation from the analysed samples and to the way in which this evaporation proceeds in the arc plasma.[10] Various metal halides and combinations of these halides in various ratios were used to find the best carrier for a given matrix.

In our analyses of natural waters, three carriers were finally chosen out from several, which would be mentioned in the experimental part of the paper. These carriers have given the best results.

In this paper a method is presented for the determination of six trace elements in drinking and river water.

EXPERIMENTAL PART

STANDARDS AND CALIBRATION CURVES

The standards were prepared from high purity salts and oxides. The respective salts and oxides were diluted with SU 609 Elektrokarbon Topolcany graphite powder. First, a 1 % solution of each element in graphite powder was prepared; by successive dilutions the necessary concentration standards were obtained. To each standard the carrier was added, and to homogenized mixture of standard and carrier, the internal standard solution of $Zr(NO_3)_4 . 5H_2O$ in water was added (10 μg Zr/ml). The standards were dried at 150°. 12—13 mg of standard mixture were introduced in the anode crater of a d.c. arc and the samples were excited in the following conditions:

- d.c. arc obtained from an ABR—3 Carl Zeiss Jena generator
- graphite electrodes of high purity (SU 113 Czechoslovak — Ceramics) — anode $\Phi = 5$ mm with crater $\Phi\ 3 \times 3.5$ mm; cathode, conic shape 60°)
- analytical gap: 4 mm
- carriers: NaCl, CsCl, Ag F + NaCl (1 : 4)
- current: 9 A
- exposure time: 60 sec for copper and lead; 120—150 sec for the other metals
- spectrograph: PGS-2 Carl Zeiss Jena
- grating: 650 lines/mm; linear dispersion: 7.4 Å/mm; first order
- slit: 15 μ
- plates: ORWO, WO_3 and WU_3
- analytical lines: Cu: 3272.9 Å; Mo: 3170.3 Å; Ni: 3414.7 Å; Pb: 2833.06 Å Co: 3405.1 Å and 3453.5 Å; Cr: 4254.3 Å and 4274.8 Å
- internal standard lines: Zr: 2571.39 Å; 3391.98 Å, 3991.13 Å

The line blackening was measured photometrically and intensity corrected using calibration curves of the plates for each spectral range and type of plate.

The analytical curves were obtained by plotting log $(I_{\text{element}}/I_{\text{Zr}})$ *vs.*log C (ppm), where I_{element} is the line intensity for the element, read from the calibration curve of the plate, I_{Zr} is the intensity of the Zr line used as internal standard, and C is the concentration of the element in ppm. In table 1 the lower detection limits for the elements (in ppm) are given.

---

[10] B. Strzyzewska, *Spectrochim. Acta, Part B*, **27**, 227 (1972).

Table 1

The lower detection limits for the elements

Element	Lower detection limit (ppm)	Relative error %
Copper	0.10	10
Molybdenum	0.01	40
Nickel	0.05	40
Lead	0.05	10
Cobalt	1.00	10
Chromium	0.03	14

THE SAMPLES

The results of the determinations of trace elements were reported to the residue obtained for 1 liter of water. The residue was obtained by slow evaporation of water extended over several days, in silica glass vessels, taking care to prevent contamination of the sample during this time. After evaporation and drying at a temperature above 150°, the residue was mixed with carrier in the ratio 6 : 1, and the obtained mixture with graphite powder type SU 609 in the ratio 1 : 1. The internal standard solution was added to the sample and this was dried at 130°. In this way were obtained the samples that were excited in the same conditions as the standards.

The concentrations Z of the element per liter of water (in mg/) were obtained from the formula:

$$Z(\text{mg element/l}) = \frac{PXA}{B} \cdot 10^{-6}$$

where

B is the weight of the residue in the sample studied (in mg)

P is formed from B and an equal quantity of graphite powder

A is the weight of the residue per liter of water (mg/l)

X is the concentration of the element in mg per 100 mg sample ($X = x_{\text{ppm}} \cdot 10^4$)

x is read on the analytical curve.

The method may be extended to the determination of the other trace elements.

Acknowledgements. We wish to express our gratitude to M. Mihăilescu for help with the experimental determinations and R. Beldie and A. Butucelea for interesting discussions related with the studied problems.

LES TENSIONS SUPERFICIELLES DES FLUIDES

N. BĂRBULESCU

Faculté de Physique, Université de Bucarest

Reçu le 31 août 1973

Les phénomènes superficiels sont caractéristiques pour tous les fluides, non seulement pour les liquides ; les gaz réels et les vapeurs présentent aussi de tels phénomènes. Dans l'étude des fluides on doit introduire trois tensions superficielles, non seulement une, comme on le fait couramment. Au point critique ce n'est que la tension interfaciale liquide/vapeur qui s'annule, tandis que la tension superficielle propre du liquide présente une valeur finie. Avec ces trois tensions superficielles on obtient trois équations d'état pour les couches périphériques des fluides.

Dans la physique on considère encore pour les fluides une seule tension superficielle : la tension superficielle des liquides. Van der Waals [1] a été le premier qui a relevé l'existence d'une seconde tension superficielle des fluides : la tension superficielle des gaz. Malheureusement, cette dernière grandeur n'a pas eu la chance d'être étudiée dès le commencement, de sorte qu'elle a été complètement oubliée pour une longue période de temps.

LA TENSION SUPERFICIELLE DE GAZ (VAPEURS)

La tension superficielle est une notion parfaitement intelligible pour les membranes élastiques, de même que pour les liquides. Les gaz ayant une très grande expansibilité on a pu croire que ces fluides n'ont pas une tension superficielle. D'autre part, les physiciens ont relié toujours l'existence de la tension superficielle à la présence d'une surface libre, comme c'est le cas des liquides. Les gaz, n'ayant pas une surface libre, on a décrété qu'ils ne pouvaient avoir une tension superficielle.

Mais la surface libre n'est pas une condition *sine qua non* de l'existence d'une tension superficielle chez les fluides, car, en réalité, une telle surface n'existe même pas pour les liquides. Elle est une simple apparence, due à l'imperfection de nos sens et a, naturellement, la même réalité que la voûte céleste. Les liquides n'ont pas une surface libre, mais une « couche périphérique » (*couche de passage* de Laplace), qui fait la transition entre le liquide et sa vapeur. La propriété principale de cette couche périphérique est d'exercer la pression interne ; comme les gaz réels ont aussi une pression interne, il s'ensuit que ces fluides possèdent de même une couche périphérique.

---

[1] J. D. Van der Waals, « La continuité des états gazeux et liquides », traduit par Dommer et Pomey, Paris.

On peut donc affirmer que *la tension superficielle des fluides n'est pas conditionnée par une surface libre, mais par la couche périphérique, qui produit la pression interne.* Ce que nous appelons tension superficielle d'un fluide n'est que la tension périphérique par laquelle le volume du fluide tend à posséder une couche périphérique minimale.

L'existence de la tension superficielle des gaz peut être encore soutenue à l'aide du principe de la continuité des états (Andrews). D'après ce principe, l'état gazeux et l'état liquide sont simplement deux termes éloignés d'une série continue d'états. Il est donc possible de passer de l'état liquide à l'état gazeux d'une manière continue, le fluide restant parfaitement homogène. Par conséquent, tous les paramètres d'état, utilisés dans l'étude des liquides, doivent être valables aussi dans l'étude des gaz, ce qui signifie que la tension superficielle, définie pour l'état liquide, doit être de même un paramètre d'état pour les gaz.

D'ailleurs, van der Waals a soutenu l'existence de la tension superficielle des gaz en se basant précisément sur ce principe de la continuité des états. Dans le travail : *La continuité des états gazeux et liquides*, en discutant la tension superficielle des liquides, van der Waals écrit : « Nous rappelons seulement les surprenantes expériences, récemment exécutées par Bosscha, qui révèlent la présence de cette tension dans des cas où on ne l'avait même pas soupçonnée. Nous verrons plus tard qu'elle n'existe pas seulement dans les liquides, mais encore dans tous les gaz ». Et il dit plus loin : « Il résulte des expériences de Bosscha que la tension de la fumée de tabac, et probablement aussi celle de la vapeur d'eau à l'état de brouillard, est assez grande pour provoquer des phénomènes capillaires. Il est vrai que ce ne sont pas là de véritables vapeurs ; mais, malgré cela, il faut regarder ces expériences comme d'importants soutiens de la théorie ici développée d'après laquelle il n'y a pas de différence qualitative entre les états d'agrégation des liquides et des vapeurs ».

Cette justification phénoménologique de la tension superficielle des gaz peut être complétée par des considérations physico-mathématiques.[2] En vérité, partons de la formule de Laplace, qui exprime la relation entre la pression interne P et la tension superficielle σ d'un ménisque liquide :

$$P = K^{\pm} \sigma\left(\frac{1}{R_1} + \frac{1}{R_2}\right)$$

où R_1 et R_2 sont les rayons principaux de courbure du ménisque, K étant la pression interne de la couche périphérique plane du même liquide. Du fait que, conformément au principe de la continuité des états, il n'existe pas une différence qualitative entre le liquide et le gaz, il s'ensuit que *la formule de Laplace peut être appliquée aussi aux gaz, c'est-à-dire*

---

[2] N. Bărbulescu, *Physik. Z.*, **31**, 48 (1930).

qu'elle convient à tous les fluides, quels que soient leurs états d'agrégation. Donc, la tension superficielle σ, figurant dans cette formule, exprime une réalité physique aussi pour les gaz (vapeurs).

Passons maintenant au calcul de la tension superficielle des gaz, dans le cas spécial de vapeurs saturantes. Considérons un tube capillaire introduit dans un liquide, qui monte dans ce tube jusqu'à la hauteur h au-dessus du niveau du liquide extérieur. La pression p des vapeurs saturantes, au-dessus du ménisque concave de la colonne capillaire, est liée à la pression interne P_v de ces vapeurs par la relation :

$$p = p_i - P_v \tag{1}$$

où p_i — est la pression du gaz idéal, correspondant aux vapeurs considérées. Le ménisque concave du liquide est en contact avec le ménisque convexe de la vapeur saturante, auquel nous pouvons appliquer la formule de Laplace :

$$P_v = K_v + \frac{2\sigma_v}{R} \tag{2}$$

où σ_v — est la tension superficielle de la vapeur saturante et R — le rayon du ménisque sphérique.

Au niveau plan du liquide extérieur, la pression de la vapeur saturante est p_0 et nous avons de même :

$$p_0 = p_i - K_v \tag{3}$$

De (1) et (3) on déduit :

$$p_0 - p = P_v - K_v \tag{4}$$

D'autre part, en tenant compte de l'effet Kelvin, d'après lequel la pression p de la vapeur saturante au-dessus du ménisque capillaire est égale à la pression de la vapeur extérieure, au niveau même de ce ménisque, on a

$$p_0 = p + h\,\rho_v g \tag{5}$$

où ρ_v — est la densité de la vapeur saturante. Introduisant en (4) les expressions (2) et (5), on obtient :

$$\sigma_v = \frac{1}{2} Rh\,\rho_v g \tag{6}$$

formule qui nous permet de calculer la tension superficielle de la vapeur saturante, en déterminant l'ascension capillaire du liquide respectif, autrement dit, la position dans le tube capillaire du ménisque convexe de la vapeur saturante. A l'aide des données expérimentales de Ramsay et Shields [3] nous avons calculé la tension superficielle σ_v de quelques substances organiques, pour diverses températures, jusqu'à proximité de la température critique. Les résultats sont inscrits dans le tableau 1.

On constate que, pour les températures ordinaires, la tension superficielle σ_v est très petite, étant de l'ordre 10^{-2} dyn/cm. Elle croît avec la température pour devenir, près de la température critique, comparable à la tension interfaciale σ_i du liquide respectif. Par exemple, la tension interfaciale de l'éther éthylique liquide est de 0,16 dyn/cm à 190° ; à cette température, la vapeur saturante respective a une tension superficielle de 0,12 dyn/cm.

On constate, de même, que la tension superficielle σ_v présente un maximum au voisinage du point critique. La température réduite de ce maximum est approximativement la même 0,91 pour toutes les substances. On peut expliquer l'existence de ce maximum, sachant que la tension superficielle diminue avec l'augmentation de la température, mais elle croît avec la densité. Pour les températures moyennes, l'effet de la densité dépasse celui de la température, de sorte que la tension superficielle de la vapeur saturante croît jusqu'à une température pour laquelle ces deux effets se compensent. Ensuite, l'effet de la température dépasse celui de la densité et la tension superficielle de la vapeur saturante commence à diminuer.

Shereshefsky [4] a établi la formule :

$$\frac{\mathrm{d} \log \rho_v}{\mathrm{d}T} = \frac{0{,}4343}{T_c(1 - T_m/T_c)} \tag{7}$$

qui permet de calculer la température T_m pour laquelle la tension superficielle σ_v présente un maximum. Dans cette formule T_c représente la température critique absolue. Shereshefsky a appliqué cette formule à 19 composés, en retrouvant pour la température réduite la valeur moyenne 0,91. En mettant la relation (7) sous la forme :

$$\frac{\mathrm{d} \ln \rho_v}{\mathrm{d} \ln T} = \frac{T_m/T_c}{(1 - T_m/T_c)} = 10{,}1$$

Shereshefsky a déduit que, dans le système des coordonnées ($\ln \rho_v$, $\ln T$), la pente de la courbe au point T_m est une constante universelle.

Shereshefsky [5] a obtenu, de même, une formule qui donne la variation de la tension superficielle σ_v avec la température :

$$v = \frac{T_c \Delta}{\rho_c^{1/3} \mu^{2/3}} (1 - T/T_c)^{0 \cdot 9} \rho_v$$

---

[3] W. Ramsay et J. Shields, *Z. phys. Chem.*, **12**, 433 (1893).

[4] L. J. Shereshefsky, *J. Phys. Chem.*, **34**, 1947 (1930).

[5] L. J. Shereshefsky, *J. Phys. Chem.*, **35**, 1712 (1931).

où μ — est la masse moléculaire et Δ — une constante ayant la même valeur pour tous les liquides normaux. Cette formule donne de bons résultats pour les températures éloignées du point critique ; pour ce point, la formule indique $\sigma_c = 0$, ce qui ne correspond pas à la réalité, car, à la température critique le fluide, ayant une pression interne, doit avoir aussi une tension superficielle.

Une formule plus exacte que celle de Shereshefsky est la suivante :

$$\sigma_v = \frac{A(\tau + c)^m}{1 + K\tau^p \rho_v^{-1} \exp\left(-\frac{r}{\tau}\right)}$$

où $\tau = t_c - t$ et A, c, m, K, p, r — sont des constantes empiriques. Pour les températures éloignées du point critique, cette formule se réduit à celle de Shereshefsky. Elle permet de calculer la tension superficielle des fluides σ_c point critique, en retrouvant les valeurs obtenues par d'autres voies.

LA TENSION INTERFACIALE LIQUIDE/VAPEUR

C'est la tension superficielle σ_v de la vapeur saturante qui détermine une tension interfaciale σ_i au contact liquide/vapeur. Ce que l'on mesure par les méthodes de laboratoire ce n'est pas la tension superficielle propre (absolue) σ_l du liquide, mais cette tension interfaciale σ_i.

Par la méthode de l'ascension capillaire, Ramsay et Shields[3] ont effectué les premières déterminations rigoureuses de cette grandeur, en utilisant la formule :

$$\sigma_i = \frac{1}{2} Rhg(\rho_l - \rho_v)$$

où ρ_l — est la densité du liquide en contact avec ses vapeurs de densité ρ_v. Cette tension interfaciale diminue avec l'augmentation de la température, pour s'annuler au point critique, quand $\rho_l = \rho_v$.

Van der Waals[7] a établi la formule qui représente la variation de cette tension avec la température :

$$\sigma_i = A\left(\frac{\rho_c}{\mu}\right)^{2/3} T_c \, \varphi(t_r)$$

[6] N. Bărbulescu, *Anal. Univ. Buc.*, **15**, 9 (1966).

[7] D. J. Van der Waals, *Z. phys. Chem.*, **13**, 695 (1894).

où $t_r = T/T_c$, A — est une constante universelle et φ — une fonction universelle. Au voisinage du point critique, on a, d'après Van der Waals : $\varphi(t_r) = (1 - t_r)^{3/2}$: mais les valeurs expérimentales sont mieux représentées par la formule générale :

$$\sigma_i = K\tau^n \tag{8}$$

où K et n — sont des constantes empiriques, dépendant de la nature du liquide et ayant des valeurs qui ne diffèrent pas trop entre elles.

Toutefois, la dépendance de température de la tension interfaciale σ_i est plus compliquée. Elle peut être représentée par la formule :

$$\sigma_i = K\tau^n \, e^{-\frac{d}{\tau}}$$

où K, n et d — sont des constantes empiriques.[8]

LA TENSION SUPERFICIELLE ABSOLUE (PROPRE) DES LIQUIDES

Pour un système de deux phases en contact, on doit considérer trois tensions superficielles : chaque phase a sa tension superficielle propre et, au contact des deux phases, il y a une tension interfaciale.

Pour le système liquide/vapeur, les tensions superficielles propres qui interviennent sont σ_v, σ_i et de même la tension superficiale propre (absolue) du liquide. Cette dernière grandeur a été longtemps négligée, étant confondue avec la tension interfaciale. Il est vrai que, pour les températures ordinaires, la différence entre ces tensions est négligeable, mais devient notable pour les températures près du point critique (tableau 1).

Pour connaître la tension superficielle absolue σ_l d'un liquide, considérons d'abord un système composé de trois phases en équilibre superficiel. Soient σ_1 et σ_2 les tensions superficielles respectives de deux phases en contact avec la troisième. Désignons par σ_{12} la tension interfaciale entre ces deux phases. La condition d'équilibre est :

$$\sigma_1^2 = \sigma_{12}^2 + \sigma_2^2 + 2\sigma_{12}\,\sigma_2 \cos \beta$$

où β — est l'angle des vecteurs $\vec{\sigma}_{12}$ et $\vec{\sigma}_2$. Pour une surface plane de contact entre les phases, l'ongle β est nul et on a :

$$\sigma_{12} = \sigma_1 - \sigma_2$$

C'est le cas du système liquide/vapeur, pour lequel nous pouvons écrire :

$$\sigma_i = \sigma_l - \sigma_v \tag{9}$$

---

c'est-à-dire, *la tension interfaciale liquide/vapeur est la différence entre les tensions superficielles respectives du liquide et de sa valeur saturante.* En introduisant ici les expressions établies plus haut pour σ_i et σ_v, on obtient :

$$\sigma_l = \frac{1}{2} Rh \, \rho_l g \tag{10}$$

formule qui permet de calculer la tension superficielle absolue d'un liquide, si l'on connaît son ascension capillaire.[9] On a, de même, la formule

$$\sigma_l = \sigma_i \frac{\rho_l}{\rho_l - \rho_v}$$

à l'aide de laquelle nous avons calculé les valeurs de σ_l (tableau 1), en utilisant les données expérimentales de Ramsay-Shields.

On obtient une autre relation entre σ_l et σ_i par les considérations suivantes. [2] Pour augmenter l'aire A de la couche périphérique d'un liquide, quand on passe de la tension interfaciale σ_i à la tension superficielle absolue σ_l, on doit dépenser le travail :

$$L = -\int_{\sigma_i}^{\sigma_l} \sigma \mathrm{d}A$$

Pour une transformation isotherme, on a :

$$\sigma A = k\tau$$

où les lettres ont les significations connues. On obtient d'ici :

$$\sigma \mathrm{d}A = -k\tau \frac{\mathrm{d}\sigma}{\sigma}$$

et en intégrant :

$$\sigma_i = \sigma_l \, \mathrm{e}^{-\frac{\mathrm{d}}{\tau}} \tag{11}$$

L'expérience vérifie très bien cette formule, d étant indépendant de la température et ayant approximativement la même valeur pour tous les liquides normaux.

La variation avec la température de la tension superficielle absolue σ_l est très bien représentée par la formule :

$$\sigma_l = A\,(\tau + c)^n \tag{12}$$

---

[9] N. Bărbulescu, *J. Chim. Phys.*, **56**, 185 (1959).

où A, c et n – sont des constantes empiriques.[9] Cette formule si simple donne des résultats parfaitement corrects aux températures, pour lesquelles Ramsay et Shields ont réussi à mesurer la tension interfaciale σ_i. C'est pourquoi nous avons appliqué cette formule même au point critique, pour calculer la nouvelle constante critique σ_c, qui est de l'ordre 10^{-2} dyn/cm. Cette constante critique peut être calculée aussi par la formule :

$$P_c = 10^{-3} \frac{\sigma_c}{D} \tag{13}$$

où P_c – est la pression interne (atm) au point critique, calculée à l'aide de la constante a de van der Waals et D – est le diamètre moléculaire (cm).[9] C'est une formule analogue à celle établie pour les liquides et perfectionnée [10] sous la forme :

$$P = \pi \frac{\sigma}{D}$$

L'existence de cette constante critique infirme complètement l'affirmation que l'on trouve encore dans les publications de physique, d'après laquelle la tension superficielle des liquides s'annule au point critique. C'est seulement la tension interfaciale σ_i qui s'annule au point critique ; au contraire, la tension superficielle propre σ_l conserve une valeur finie, égale à celle des vapeurs saturantes.

LES ÉQUATIONS D'ÉTAT DE LA COUCHE PÉRIPHÉRIQUE DES FLUIDES

La physique connaît depuis un siècle l'équation d'état de la surface liquide, obtenue pour la première fois par Eötvös [11] et vérifiée expérimentalement par Ramsay-Shields [3] :

$$\sigma V_{\mu}^{2/3} = k(t_c - t - d)$$

où V_{μ} – est le volume molaire du liquide. Ostwald a donné à l'expression $\sigma V_{\mu}^{2/3}$ le nom d'*énergie superficielle moléculaire.* D'après Born et Courant [12] la formule d'Eötvös représente *l'équation d'état de la surface liquide.*

On considère aujourd'hui seulement cette équation d'état pour la surface d'un liquide. Mais les résultats précédents imposent trois équations d'état, correspondant aux trois tensions superficielles que nous avons définies plus haut.

1) La formule d'Eötvös exprime en réalité *l'équation d'état de l'interface liquide/vapeur*. Elle a été obtenue en partant du fait expérimental,

---

[10] N. Bărbulescu, *Bull. Soc. Sciences Cluj*, **8**, 462 (1936).

[11] R. Eötvös, *Wied. Ann.*, **27**, 448 (1886).

[12] M. Born et R. Courant, *Physik. Z.*, **14**, 731 (1913).

que le coefficient de température de l'expression $\sigma_i V_\mu^{2/3}$ est une constante, la même pour tous les liquides normaux :

$$\frac{\mathrm{d}}{\mathrm{d}t}(\sigma_i V_\mu^{2/3}) = -k$$

Comme l'expression $\sigma_i V_\mu^{2/3}$ s'annule au point critique, on obtient par l'intégration :

$$\sigma_i V_\mu^{2/3} = k(t_c - t) \tag{14}$$

formule qui ne contient pas la constante *d*, contrairement à celle vérifiée par l'expérience. Ce désaccord entre la théorie et l'expérience a subsisté longtemps, car il été impossible d'élucider la nature de la constante *d*.

Le problème de la constante *d* se résout d'une manière très simple [2], si nous partons de l'équation d'état de la couche périphérique du liquide, que nous avons obtenue et dans laquelle nous négligeons, dans une première approximation, la constante ω

$$\sigma_l V_\mu^{2/3} = k\tau$$

Combinant cette formule avec (11), on a :

$$\sigma_i V_\mu^{2/3} = k\tau\, \mathrm{e}^{-\frac{\mathrm{d}}{\tau}} \tag{15}$$

qui est la vraie équation d'état de l'interface liquide/vapeur. Pour des températures éloignées du point critique, on obtient :

$$\sigma_i V_\mu^{2/3} = k\tau\left(1 - \frac{d}{\tau}\right) = k(\tau - d)$$

c'est-à-dire l'équation d'Eötvös, avec la constante *d*. D'après ce que nous avons vu, *d* représente une grandeur proportionnelle au travail nécessaire pour faire passer l'air de la couche périphérique d'un liquide de la tension interfaciale σ_i à la tension superficielle σ_l.

L'équation d'état de l'interface liquide/vapeur (15) présente, en général, la même approximation que l'équation d'Eötvös-Ramsay-Shields. Mais au voisinage du point critique, l'équation (15) est supérieure à l'autre, parce qu'elle ne donne pas des valeurs négatives pour le produit $\sigma_i V_\mu^{2/3}$.[2]

2) *L'équation d'état de la surface liquide* (correctement : de la couche périphérique) s'obtient en considérant que le produit $\sigma_l V_\mu^{2/3}$ diminue linéairement avec la température jusqu'au point critique :

$$\sigma_l V_\mu^{2/3} = a - kt$$

En posant :

$$\omega = \frac{\sigma_c V_\mu^{2/3}}{k}$$

on obtient :

$$\sigma_l V_\mu^{2/3} = k(\tau + \omega) \tag{16}$$

qui est l'équation d'état cherchée.[9] C'est très surprenant le fait que cette équation, si simple, est parfaitement valable pour toutes les températures auxquelles Ramsay et Shields ont pu effectuer leurs mesures. Comme nous avons vu, ce n'est pas le cas de l'équation d'état de l'interface liquide/vapeur, qui perd complètement sa validité au voisinage du point critique.

L'équation (16) permet aussi de calculer la tension superficielle critique σ_c. Les valeurs obtenues par cette voie sont très rapprochées de celles calculées par les formules (12) et (13), comme on peut voir dans le tableau 2.

Tableau 2

La tension superficielle critique

	a_c atm. litres^2 mol^{-2}	P_c atm	10^8 D cm	σ_c dyn.cm^{-1} calculée par		
				(12)	(13)	(16)
Ether éthylique	17,40	220	4,08	0,010	0,009	0,010
Formiate de méthyle	11,39	385	3,46	0,013	0,014	0,013
Acétate d'éthyle	20,48	250	3,96	0,010	0,010	0,010
Tétrachlorure de carbone	19,56	257	4,36	0,012	0,011	0,012
Benzène	18,72	285	4,21	0,012	0,012	0,012
Benzène monochloré	25,52	269	4,35	0,012	0,012	0,013

3) *L'équation d'état périphérique de la vapeur saturante* [13] correspond au produit $\sigma_v V_\mu^{2/3}$ qu'on peut calculer à l'aide des valeurs de σ_v obtenues ci-dessus. On constate que ce produit croît avec la température, en présentant un maximum pour la température réduite 0,761. L'équation d'état périphérique, que nous avons trouvée dans ce cas est :

$$\sigma_v V_\mu^{2/3} = K\tau^{0,9} \rho_v^{1/3} \tag{17}$$

mais elle est valable seulement pour les températures éloignées du point critique.

LA TENSION SUPERFICIELLE DES LIQUIDES RARÉFIÉS

Les liquides raréfiés ont été obtenus jusqu'à présent par divers expérimentateurs, qui ont interprété leurs résultats par l'existence des pressions négatives. En réalité, il s'agit des liquides qui occupent un volume plus grand que dans les conditions normales.

---

[13] N. Bărbulescu et F. Bărbulescu, *Koll. Z.*, **101**, 161 (1942).

La plus simple méthode d'obtenir un liquide raréfié c'est de la mélanger avec un autre, en l'absence de tout solvat (mélange idéal). En occupant le volume total du mélange, les deux liquids sont raréfiés, pouvant être caractérisés par leurs *densités partielles.*[14]

Désignons par ρ la densité d'un mélange binaire idéal (où il n'existe pas des solvats) et par g la fraction massique d'un de ces composants. Les densités partielles des composants raréfiés sont :

$$\rho_1 = g\,\rho \quad \text{et} \quad \rho_2 = (1 - g)\,\rho$$

On démontre que, pour toute transformation isotherme d'un fluide on a :

$$\sigma(V - b) = \text{const.} \tag{18}$$

formule qui permet de calculer la tension superficielle d'un liquide raréfié.[15] Le tableau 3 contient les densités partielles et les tensions superficielles respectives des deux liquides raréfiés, formant un mélange idéal : benzène et acétate d'éthyle à 20°. La constante b de ces liquides raréfiés a été obtenue d'une manière empirique. Les valeurs calculées pour σ_1 et σ_2 montrent, conformément aux prévisions, que la tension superficielle des fluides diminue quand la raréfaction croît.

Tableau 3

Benzène – Acétate d'éthyle à 20°

b (benzène) = 2.1 cm³/mole b (acétate) = 2,6 cm³/mole

g	ρ_1 benzène	ρ_2 acétate	σ_1 benzène	σ_2 acétate	σ	
					exp.	calc.
1,0000	0,8783	0,0000	28,05	—	28,05	—
0,8989	0,7910	0,0890	25,20	2,22	27,51	27,42
0,7910	0,6973	0,1843	22,17	4,60	26,75	26,77
0,6004	0,5313	0,3536	16,69	8,88	25,64	25,57
0,3967	0,3526	0,5351	11,10	13,54	24,51	24,64
0,1960	0,1750	0,7180	5,48	18,22	23,74	23,70
0,1160	0,1038	0,7911	3,24	20,13	23,50	23,37
0,0000	0,0000	0,8976	—	22,92	22,92	—

On a montré, de même, que *la tension superficielle d'un mélange binaire idéal est la somme des tensions superficielles partielles des liquides raréfiés.*[15] Les valeurs numériques du tableau 3, sont calculées d'après les données expérimentales de Herzen.[16]

INFLUENCE OF NaCl AND LiF ON THE DENSITY AND VISCOSITY OF MOLTEN $Na_3AlF_6-BaCl_2$ SYSTEM

ȘTEFANIA ZUCA, RODICA COSTIN and M. OLTEANU

Institute of Physical Chemistry,
Str. Galați 31, Bucharest 9, Romania

Received June 29, 1973

The density and viscosity of 40 % Na_3AlF_6 + 60 % $BaCl_2$ mixture and the influence upon them of LiF and NaCl additions are studied, over a temperature range of about 100°. The ionic interactions occurring on mixing and the most suitable composition of electrolytic bath are discussed.

The molten $NaF-AlF_3-BaCl_2$ mixtures form the basis of electrolytic bath for aluminium refining, known as Gadeau's bath. The physico-chemical properties of these mixtures have been investigated both from the theoretical viewpoint, attempting to gain structural information on ionic mixtures, and from the practical one, aiming at establishing the most suitable electrolyte for the technical process.

A special interest has been given to studying the temperature of the primary crystallization of electrolyte,[1-3] the density[4,5] and electrical conductivity.[6,7] The measurements of the viscosity of fluoride melts are rather difficult; for this reason very little is known about it in the $NaF-AlF_3-BaCl_2$ system.[8]

The viscosity as well as the density are important mainly in the separation of the metal and influence, thus, the total production, but can also provide information on the structure of the melts studied.

The present work is concerned with the binary system AlF_6Na_3 + + $BaCl_2$ and the influence of LiF and NaCl additions on the density and viscosity. These two named electrolytes have already been recommended as additives improving those physico-chemical properties of aluminium electrolyte which enhance the economics of electrolysis.[9-11]

Therefore, we thought of as interesting to study their influence on the density and viscosity of the refining electrolyte too.

According to Gadeau's method,[12] at the working temperature (740°), the density at the cathode and at the anode is of 2.35 g/cm^3 and 3.14 g/cm^3, respectively,[1,13,14] and, consequently, the density of the electrolyte has to be maintained within 2.6—2.8 g/cm^3 range in order to ensure a good separation of the metal. The data in literature[4,5] indicate that this requirement is accomplished in the electrolyte with 60—70% $BaCl_2$ no matter the cryolite ratio (NaF/AlF_3). Therefore, we have chosen as basic electrolyte for our experiments, the one of composition 40% AlF_6Na_3 + 60% $BaCl_2$.

EXPERIMENTAL

The density was measured by the platinum sinker method, previously described,[15] with an accuracy of 0.2—0.3%. The oscillating sphere method has been employed for viscosity measurement,[16,17] the accuracy being of ± 3%. A vertical furnace provided for working in a controlled atmosphere was used and a constant temperature within ±0.5° was mentioned during the experiments. The temperature was measured by a calibrated Pt—Pt 10% Rh thermocouple, its hot jonction being immersed into the melt.

The density and viscosity determinations were carried out on the following grade reagents : Merck *p.a.* NaF, $BaCl_2$, NaCl and LiF, Serva *p.a.* AlF_3. Cryolite was prepared by fusing the reagent grade NaF and AlF_3, previously dried at 400°, mixed in stoichiometric ratio. The $BaCl_2$, NaCl and LiF reagents were recrystallized from distilled water, dried for 24 h at 150° and melted before mixing, while a dried HCl or argon gas was bubbled through the melt. All experiments were performed in an argon atmosphere. The melts were submitted to measurement both at heating and on cooling.

The density and viscosity have been measured over a temperature range of about 100° in binary 40% Na_3AlF_6 + 60% $BaCl_2$ mixture and with 3 ; 5 ; 7% LiF or 2 ; 4 ; 6 ; 8% NaCl added.

The coefficients of equations representing the density *vs.* temperature and viscosity *vs.* temperature plots were calculated by the least squares method.

RESULTS AND DISCUSSIONS

The results obtained for the density of presently studied mixtures are summarized as linear function of temperature in tables 1 and 2. The present results for the density of 40% Na_3AlF_6 + 60% $BaCl_2$ mixture

* η is given in cP.

Our experimental data for viscosity are shown in figs. 1 and 2. The plot of $\log \eta$ vs $^1/T$ (K) is linear for all studied mixtures, attesting the validity of Arrhenius equation $\eta = A_\eta e^{E_\eta/RT}$. Tables 3 and 4 give numerical values of the pre-exponential constant A_η and the activation energy of viscosity E_η, as well as the equations for viscosity *vs.* temperature dependence. As can be seen in fig. 3, both NaCl and LiF additions decrease the density of the fused $Na_3AlF_6+BaCl_2$ system, the influence of NaCl being more pronounced. The corresponding values are of 0.2% per 1% LiF and of 0.5% per 1% NaCl. The relatively weak influence of LiF on the density of the basic electrolyte is probably due to the fact that the volume of the melt is mainly determined by the large complex anions AlF_6^{3-}. At NaCl addition, the larger Cl^- ions (r = 1,81 Å) compared to F^- ions (r = 1.36 Å) are expected to influence to a greater extent the volume of the melt, what is experimentally proved (fig. 3).

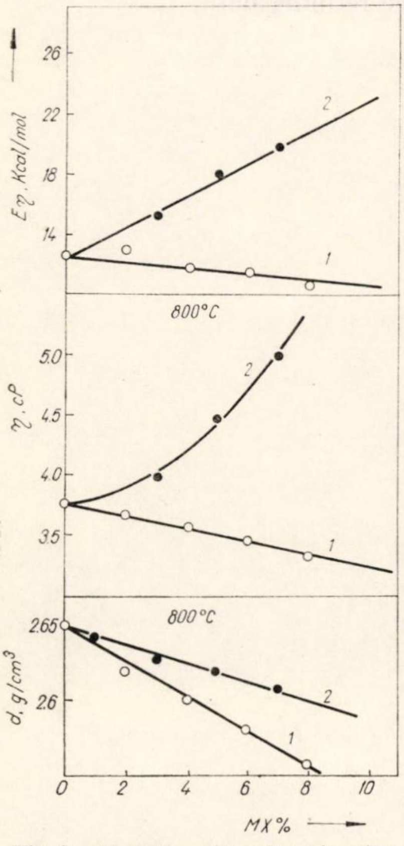

Fig. 3. — Variation of density, viscosity and E_η as a function of NaCl and LiF content in the 40% AlF_6Na_3 + + 60% $BaCl_2$ system :
1, NaCl; *2*, LiF.

Unlike the density behaviour, the viscosity is very little influenced by NaCl additions, while a substantial increase of the viscosity with increasing of LiF content in the melt takes place. Thus, an addition of 8% NaCl decreases the viscosity by 9% while, for 7% LiF added, a viscosity increase of 40% is observed. This can be explained by taking into account the small size of Li^+ ions, which allows them to occupy the free spaces existing among the large complex anions AlF_6^{3-}. Hence, the viscous flow is rended more difficult in the presence of Li^+ ions, which is also felt in the noticeable increase of the activation energy of viscosity (fig. 3). The linear dependence of both density and viscosity isotherms on composition, denote that in the concentration range studied, neither LiF nor NaCl take part in the chemical reaction on mixing and that they are, most probably, dissociated in the constituent ions. This is also supported by the linearity of E_η *vs.* composition curves.

In conclusion, we mention that from technical point of view, the NaCl addition is more advantageous, since it influences positively both density and viscosity of electrolyte. With regard to LiF, no content higher than 3% is recommended. It is certain that other parameters, as melting temperature, electrical conductivity, must be studied in order to establish the optimum composition of the refining bath.

DIFFUSIVE ATOMIC TRANSPORT IN MOLTEN ANTIMONY

N. PETRESCU and LUCIA GANOVICI

Centre of Physical Chemistry,
Str. Galaţi 31, Bucharest 9, Romania

Received June 11, 1973

Self-diffusion determinations in liquid antimony were carried out by the capillary-reservoir technique. The experimental results obtained in a temperature range from 640° to 800° are discussed according to several diffusion mechanisms. By statistical treatment of the data, the diffusion equations of liquid antimony are established, according to the activated mechanism of diffusion as well as for the small cooperative atomic motions mechanism based on the density fluctuations.

The observation is made that the parameters in the equation obtained for the self-diffusion in liquid antimony,

$$D = 11.48 \times 10^{-4} \exp(-5580/RT)$$

together with the parameters in the Arrhenius type diffusion equations for other elements non-closely packed in solid state, can lead to an interpretation of the diffusion phenomenon as function of the structure of the melt, expressed by the coordination number.

The self-diffusion coefficients of the molten metals represent fundamental data of great importance both for the theory of the liquid state and for numerous applications in different modern fields of technics.

Experimental determinations of the self-diffusion coefficients were performed especially for the liquid metals situated in the first four groups of the periodic table of elements. We tried in our works to enlarge the number of liquid state diffusivity determinations in metals, choosing to this purpose elements which were not studied before. So we carried out self-diffusion determinations in semimetals belonging to groups V_a and VI_a, namely in bismuth [1] and tellurium.[2] In the present paper we present the results of the self-diffusion determinations in another element of group V_a, that is in liquid antimony.

EXPERIMENTAL

The experimental device we used for the determination of the self-diffusion coefficients in liquid antimony was in principle the same we devised in previous works.[3,4] Several modifications were, however, necessary because of the particular surface properties of liquid antimony.

We carried out the diffusivity determination by the capillary-reservoir technique, with radioactive labelling of the liquid antimony in the reservoir. The radioactive tracer, needed to label the molten bath in the reservoir, was obtained by the activation of antimony in a nuclear reactor. The isotopic composition of antimony and the neutron cross-sections of its natural isotopes are such that the neutron irradiation leads in fact to two radioactive isotopes, namely Sb^{122} ($T_{1/2} = 2.80$ days) and Sb^{124} ($T_{1/2} = 60$ days). To diminish the contribution of the radioactivity from the short-lived isotope Sb^{122} and, thus, to ensure a better precision to the radioactivity measurements, the tracer was used after a hundred days storage since the moment of the irradiation in the reactor. The decay of the short lived isotopes allowed the radioactivity of the long-lived isotope Sb^{124} to be taken solely into account.

In the first runs we used capillaries bored in spectrally pure graphite rods, filled with antimony by the technique we described in a previous paper.[3] Although we used for the diffusion runs only the sound capillary samples, selected by a careful radiographic control, the number of samples in which diffusion did not take place was excessively large. We ascribed this fact to the graphite that we used to contain the capillary samples, the liquid antimony having a rather bad capacity of wetting the graphite. On this account it was possible that the contact between the antimony in the capillary and the labelled antimony in the reservoir be interrupted at the diffusion interface, when introducing the capillary samples into the reservoir.

Other series of runs were performed using capillary recipients made of sintered alumina tubes (0.8 mm inner diameter and 0.3 mm uniform wall thickness). The alumina tubes were cut to about 20 mm length, sealed at one end and fixed two by two in the same specimen holder. The filling of the capillaries was carried out by immersing them in a bath of liquid antimony under vacuum, followed by argon admission under pressure.

The experimental device allowed the diffusion runs to be made continuously without solidification of the bath for changing the samples. Pure argon atmosphere was used; the temperature was kept constant within the limits $\pm 1°$.

The diffusion coefficients were derived from radioactivity measurements made on the diffusion samples and on reference samples taken from the radioactive bath. The geometry of the diffusion samples and of the reference samples was the same. The reference samples were taken from the bath by the immersion filling technique already described for the diffusion samples. The radioactivity measurements were made either on the whole sample or on sections of the sample. The radioactivity measurements on sections were performed by a screening technique, using a 1.5 mm slit width in a thick lead plate which allows the measurements on small finite portions along the sample length. Moving the sample stepwise under the slit, about 10 portions of the sample length could be exposed to measurement. From each measurement, a value of the diffusion coefficient was derived according to the relation (1):

---

[3] N. Petrescu, St. Zămîrcă, L. Ganovici and I. Ganovici, *Rev. Roumaine Chim.*, **13**, 865 (1968).

[4] M. Petrescu, *Z. Metallkde.*, **61**, 14 (1970).

$$\frac{c}{c_0} = 1 - \frac{4}{\pi} \sum_{n=0}^{\infty} \frac{1}{2n+1} \sin \frac{(2n+1)\,\pi x}{2l} \exp\left[-(2n+1)^2 \frac{\pi^2}{4} \frac{Dt}{l^2}\right] \qquad (1)$$

where c is the specific radioactivity of the sample, c_0 is the specific radioactivity of the bath in the reservoir, D is the self-diffusion coefficient (cm^2/s), t is the diffusion time (s), l is the length of the capillary column in which diffusion took place (cm) and x is the distance from the measured portion to the diffusion interface (cm).

By averaging equation (1) on the whole length of the sample, equation (2) is obtained and it was this last equation that we used for deriving the diffusion coefficients from radioactivity measurements on integral samples:

$$\frac{c}{c_0} = 1 - \frac{8}{\pi^2} \sum_{n=0}^{\infty} \frac{1}{(2n+1)^2} \exp\left[-(2n+1)^2 \frac{\pi^2}{4} \frac{Dt}{l^2}\right] \qquad (2)$$

Both equations (1) and (2) are obtained by integration of the Fick's second law for the following initial and boundary conditions: $c = 0$ for $0 < x < l$ at $t = 0$; $c = c_0$ for $\leqslant 0$ at $t \geqslant 0$ and $\partial c/\partial x = 0$ for $x = l$ at $t > 0$.

RESULTS AND DISCUSSION

The results for the self-diffusion coefficients in molten antimony as obtained from radioactivity measurements on integral samples are given in table 1. The values of the specific radioactivity in table 1 are the averages of several measurements so that the error owing to the statistical character of the decay phenomenon was less than 0.5%.

The radioactivity measurements on portions of the diffusion sample allowed more information to be gained. Penetration curves were drawn from this kind of measurements and a value of the diffusion coefficient was derived from the measurement on each portion. An experimental penetration curve is presented in fig. 1 together with the self-diffusion coefficients derived from it. The penetration curve gives an image of how the diffusion took place, but this must be taken with caution because solidification may cause perturbations in the penetration profile. A series of examples where the diffusion coefficients computed from measurements on different portions of the same sample vary very little around a mean value (as in fig. 1), attest the fact that the diffusion took place in normal conditions.

The average of the values of the diffusion coefficients derived from measurements on different portions of the same sample was generally larger than the diffusion coefficient derived from a measurement on the integral sample.

The temperature dependence of the diffusion coefficients of the molten metals can be interpreted according to several formalisms, corresponding to different equations, whose theoretical elaboration and taking into account of the structural characteristics of the melt are different. From the fact that several types of relations can account successfully for the temperature dependence of the diffusivity, we may infer that the diffusion in metallic melts depends firstly on other factors, the temperature being a consequential parameter of these primary factors.[5] If we adopt such a point of view, a first order importance is to be given to the interpretation of the parameters in the equations which express the temperature dependence of diffusivity. The general forms of these equations are:

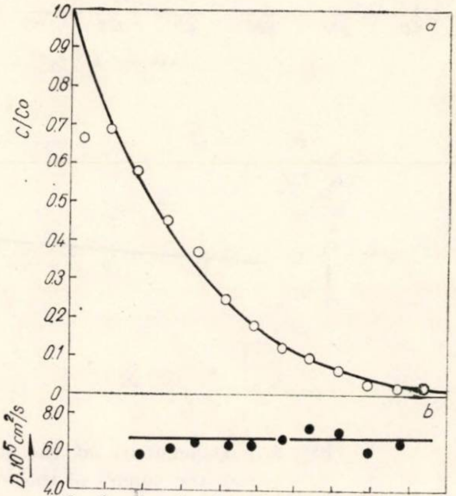

Fig. 1.— *a*) Radioactivity penetration curve along the capillary length; *b*) Values of the diffusion coefficients derived from measurements on portions along the length of the sample.

$$\ln D = AT^{-1} + B \tag{3}$$

$$D = AT^{n} + B \tag{4}$$

where n can have the values 1/2, 1, 3/2, 2.

The parameters A and B, derived from experimental sets of data for a certain type of equation, allow the diffusion phenomenon to be related to physical or structural characteristics of the melt. Among the diffusion equations whose parameters were physically interpreted it is to be noted the Arrhenius type equation, largely used to represent the variation of diffusivity with temperature. Our experimental results on the diffusivity in liquid antimony are also well rationalized by an Arrhenius type equation (fig. 2). The experimental data are to the same extent satisfactorily corroborated by a polynomial temperature function in T or T^2 (generally expressed by eq. 4) as we can see in figures 3 and 4.

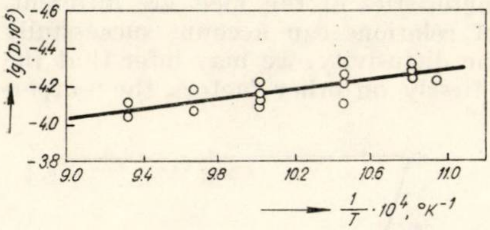

Fig. 2. — Arrhenius temperature dependence of the self-diffusion coefficients in liquid antimony.

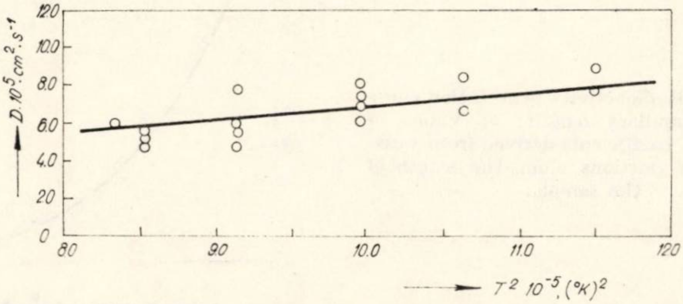

Fig. 3. — Dependence of the diffusivities in liquid antimony on the square of the absolute temperature.

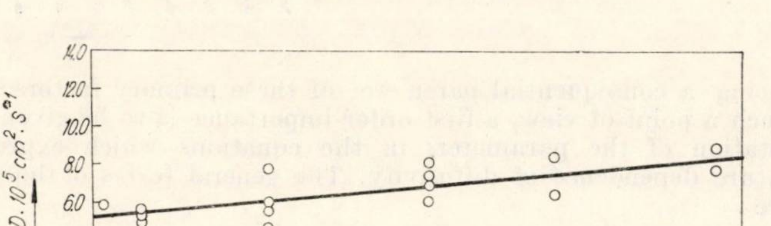

Fig. 4. — Dependence of the diffusivities in liquid antimony on the absolute temperature.

The analytical expressions of these dependences computed by a least squares statistical treatment of the experimental data are the following :

$$D = 11.48 \times 10^{-4} \exp\ (-5580/RT) \tag{5}$$

$$D = 0.684 \times 10^{-10} T^2 \tag{6}$$

$$D = -12.02 \times 10^{-5} + 0.02 \times 10^{-5}\, T \tag{7}$$

The significance of the parameters in equations (5)—(7) (plotted in figures 2—4) is worth to be discussed. The parameters in equation (5) — the preexponential factor and the activation energy — form the object of numerous attempts of correlation with several characteristics of the diffusing element or with its structural features in liquid state.

As the preexponential factor D_0 is concerned, we mention for instance that in a previous paper [1] we proposed that the dependence of D_0 on the solid state structure of the diffusing element [6] be replaced by a more adequate dependence on the coordination number in the melt. The test of this proposal that we made on the basis of the data then available can be completed successfully with the value of the preexponential factor of the diffusion equation that we obtained for molten antimony, as we can see in figure 5.

By substituting semilogarithmic coordinates in fig. 5 the dependence is linearized (fig. 6); thus, the possibility arises of expressing the coefficient D_0 by the equation:

$$D_0 = M^{-1/2} \exp\ (-Z) \tag{8}$$

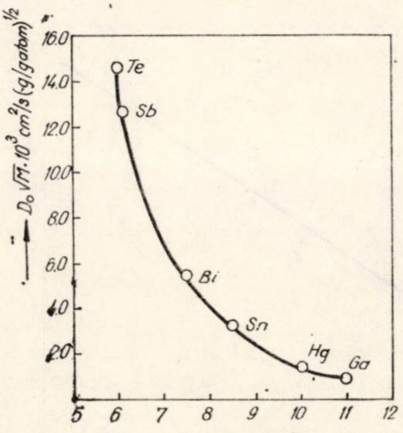

Fig. 5. — Dependence of the preexponential factor in the Arrhenius equation of several unclosely packed elements on the coordination number in liquid state.

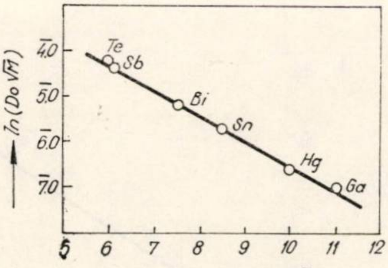

Fig. 6. — Linearization of the dependence of the preexponential factor on the coordination number in liquid state.

Further, by using the preexponential factor of eq. (8), the diffusion equation becomes:

$$D = M^{-1'2} \exp\ [-(Z + Q/RT)] \tag{9}$$

---

[6] H. J. Saxton and O. D. Sherby, *Trans. A.S M.*, **55**, 826 (1962).

and replacing the activation energy Q by the expression $Q = ART_m$, which is satisfactorily verified by most liquid metals, we obtain:

$$D = M^{-1/2} \exp\left[-(Z + AT_m/T)\right] \quad (10)$$

From eq. (10) we may infer that for the group of elements we refer to, and which was considered in previous papers [1,3] too, the self-diffusion coefficient in liquid state can be correlated with the temperature by means of two physical constants — e.g. the atomic mass M and the melting point T_m — and one structural characteristic of the melt, namely the coordination number Z.

The physical data used to check this relation (fig. 6) are the experimental self-diffusion data [1,2,7–11] and the coordination numbers in the molten elements.[12–14]

As concerning the constant A in eq. (10) we may consider the following: in figure 7 we may see that the activation energy for self-diffusion in liquid semimetals falls beneath the line $Q=3.35\ RT_m$ observed by typical metals. Saxton and Sherby [6] proposed for the semi-

[14] G. TOURAND, B. CABANE and M. BREUIL, *J. Non-Cryst. Sollids*, **8—10**, 676 (1972).

metals the expression $Q = 2.75\ RT_m$. By substituting this latter value in eq. (10) we get :

$$D = M^{-1/2} \exp\,[-(Z + 2.75/T_r)] \tag{11}$$

where T_r is a reduced temperature T/T_m.

The interpretation of the temperature dependence of the diffusivity according to the functions in T or T^2 (eq. 4) can find a theoretical support in supposing a diffusion mechanism based on small and variable cooperative atomic movements consequential to the small density fluctuations in the liquid. According to Swalin,[15] such a mechanism results in the following expression of the self-diffusion coefficient :

$$D = 2.39 \times 10^{-7} \frac{Z}{K} T^2 \tag{12}$$

where Z is the coordination number in the liquid and K is the force constant of the interatomic bond (dyne/cm).

Further theoretical treatments within this diffusion mechanism performed by Reynik [16] and experimental testings [17] lead to a linear temperature dependence of the diffusivity according to relation :

$$D = -1.72 \times 10^{24} Z X_0^4 K + 2.08 \times 10^9 Z X_0^2 T \tag{13}$$

where X_0 is the maximum jump distance.

By identifying equations (6) and (12) a value of 2.19×10^4 dyne/cm resulted for the force constant K in antimony ; a value $K = 5.12 \times 10^4$ dyne/cm resulted from the identification of equations (7) and (13).

Equation (13) allows the maximum jump distance X_0 to be computed from diffusion data : the experimental diffusion data in liquid antimony lead to a value $X_0 = 0.386$ Å. This jump distance compared to the average interatomic distance in liquid antimony gives a ratio of 0.12 ; this figure confirming the theoretical premise of the small fluctuations mechanism of diffusion.

Another theoretical justification for the linear temperature dependence of diffusivity is given by Nachtrieb,[7] by supposing the existence of several atomic configurations with different contributions to the diffusive motion, still directly varying with temperature. By considering the cooperative atomic movement as a result of the irreversible displacement of the oscillating center of each atom on distances equal to the mean square values of the amplitudes of the thermal vibrations, the following relation is established :

---

[15] R. A. Swalin, *Acta Met.*, **7**, 736 (1959).

[16] R. J. Reynik, *Appl. Phys. Letters*, **9**, 239 (1966).

[17] M. Petrescu, *Rev. Roumaine Chim.*, **13**, 687 (1968).

$$D = \frac{k^2 \theta_D T}{hK} \tag{14}$$

where θ_D is the Debye characteristic temperature, (K).

By interpreting our experimental data on liquid antimony diffusivity, according to eq. (14), it is obtained a value of the force constant $K = 0.723 \times 10^4$ dyne/cm, considerable inferior to that obtained from equations (12) and (13). It is worth mentioning that for typical metal (K, Na, Cu, Ag) the agreement between the value of the force constant computed from diffusivity data by means of eq. (14) and the value derived from spectroscopical or compressibility data is quite good. The force constant computed for semi-metals by means of eq. (14) leads to lower values. The fair agreement obtained with eq. (14) for the typical metals and the less satisfactory corroboration observed for the semi-metals can be ascribed to the differences between the liquid structure of the metallic elements and that of the semi-metals, eq. (14), lacking the possibility to take into account such structural effects. Equations (12) and (13), in which structural characteristics of the liquid are involved, give good results both for metals and for semi-metals.

The structure of the liquid semi-metals is different from that of the liquid metals, but what is more there are marked differences from the structure of one semi-metal to another. This is why the preexponential coefficient in eq. (3) can be expressed as function of several physical characteristics including a specific structural characteristic, as we proceeded in the present paper when establishing eq. (11). The correlation expressed by eq. (11) holds well, at least for a series of semi-metals and liquid metals having an unclosely packed structure.

CHRONOPOTENTIOMETRIC METHOD AT HIGH TEMPERATURES

S. STERNBERG and CONSTANȚA HERDLICKA

Institute of Physical Chemistry,
str. Galați 31, Bucharest, Romania

Received April 9, 1973

The influence of different factors on the chronopotentiometric measurements used for interdiffusion coefficient determination in salts melting at high temperature, such as alkali chlorides, has been studied. A graphical method for transient estimation was checked up by using the method of potential-time curves analysis which allows a correct estimation of the transition time. The values of current densities and concentrations of the diffusing substance, for which both methods of the transient estimation give comparable results, have been established.

Among the electrochemical methods, the chronopotentiometric method is more frequently used to determine the interdiffusion coefficients in molten salt media.

The diffusion coefficient is calculated from the Sand's equation:

$$\tau^{1/2} = \pi^{1/2} nFD^{1/2}C_0/2i_0 \tag{1}$$

where τ (sec) is the transition time, i_0(A/cm^2) the current density, D (cm^2/sec) the diffusion coefficient of the reacting species of bulk concentration C_0 (mol/cm^3), n the number of electrons participating to the electrode reaction and F (coulombs) the Faraday constant.

The Sand's equation is applicable only when the transport of ions to the electrode surface takes place by a semi-infinite linear diffusion process. According to eq. (1), for a given concentration of the diffusing ion, the product $i_0\tau^{1/2}$ should be independent of current density and the ratio $i_0\tau^{1/2}/C_0$ has to be constant for different current densities and concentrations.

The constancy of $i_0\tau^{1/2}$ product and $i_0\tau^{1/2}/C_0$ ratio represents verification criteria for semi-infinite linear diffusion.

Laitinen and co-workers[1,2] have investigated, for the first time, the validity of the transition-time eq. (1) at molten salt systems. These

[2] H. A. Laitinen and H. C. Gaur, *Analyt. Chim. Acta*, **18**, 1 (1958).

authors have studied the factors which influence the chronopotentiometric measurements at the diffusion of some metallic ions in LiCl + KCl at 450° and have established the ranges of current density and concentration for which Sand's equation is applicable. Laitinen and co-workers' studies have been considered as a base in chronopotentiometric measurements in molten salts made by many authors.

In our previous publications we have used the chronopotentiometric method in order to determine the diffusion coefficients of the silver ion in alkali nitrates [3,4] and chlorides [5] as well as of the lead ion in alkali chlorides.[6] The working temperatures for nitrate mixtures ranged between 260 and 480° and the working conditions were similar to those of Laitinen and co-workers.[1,2] Our measurements performed in alkali chloride media [5,6] demanding working temperatures of 400–500°, higher than in alkali nitrates, have imposed the establishing of new conditions for Sand's equation to apply. Our present work gives details about the chronopotentiometric measurements at temperatures as high as 900°.

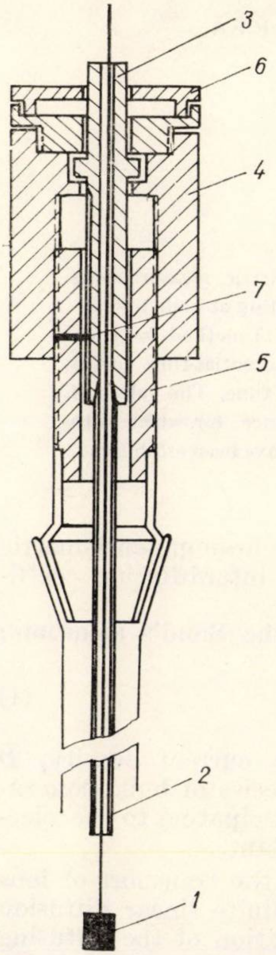

Fig. 1. – Vertical advance system for the working electrode.

1, working electrode; *2*, silica capillary; *3*, metallic holder for the electrode; *4*, movable axial advance system; *5*, fixed advance system; *6*, disk with mark; *7*, guiding peg.

EXPERIMENTAL

Chronopotentiometric equipment and experimental procedure have been described elsewere.[3–6] A quartz cell with three joint ended arms allowing the fastening of the three electrodes have been used.

The working electrode was a platinum plate hanging on a platinum wire of 0.5 mm diameter. Above 600°, which is the temperature range characteristic for alkali chlorides experiments, the delimitation of the working electrode surface area by framing it in insulators is not possible. In this temperature range any kind of glass, even quartz, cannot be used to seal the Pt wire. For this reason we have used the device in figure 1 to delimitate the working electrode surface.

The supporting wire of the plate was passed through a quartz capillary, the latter being attached to a metallic device consisting of two concentric hollow cylinders screwed in one another with a 2 cm long, M 0.5 mm thread. The electrode can be moved up and down on the desired distance, the electrical contact with the melt being signaled on a separated electrical circuit. The whole surface and 1–2 mm from the wire introduced into the melt.

The counter-electrode was a greater platinum plate (~2 cm^2) placed in a separate compartment.

The reference electrode consisted of a silver wire (Ø 1 mm) introduced into a melt containing Ag Cl dissolved in the same alkali chloride with the solvent used in the diffusion experiment. The concentration of silver ion (~0.1 M) was close to that of the studied solution.

The reference electrode Ag/Ag (I) has the advantage that it is easily prepared and can be used on a large temperature range, even above 900°.[7] The thin wall of the silica tube, which contained the reference electrode, allowed the electrical contact with the studied electrolyte.

The direct contact between the studied melt and the reference electrode, through a hole in the wall of the test tube has to be eliminated since the silver wire dissolves in alkali halides changing the concentration of silver ion in solution. In this case we have observed an increase in time of the constant $i_0\tau^{1/2}$ (table 1) that may be due to an Ag^+ concentration increase in the solution studied.

Table 1

The time change of the product $i_0\ \tau^{1/2}$ when the reference electrolyte is in a direct contact with the studied electrolyte
Solvent – KCl + NaCl (1.1)
Electrochemically active substance – AgCl
$C_{Ag^+} = 33.99 \cdot 10^{-5}$ mol/cm^3. Contact time of the electrolytes – 2 hours

PURE SOLVENT STUDY

It is characteristic for the chronopotentiometric method that the concentration of the electrochemically active substance is small (10^{-5}–10^{-4} mol/cm^3) compared to that of its support, an inert electrolyte (the diffusion medium), whose concentration is much higher (about 200 times) so that to allow the transport of the electrochemically active substance only by diffusion. For this reason, the purity of the solvent is of great importance in obtaining the correct values of the transition time characterizing the diffusion of the metal ion to the electrode surface.

The chronopotentiometry allows very small quantities of impurities to be detected in the molten salts and may be used to establish the purity of a molten solvent.

---

[7] J. Hladik, Y. Pointud, M. C. Bellisent and G. Morand, *Electrochim. Acta*, **15**, 405 (1970).

Alkali halides, especially LiCl, retain easily the water which is not eliminated on heating and alkali hydroxides are formed at melting. In the literature, experimental procedures of water removing from alkali halides are described. Their efficiency can be controlled by recording the potential-time curves.

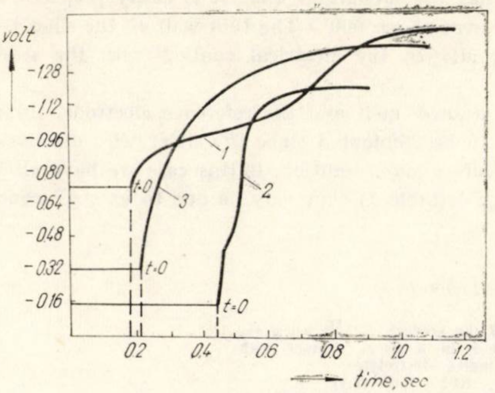

Fig. 2.—Chronopotentiograms of molten solvent.

1, untreated KCl at $i_0 = 3.55\cdot10^{-3}$ A/cm^3; *2*, KCl under vacuum and argon bubbling at $i_0 = 2.02\cdot10^{-3}$ A/cm^3; *3*, KCl untreated at $i_0 = 14.5\cdot10^{-3}$ A/cm^3.

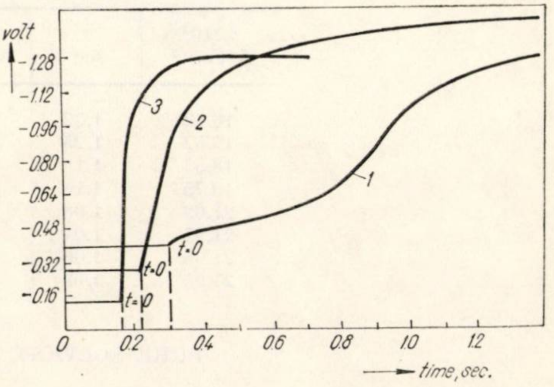

Fig. 3. — Chronopotentiograms of molten solvent.

1, KCl fused in HCl atmosphere and insufficient argon bubbling at $i_0 = 4.45\cdot10^{-3}$ A/cm^2; *2*, *3*, KCl melted in HCl atmosphere and enough argon bubbling to remove dissolved HCl traces. $i_0 = 4.45\cdot10^{-3}$ A/cm^2 (curve *2*) and $i_0 = 9.4.10^{-3}$ A/cm^2 (curve *3*).

If the potential of the working electrode is recorded *versus* time for a recrystallized, dried and melted KCl, a transition time is found which points out the traces of water (fig. 2, curve *1*). This transition time may be observed even for an electrolysis made at a current density as high as that used for a solvent containing electrochemically active substance. Removing of water may be achieved by pumping out the salt for at least 10 hours and melting it in argon atmosphere. This way, even at low current densities, ~ 2 mA/cm^2, a sudden increase of potential up to the value of the decomposition potential of the salt is recorded (fig. 2, curve *3*). A method often used for removing alkali hydroxides from the melt is HCl bubbling, but after that a great quantity of HCl remains dissolved in the melt. As can be seen from fig. 3, an incomplete removing of HCl is followed by a considerable transition time (curve *1*). This situation may be avoided by passing a big quantity of argon through the melt to remove HCl completely (fig. 3, curves *2*, *3*).

TRANSITION TIME DETERMINATION

To determine the transition time from potential-time curves, we have chosen the graphical method used for molten salts by Thalmayer and co-workers.[8]

The graphical methods for transition time determination need an extrapolation of the chronopotentiometric curve at the initial and final points, where the electrode potential suddenly changes. These points can hardly be estimated on a distorted chronopotentiogram because of the capacity current arising from electrical double layer charging. Therefore, it is very important to find out the values of concentration and current density for which the capacity current is negligible, so that τ graphically measured should represent the real transition time.

Sternberg and Vişan [9] have recently published an extensive study concerning the part played by the capacity current in the chronopotentiograms of $AgNO_3$ and alkali nitrate systems, showing that for high capacity currents the graphical method of transient estimation becomes inadequate.

To make sure that the graphical method is valid we have used the same method as Sternberg and Vişan, to get the transient and diffusion coefficient from the analyses of the potential-time curves.

The dependence of the working electrode potential, E, on the concentration according to Nernst equation is:

$$E = E_0 + \frac{RT}{nF} \ln \left(C_0 - \frac{2 i_0 t^{1/2}}{nF\, \pi^{1/2}\, D^{1/2}} \right) \tag{2}$$

where E_0 is the standard electrode potential and the paranthesis gives the concentration of the electrochemically active substance next to the electrode surface, at a time t, after the electrolysis starting. The variation of electrode potential at times t_1 and t_2 would then be:

$$\Delta E = E_2 - E_1 = - \frac{RT}{nF} \ln \left[\frac{\pi^{1/2} nFD^{1/2}\, C_0 - 2 i_0 t_2^{1/2}}{\pi^{1/2}\, nFD^{1/2} C_0 - 2 i_0 t_1^{1/2}} \right] \tag{3}$$

The equation (3) may be conveniently rearranged in an exponential form, as follows:

$$t_2^{1/2} - t_1^{1/2}\, e^{-\frac{\Delta EnF}{RT}} = \frac{\pi^{1/2}\, nFD^{1/2}}{2 i_0} \left[1 - e^{\frac{\Delta EnF}{RT}} \right] \tag{4}$$

On a graphical plot with $y = t_2^{1/2} - t_1^{1/2}\, e^{-\frac{\Delta EnF}{RT}}$ and $x = 1 - e^{-\frac{\Delta EnF}{RT}}$ as co-ordinates, a straight line is obtained whose extrapolation to $x = 1$ (for infinite potential) gives the transient $\tau^{1/2}$ from Sand's equation (1).

---

[9] S. Sternberg and T. Vişan, *Rev. Roumaine Chim.*, (under press).

We have used equation (4) to analyse a large number of potential-time curves for the AgCl – (KCl + NaCl) system under different experimental conditions (concentrations, current densities and temperatures).

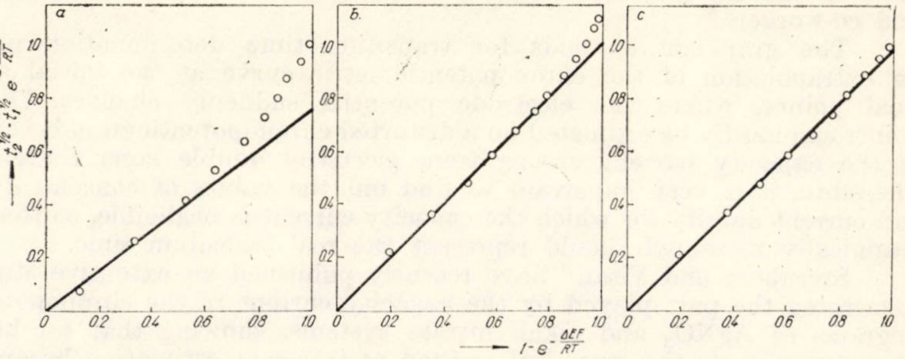

Fig. 4. – Transition time estimation by eq. (4) for Ag^+ diffusion in KCl + NaCl at. 710°.

a. $C_0 = 2.27 \cdot 10^{-5}$ mol/cm³; $i_0 = 14.23 \cdot 10^{-3}$ A/cm²; $\tau_{\text{calcd.}} = 0.60$ sec; $\tau_{\text{graph.}} = 0.77$ sec.

b. $C_0 = 5.25 \cdot 10^{-5}$ mol/cm³; $i_0 = 27.33 \cdot 10^{-3}$ A/cm²; $\tau_{\text{calcd.}} = 1.02$ sec; $\tau_{\text{graph.}} = 1.06$ sec.

c. $C_0 = 7.54 \cdot 10^{-5}$ mol/cm³; $i_0 = 41.96 \cdot 10^{-3}$ A/cm²; $\tau_{\text{calcd.}} = 0.96$ sec; $\tau_{\text{graph.}} = 0.96$ sec.

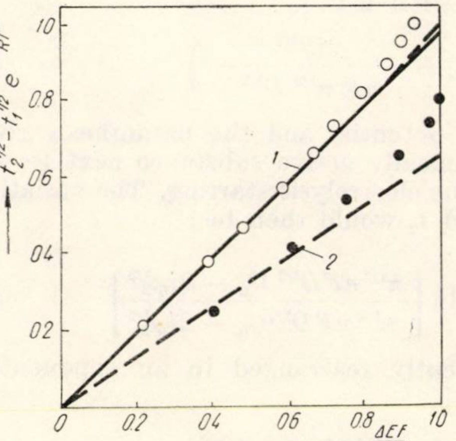

Fig. 5. – Transition time estimation by eq. (4) for Ag^+ diffusion in KCl + NaCl at 710° and $C_0 = 3.77 \cdot 10^{-5}$ mol/cm³.

1, $i_0 = 21.2 \cdot 10^{-3}$ A/cm²; $\tau_{\text{calcd.}} = 0.97$ sec.; $\tau_{\text{graph.}} = 0.98$ sec; *2*, $i_0 = 32 \cdot 10^{-3}$ A/cm²; $\tau_{\text{calcd.}} =$ = unobtainable. $\tau_{\text{graph.}} = 0.43$ sec.

In our experiments t_1 was kept constant (0.04 sec) and t_2 was varied every 0.2 sec. We supposed that i_0 is wholly a faradic current.

Appling equation (4) to curves recorded at different current densities and concentrations which give similar values of the C_0/i_0 ratio, we have obtained plots like those shown in fig. 4.

In figure 4 the values of the transition time, obtained both by eq. (4) and the graphical method, are listed.

Examination of fig. 4.*a* shows that at low concentrations some deviations from the straight line are evidently present. The chronopotentiograms recorded in the conditions indicated in figs. 4.*b*. and 4.*c*.

show a good agreement between the transition time values obtained by the graphical method and eq. (4). In the case of low concentrations (fig. 4.*a*.) the results of the two methods strongly disagree with each other.

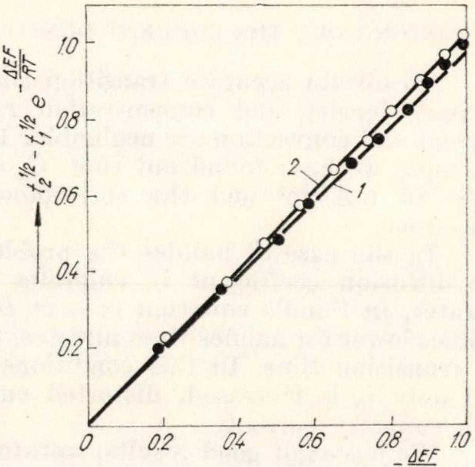

Fig. 6. — Transition time estimation by eq. (4) for Ag+ diffusion in KCl+ NaCl at 750°.

1, $C_0 = 6.91.10^{-5}$ mol/cm³; $i_0 = 57.35 \cdot 10^{-3}$ A/cm²; $\tau_{\text{calcd.}} = 0.96$ sec. and $\tau_{\text{graph.}} = 0.956$ sec.
2, $C_0 = 5.38 \cdot 10^{-5}$ mol/cm³; $i_0 = 42.04 \cdot 10^{-3}$ A/cm²; $\tau_{\text{calcd.}} = 1.025$ sec. and $\tau_{\text{graph.}} = 1.03$ sec.

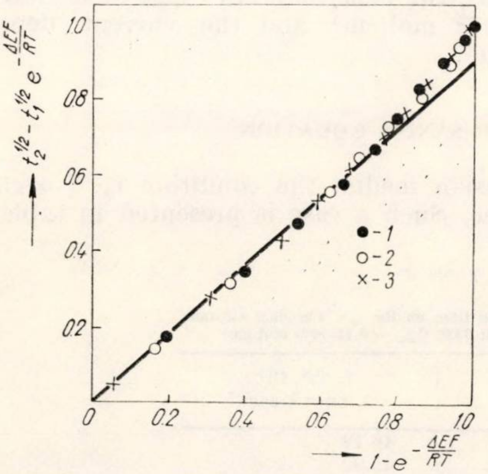

Fig. 7. — Transition time estimation by eq. (4) for Ag+ diffusion in NaCl + KCl at 808° and $C_0/i_0 \sim 1.07 \cdot 10^{-3}$.

C_0, mol/cm³	i_0, A/cm²
1, $3.40 \cdot 10^{-5}$	*1*, $31.69 \cdot 10^{-3}$
2, $5.68 \cdot 10^{-5}$	*2*, $42.57 \cdot 10^{-3}$
3, $6.74 \cdot 10^{-5}$	*3*, $62.61 \cdot 10^{-3}$

The greatest deviations from linearity are observed at high current densities and relatively small concentrations (fig. 5). At the same concentration, the higher the current density the more pronounced the deviations from linearity (figure 5, curve *2*) and τ cannot be estimated. The τ value obtained by the graphical method (dashed line in fig. 5, curve *2*) is in fact an apparent transition time.

A good agreement between the two methods (small deviations from linearity) is found in the following conditions : $C_0 > 3.10^{-5}$ mol/cm³, $i_0 < 70$ mA/cm² and transition time between 0.5 and 1.5 sec. These observations are illustrated in figures 6 and 7.

This way, we have established the conditions for obtaining slightly distorted curves so that the graphical method (which is simpler and faster) to allow a correct estimation of the transition time.

FINDING OUT THE CURRENT DENSITY AND CONCENTRATION RANGES

To obtain accurate transition times it is necessary to find out the current density and concentration ranges within which the capacity current and convection are negligible. In nitrates systems,[3,4] by successive attempts we have found out that $C_0 = 1.5 \cdot 10^{-5} - 3 \cdot 10^{-5}$ mol/cm³, $i_0 = 5 - 10$ mA/cm² and the corresponding transition time is equal to 0.5—2 sec.

In the case of halides the problem was a little more difficult. As the diffusion coefficient in chlorides is about 5 times higher than in nitrates, in Sand's equation ($\tau = ct . D(C_0/i_0)^2_2$) the ratio C_0/i_0 should be 5 times lower for halides than nitrates, to obtain the same range of values for transition time. In this conditions, if the concentration is kept low and only i_0 is increased, distorted curves are obtained because of the high capacity current.

We have got good results, working with 2—3 times greater concentrations and 4—6 times higher current densities than in nitrates.

So that, for chloride systems, the concentration range of the diffusing substance was $3 \cdot 10^{-5} - 8 \cdot 10^{-5}$ mol/cm³ and the current density range of $35 \cdot 10^{-3} - 65 \cdot 10^{-3}$ A/cm².

CHECKING UP SAND'S EQUATION

In alkali chlorides as diffusion media, the condition $i_0 \tau^{1/2} = ct.$ is fulfilled when 1 sec $\leqslant \tau < 0.5$ sec. Such a case is presented in table 2.

Table 2

The influence of the transition time on the $i_0 \tau^{1/2}$ product constant. AgCl in KCl + NaCl at 710° $C_{Ag} = 6.41 \cdot 10^{-5}$ mol/cm³

$i_0 . 10^3$ A.cm^{-3}	τ sec	$i_0 \tau^{1/2} . 10^3$ A.cm^{-2}.sec$^{1/2}$	
31.10	2.20	46.12	
34.66	1.75	45.92	
36.79	1.55	45.80	
41.37	1.23	45.87	
42.71	1.13	45.49	Average value 45.27
45.04	1.01	45.35	
47.23	0.91	45.11	
48.63	0.87	45.36	
51.09	0.78	45.15	
57.86	0.61	45.18	
69.10	0.41	44.20	

Since high temperatures facilitate convection and capacity currents enhancement, the range of transition time should be narrower in chlorides than in nitrates.

In tables 3 and 4, two examples, illustrating how the condition $i_0\tau^{1/2}/C_0 = ct$ holds in the case of chlorides mixtures, are given.

Table 3

Checking up Sand's equation in the AgCl + (KCl–NaCl) system at 710°

$C_{Ag} + .10^5$ mol.cm^{-3}	$i_0\ \tau^{1/2}.10^3$ A. sec$^{1/2}$.cm^{-2}	$i_0\ \tau^{1/2}/C_0$ A.cm.sec$^{1/2}$.mol^{-1}
3.16	22.61	715
3.67	25.38	691
4.64	33.52	722
5.43	37.68	694
6.41	45.67	711

Average value 707±11

Table 4

Checking up Sand's equation in the AgCl + KCl system at 800°

Current density number	$C_{Ag} + .10^5$ mol.cm^{-3}	$i_0^{1/2}.10^3$ A.sec$^{1/2}$.cm^{-2}	$i_0\tau^{1/2}/C_0$ A.cm.sec$^{1/2}$.mol^{-1}
4	1.61	15.30	950
6	1.90	17.10	900
4	2.13	18.76	880
6	4.40	35.80	813
6	5.72	46.00	804
7	6.29	51.10	812
5	6.57	52.68	803

From these tables it results that the ratio $i_0\tau^{1/2}/C_0$ is constant when the concentration of Ag^+ is greater than $3 \cdot 10^{-5}$ mol/cm^3.

The value $6.94.10^{-5}$ cm^2/sec we found for the diffusion coefficient of Ag^+ in the KCl – NaCl mixture at 710° is comparable to that obtained by Smirnov and co-workers,[10] using the same method, i.e. 7.06. $7.06 \cdot 10^{-5}$ cm^2/sec.

CONCLUSIONS

The chronopotentiometric measurements carried out under different conditions have shown that accurate values for transition time and interdiffusion coefficient above 500° may be obtained, provided that the current densities are 4–5 times higher and the concentrations are 2–3 times greater than those used at lower temperatures.

Revue Roumaine de Chimie, **19**, *2*, 197–206 (1974)

To avoid the effects of convection and capacity current, the transition time should lie within a narrow range of 0.5—1 sec.

The analysis method of potential-time curves allows the determining of transition time from chronopotentiograms recorded in any conditions. It also allows to find out the concentration and current density ranges for which the graphical method of transition time estimation gives correct results.

Establishing of the limit value for these parameters is of great importance in the application of any graphical method for transition time determination. The graphical methods are convenient because they are simple, fast and they do not require accurate potential measurements, but only time measurements.

TRANSFORMATION OF THE TOLUENE-WATER MIXTURE IN THE HIGH FREQUENCY DISCHARGE PLASMA. I

G. BOURCEANU, GH. POPA, M. SANDULOVICIU and V. ABABI

Laboratory of Chemical Technology, "Al. I. Cuza" University,
Jassy, Calea 23 August 11, Romania

Received February 2, 1973

Using the high frequency discharge plasma, the transformation of the toluene-water mixture was investigated. The experiments carried out with a small power oscillator led to a slight transformation degree of toluene. On the basis of the experimental results a series of theoretical considerations on the reactions mechanism have been made.

In the recent years plasma has played an even greater role in the modern chemical technology. By means of plasma, the realization of many chemical reactions as acetylene manufacture,[1–3] hydrocyanic acid manufacture,[4] etc. that require high temperatures, has become possible.

Plasma is not only used for the realization of the chemical reactions which do not take place in usual conditions, but it is used too in the case of those reactions for which the presence of plasma leads to the increasing of their yields. Thus, Leuthner[5] succeeded in preparing dicyanogen in a nitrogen plasma jet using a consumable graphite cathode. Those reactions cited above are carried out in the arc discharge plasma, i.e. in isothermal plasma at high temperature, where the cause of the chemical reactions development is heat generation.

There are known a series of reactions which take place more intensively and selectively in those forms of discharges in which the heat generation is minimum. In this case, the influence of discharge on the chemical reactions development is the direct action of the electrons from

the discharge plasma on the reactant molecules. Comparison of the critical velocities of the electrons with the excitation and ionization potential of the molecules shows, indeed, the formation of excited and ionized particles. Such types of reactions are met into the high frequency discharges, luminescence, microwaves, etc.[6-8] In the present paper we have studied the transformation that takes place with the toluene-water mixture in the high frequency discharge plasma.

EXPERIMENTAL

The discharge was obtained using a high frequency electromagnetic field in a Jena glass tube (3 cm in diameter) placed inside of the oscillator coil. The device sketch is presented in fig. 1.

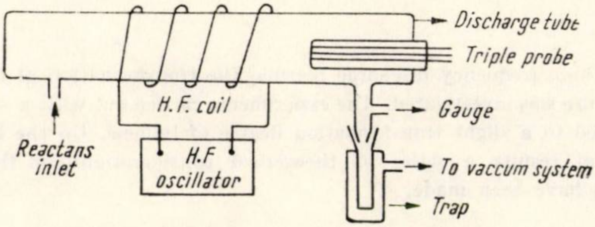

Fig. 1. — Scheme of the installation.

The oscillator power was 20 W and the frequency of the field was about 20 MHz. The reactant mixture toluene-water was fed in continuous stream. The pressure of the gaseous mixture from the discharge tube was measured by means of a differential manometer with silicone oil placed very close to the discharge zone. The condensable part of the reaction products, in given conditions of temperature and pressure, was captured by two trapes cooled with liquid nitrogen.

Analysis of products. The mixture containing the liquid and gaseous products obtained from reaction was analysed using the chromatography in gaseous phase. Carbowax-20 M and Apiezon L Grease were used as stationary phases and hydrogen was used as carrier. In order to detect all components of the mixture, a large range of flow rates and temperatures were utilized. Their identification was made by comparison of the retention distance of the components in mixture with those of the pure components. In addition to this, the NMR and IR spectra in solution of CCl_4 were carried out.

On the basis of analytical investigation, benzene, ethylbenzene, benzyl alcohol, phenol, diphenylmethane and dibenzyl were identified in the liquid phase. Ethane, ethylene and acetylene were identified in the gaseous phase.

The conditions of experiments and the composition of the obtained products, expressed in percent, are summarized in table 1.

Ethane	45	46	44
Ethylene	16	15	16
Acetylene	24	23	25

* Percentages of these products are accounted in the liquid without toluene.

DISCUSSION

From theoretical point of view, it is interesting to know the transfer model of the electron energy to toluene or water molecule. Since, in plasma more complex processes take place, there are more possibilities of the energy transfer between species of the plasma, so that many types of intermediaries can occur. The primary processes that are responsible for the nature of the products obtained from reaction are of interest in these conditions.

Taking into account the obtained products as well as their proportion, two modes of the electron energy transfer are possible. One is referring to the fact that after electron-molecule collision, the molecule becomes excited and a radicalic breaking takes place. The other type of transfer should be by electron capturing.

The first hypothesis is based on the fact that the bond energy of $\gg C-CH_3$ is about 3.8 eV, whereas for the C—H bond from methyl groups, the bond energy is only 3.3 eV.[9,10] Assuming that the electrons distribution according to their energies is a Maxwellian one, it was found by means of triple probe [11] that mean energy of the electrons is 1.5 eV. Therefore, a part of these electrons of plasma, for which by means of the same method, it was found that they have a concentration of 10^8 cc^{-1}, will have an energy that ranges between 3.3—3.8 eV. In the favour of the first hypothesis pleads the fact that the maximum collision probability of the electrons with the molecule of toluene corresponds

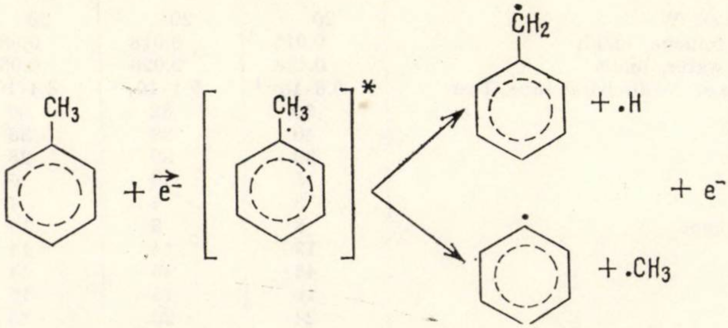
---

[9] M. Szware, *J. Chem. Phys.*, **16**, 128 (1948).

[10] D. O. Schissler and D. P. Stevensons, *J. Chem. Phys.*, **22**, 151 (1954).

[11] Sin-Li Chen and T. Sekiguchi, *J. Appl. Phys.*, **36**, 2363 (1965).

to an electron energy of about 2 eV,[12] which is comparable with the mean energy of the plasma electrons. In this case, collisions of the electrons with the molecules of toluene lead to the following type of energy transfer :



(1)

Since the energy of the C—H bond from methyl groups is weaker it is expected that benzyl radicals may occur in a larger proportion. The experimental data have confirmed this observation.

In the case of the water molecule, the maximum of the collision probability corresponds to an energy of 3.5 eV,[12] i.e. much larger than the mean energy of the electrons from plasma. Also, the energy of the H—O bond from the water molecule being 4.7 eV,[13] we consider that breaking takes place at radicals as follows :

$$\mathrm{H{-}OH} + \vec{e}^{\,-} \rightarrow \mathrm{H.} + \mathrm{.OH} + e^{-} \tag{2}$$

but in a less proportion. This fact is confirmed by the presence of small quantities of phenol and benzyl alcohol formed.

The radicals formed initially can generate the following reactions :

$$2\mathrm{C_6H_5{-}CH_2.} \rightarrow \mathrm{C_6H_5{-}CH_2{-}CH_2{-}C_6H_5} \tag{3}$$

$$\mathrm{C_6H_5{-}CH_2.} + \mathrm{.CH_3} \rightarrow \mathrm{C_6H_5{-}CH_2{-}CH_3} \tag{4}$$

$$\mathrm{C_6H_5{-}CH_2.} + \mathrm{.C_6H_5} \rightarrow \mathrm{C_6H_5{-}CH_2{-}C_6H_5} \tag{5}$$

$$\mathrm{C_6H_5{-}CH_2.} + \mathrm{.OH} \rightarrow \mathrm{C_6H_5{-}CH_2{-}OH} \tag{6}$$

$$\mathrm{C_6H_5.} + \mathrm{.H} \rightarrow \mathrm{C_6H_6} \tag{7}$$

$$\mathrm{C_6H_5.} + \mathrm{.OH} \rightarrow \mathrm{C_6H_5{-}OH} \tag{8}$$

---

[12] S. C. Brown, "Basic Data of Plasma Physics", Chap. I, M.I.T. Press, Massachusetts, 1959.

[13] L. Pauling, "The Nature of Chemical Bond" (3rd edition), Cornell, Ithaca, 1960, p. 262.

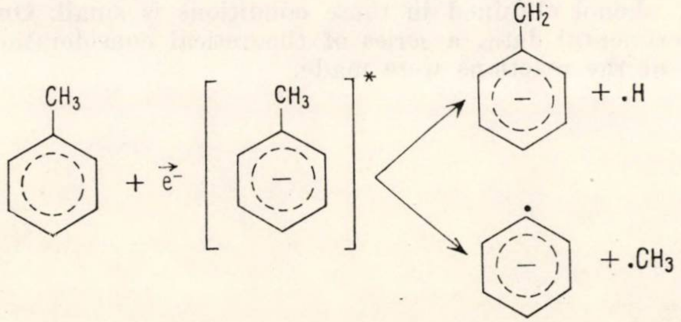
Ethane is obtained by unifying two $.CH_3$ radicals. Ethylene and acetylene form through symmetrical recombination of the $:CH_2$ and $\vdots CH$ radicals, respectively, these being formed from the decomposition of the $.CH_3$ radicals. This decomposition of $.CH_3$ was pointed out by I. A. Schneider[14] studying the decomposition of methane.

But, the $:CH_2$ radical can also be generated from the benzyl radical decomposition :

$$C_6H_5{-}CH_2. \longrightarrow C_6H_5. + :CH_2 \qquad (9)$$

The second possible transfer type of the electrons energy to the molecule of toluene, electrons capturing, is based on the fact that the affinity for electrons of the aromatic molecule, theoretically accounted, is −1.6 eV,[15] i.e. it is very close to the mean energy of the electrons from plasma for which this is 1.5 eV. In this case, the toluene molecule catches an electron and generates an anion.

The dissociative capturing should be the most possible path of the negative ions formation, when the delivered energy by the attached electron at the toluene molecule leads to such a high increase of the vibration energy of the molecule so that the excited anion molecule of toluene dissociates according to the mechanism :



10

The following question must obviously be risen up. How can be explained that anion-radicals can generate a molecule, e.g. of dibenzyl? We have not enough data for the calculation of the energy which should be changed when, e.g., a molecule of dibenzyl is formed from two anion-benzyl radicals in order to establish if such a reaction is or not possible.

The hypothesis referring to the formation of such anion-radicals is emphasized by two arguments. The first argument is that the affinity of the aromatic molecule is −1.6 eV. The second argument starts from the observation that easier will react an anion-radical with one radical than with two radicals, because the anion-radical is more instable. The last argument is confirmed too by the larger quantity of benzene and ethylbenzene which can be generated from the following reactions:

Dibenzyl and all others components will be generated analogously.

CONCLUSIONS

In the given conditions, it was obtained a small transformation degree of toluene, because the oscillator power was small.

Since the breaking energy of the H–O bond of water molecule is 4.7 eV and only a small portion of electrons had such energy, the quantity of phenol obtained in these conditions is small. On the basis of the experimental data, a series of theoretical considerations on the mechanism of the reactions were made.

Centre of Organic Chemistry, Bucharest, Spl. Independenţei 202-B, Romania

Received September 15, 1973

The 2:3.5:6-dibenzobicyclo [5.1.0] octa-2.5-dien-4-yl-methyl tosylate (**14a**) and 2:3.5:6-dibenzobicyclo [5.1.0] octa-2.5-dien-4-yl-ethyl-β-tosylate (**14b**) were synthesized and solvolyzed in order to investigate the possibility of nucleophilic participation of the remote cyclopropyl ring. The main product (94.5%) of the buffered acetolysis of **14a** is the ring-enlarged alcohol *trans*-**28**; the reaction is highly stereospecific. The unbuffered acetolysis as well as the buffered formolysis yield, with shorter reaction times, the two epimers *trans*- and *cis*-**28**, which subsequently undergo elimination leading to hydrocarbon **27**. The stereospecificity of the buffered acetolysis may be accounted for by the intervention of a phenonium ion. In the unbuffered acetolysis of **14b**, besides the unrearranged alcohol **35**, two products of cyclopropyl ring opening **38** and **39** were identified. The lack of cyclopropyl participation (as shown also by kinetic measurements) is ascribed — in the case of **14a** — to the competition with the strong stabilizing influence of the aromatic ring, whereas in the case of **14b** to the unfavourable geometric conditions for interaction between the cationic center and the cyclopropane orbitals.

In the last years the solvolytic nucleophilic participation of remote cyclopropyl ring was extensively investigated.[1–8] Comparisons with double bond participation were also made on the basis of the known resemblance in some properties between double bond and cyclopropyl ring.

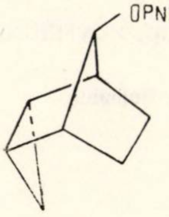
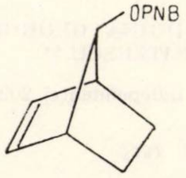
Kaplan, J. J. Bloomfield and L. F. Hatch, *J. Org. Chem.*, **27**, 733 (1962); A. Banciu, *Studii şi Cercetări Chim. Acad. Bucureşti*, **21**, 535 (1973).

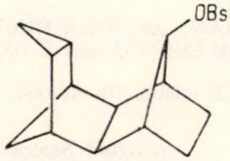
Theoretical calculations[2] indicated that in some cases cyclopropyl participation could be more important than double bond participation. Such comparisons have shown in many cases a very different behaviour *e.g.*: cyclopropyl participation in compound **1**[3] is much stronger than double bond assistance in **2** (the rate ratio being 10^3), but in other systems such as **3**[4] the important participation of the cyclopropyl ring is however inferior as compared to the double bond effect in **4** (the rate ratio of the order 10^{-2}).



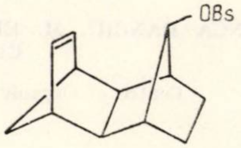
1



2



3



4

From the examples described in the literature some general conclusions could be drawn. The steric factors have a decisive influence on cyclopropyl participation. Due to the great difference between edge- and face-reactivity, the cyclopropane ring must be so oriented that an edge-participation be accomplished. Such a participation is greater when the interaction with the cationic *p*-orbital is symmetrical at both ends of the cyclopropyl bond (greater participation in the case of system **5** in comparison with **6**) and whenever during the ionization the distance between interacting orbitals is diminished (*e.g.* **1** in opposition to **7**[5]). The geometric requirements for overlap between cyclopropane orbitals and the vacant *p*-orbital are more strict than in the case of double bond

12

Previous work in this laboratory has evidenced limited transannular participation (6.5–8.5%) of the double bond in the system **13a**[10] and a considerable participation (>90%) in the solvolyses of the homologous tosylate **13b**.[11]

In the present paper we report the synthesis of tosylates **14a** and **14b** and the study of their solvolyses products.

A. SYNTHESIS AND SOLVOLYSIS OF TOSYLATE 14a

Synthesis and stereochemistry of the starting compounds. The starting materials in the synthesis of alcohol **15** were the dibenzocycloheptatrienyl compounds **18**[12] or **19**.[13] The cyclopropylation after usual methods (Simmons-Smith [14] or with chloroform and potassium-*t*-butoxide [15]) failed. A similar behaviour was observed by Winstein and co-workers [9] in the case of related compounds. The esters **16** and **17** were obtained * using, like the American authors, dibromocarbene generated from phenylmercuric tribromomethane after the Seyferth's procedure. [16,17]

The phenylmercuric bromide (C_6H_5HgBr) used in the preparation of $C_6H_5HgCBr_3$ was obtained after a simpler procedure [18] than the usual one.[17]

The removal of geminal bromine atoms from **16** and **17** was achieved by treatment with $LiAlH_4$ in tetrahydrofurane,[19] which leads to alcohol **15**. The subsequent treatment with tosyl chloride afforded the tosylate **14a**.

The IR, NMR spectra and elemental analyses (see Experimental) are in agreement with the structures **14a**, **15**, **16** and **17**.

The stereochemistry of the dibenzobicyclo[5.1.0]octadiene system **21**** was discussed by Winstein and co-workers [9b] in the course of their study of dibenzohomotropylium cation **10**. The American authors have shown that, from the two possible boat forms **21a** and **21b**, the one

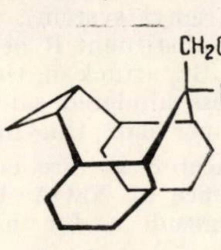
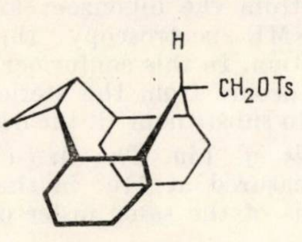
solvolytic behaviour of **14a**, a discussion of the conformation of this compound, which can exist in the form of the two *cis-trans* diastereoisomers, seems necessary.

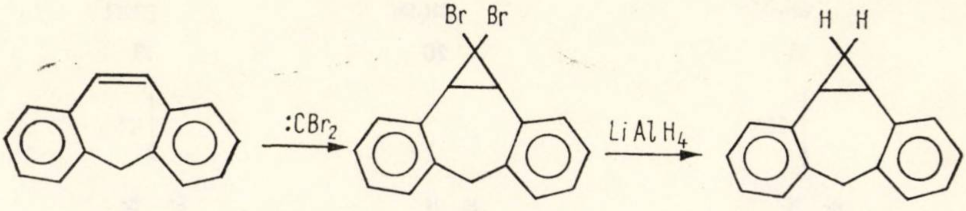


14 a (trans)



14 a (cis)

Hydrocarbon **21** was utilized for comparison in this respect. This hydrocarbon was synthesized after the following scheme, which differs slightly from the known one.[9b]



22 **23** **21**

The NMR spectrum of **21** shows that the two protons from the position 4 differ by 1 ppm in the chemical shift ($\delta_1 = 4.78$; $\delta_2 = 3.56$ ppm) due to the deshielding effect of the cyclopropane ring on the pseudoaxial proton H^1. A similar effect was observed in the case of a related compound, containing an oxirane ring in the place of cyclopropane.[20]

Starting from the values of the chemical shift for the H^1 and H^2-protons in hydrocarbon **21**, the configuration of tosylate **14a** or of other compounds resulting formally by the replacement of a proton with an R radical, may be established by taking into account the chemical shift of the remaining proton at C^4. In the tosylate **14a** and alcohol **15** the signals corresponding to this proton appear at $\delta = 3.90$ and 3.76 ppm, respectively. The introduction of the $-CH_2OTs$ or $-CH_2OH$ moieties must lead to a slight deshielding on the remaining proton at C^4. The observed chemical shift value indicates that this proton corresponds to pseudoequatorial proton H^2 from hydrocarbon **21**. It follows that the substituent ($-CH_2OTs$ or $-CH_2OH$) occupies the pseudoaxial position, which corresponds to a *trans*-configuration. The *trans*-configuration for **16** and **17** was established in a similar way.

The formation of only one of the two possible diastereoisomers, namely the *trans*-one, in the addition of :CBr$_2$ to compounds of the type **18** and **19**, could be explained by the preferred conformation of the starting compounds. Indeed, in the case of compounds **18** and **19** (and in other analogous compounds in which the substituent is separated by one C atom from the dibenzocycloheptatrienyl system), it was proved by dynamic NMR spectroscopy * that the substituent R occupies mainly the *axial* position. In this conformer the : CBr$_2$ attack on the middle-ring double bond occurs from the sterically less hindered side, namely the side opposed to substituent R, the *trans*-isomer being thus formed.

Solvolysis of **14a**. The first-order acetolysis rate constant (titrimetrically measured at 110° in the presence of NaOAc-buffer) of the tosylate **14a** is of the same order of magnitude as for the unsaturated tosylate **13a**.[21] Both rate constants are smaller than those of the saturated analog **26**, due to the rate-retarding effect of the double bond or of the cyclopropane ring, the latter exerting an inductive effect analogous to that of the double bond.

---

* Unpublished results obtained in this laboratory.

$k^{110°}_{AcOH+AcONa}$ $2.33 \times 10^{-5}\ s^{-1}$ $5.40 \times 10^{-5}\ s^{-1}$ $10.70 \times 10^{-5}\ s^{-1}$

In the case of tosylate **14a**, the degree of cyclopropyl participation (if any) seems to be smaller than that of double bond participation in **13a**, if one takes into account that it is solvolyzed two times slower than **13a**. (The double bond participation during the solvolyses of **13a** was proved by isolation of bridged products, 6.5–8.5% [10a]).

The acetolyses of **14a** were performed at reflux for 24 hrs with or without added NaOAc. The formolyses were carried out in the presence of sodium formate (at 100°) because in unbuffered solutions polymeric materials were soon formed (10% after 1 hr).

The solvolysis products (95% yield) were v.p.c.-analysed after $LiAlH_4$-reduction (table 1).

The results presented in table 1 show that the buffered as well as the unbuffered acetolysis of **14a** is accompanied by a middle ring

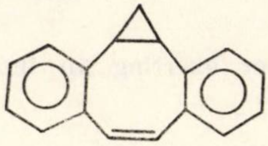
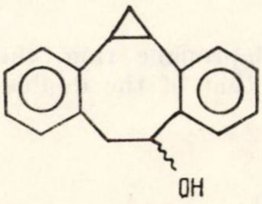
enlargement through which the bicyclo[5.1.0]octanic system **14a** rearranges to the bicyclo[6.1.0]nonanic system.



27



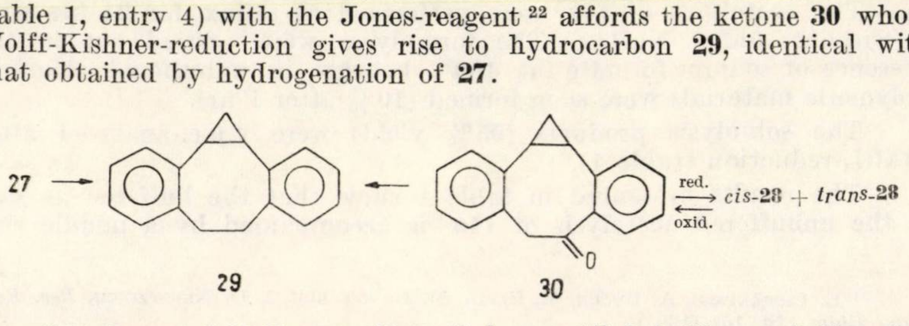
28

The major product (94.5%) in the buffered acetolysis is the alcohol *trans*-**28** (m.p. 131—133°) and in the unbuffered one the hydrocarbon **27** (m.p. 114—115°). This hydrocarbon is also obtained in the buffered formolysis, with a long reaction time (24 hrs). Using a shorter reaction time (1 hr) the product of the formolysis consists of a mixture of the two alcohols *trans*-**28** and *cis*-**28**.

The figures from the last column in table 1 represent the amount of 3—4 components with different v.p.c. retention times, which could not be identified.

The structure of the hydrocarbon **27** results from the elemental analysis, IR and NMR spectra. The catalytic hydrogenation affords the hydrocarbon **29** (m.p. 84—85°).

The alcohols **28** contain the same skeleton as the hydrocarbon **27**. The oxidation of the mixture of the two diastereoisomeric alcohols **28** (table 1, entry 4) with the Jones-reagent [22] affords the ketone **30** whose Wolff-Kishner-reduction gives rise to hydrocarbon **29**, identical with that obtained by hydrogenation of **27**.



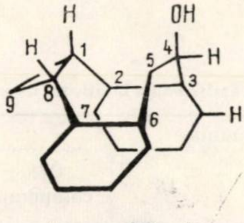
---

[22] K. Bowden, I. M. Heilbron, E. R. H. Jones and B. L. L. Weedon, *J. Chem. Soc.*, **1946**, 39; A. Bowers, T. G. Halsall, E. R. H. Jones and A. J. Lemin, *ibid.*, **1953**, 2555.

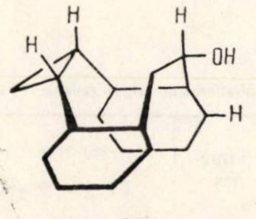
$NaBH_4$-reduction of ketone **30** affords a mixture of two epimeric alcohols **28** (*trans*/*cis* = 39/61). From this mixture the alcohol *cis*-**28** (m.p. 146–148°) was isolated by preparative v.p.c.

As in the case of the system **21** it is plausible that only one of the two boat conformations of the system **28** (pseudoequatorial cyclopropane) is stable: the substituted derivatives also present *cis*-*trans* isomerism.

The configuration of the alcohols *cis*-**28** and *trans*-**28** was established by examination of their NMR spectra recorded in the presence of tris-(dipyvaloilmethanato) europium(III), $Eu(DPM)_3$[23]. In the spectrum of one of the isomers (*cis*-**28**), one of the aromatic protons rapidly shifts on addition of europium shift reagent. In the spectrum of the other



trans - **28**



cis - **28**

somer (trans-**28**) the shift of the corresponding aromatic proton is less pronounced; however, one of the cyclopropane protons (from the position 1) is strongly influenced by $Eu(DPM)_3$ addition.

DISCUSSION

Two results from table 1 need special comment.

We shall first consider the formation of 94.5% alcohol *trans*-**28** and only 2% isomeric alcohol *cis*-**28** in the buffered acetolysis (neutralization of the resulting TsOH). For a discussion about the mechanism of the solvolysis of **14a** it would be useful to know precisely if the *trans*-isomer is the primary reaction product or if *cis*-**28** was initially formed (in addition to *trans*-**28** or as single product) and then rearranged to the *trans*-epimer.

In a control experiment, in which each alcohol (*cis* or *trans*) was heated under the conditions used for buffered acetolysis (acetic acid – NaOAc, 24 hrs, reflux), the starting compounds were recovered unchanged. The analysis of the buffered acetolysis product after a short reaction time (1–4 hrs) indicated that the *cis*-isomer was not formed in more than 1.5% yield (the remaining products were the *trans*-isomer and unreacted tosylate). We may conclude that the *trans*-isomer is the primary product in the buffered acetolysis and that no epimerization of the alcohols occurred under these conditions.

---

[23] C. C. Hinckley, *J. Amer. Chem. Soc.*, **91**, 5160 (1969); J. K. M. Sanders, D. H. Williams, *Chem. Comm.*, **1970**, 422.

Another striking result appearing in table 1 is the formation of a 54.5 : 43.5 mixture of *cis*- and *trans*-**28** alcohols in the buffered formolysis of **14a**, after a short reaction time (1 hr). It was observed [10a] that in some cases the formic acid, even in the presence of HCOONa-buffer (neutralization of the TsOH formed), is strong enough to lead to similar reaction products as in the unbuffered acetolysis. Consequently, some unbuffered acetolyses were performed at short reaction time. The results of such determinations (table 2) indicate that after 1 hr, or even after 7 hrs (reflux), the reaction product contains both *cis* and *trans*-**28** isomers, besides the alkene **27**. The latter becomes the main component of the reaction mixture after 24 hrs.

Table 2

Unbuffered acetolysis products of 14 a (118°; v.p.c. analysis after $LiAlH_4$-reduction)

Time hrs	% Compounds				
	27	*trans*-**28**	*cis*-**28**	**15**	Other compounds
1	3.5	9.0	7.5	77.0	3.0
5	14.0	8.0	36.0	38.0	4.0
7	31.5	7.5	29.5	29.0	2.5
24	90.0	3.0	6.0	—	1.0

The starting alcohol **15**, registered in table 2, results from the unreacted tosylate **14a** during $LiAlH_4$-reduction; the $-CH_2OH$ group was not found to be further reduced to $-CH_3$. A similar behaviour was also observed in the case of other tosylates.[24]

The control experiments showed an interconvertibility of *cis*- and *trans*- alcohols under unbuffered acetolysis conditions. On treatment of the *trans*- alcohol (or more correctly, an acetolysis product containing 91% *trans*-**28**) with *p*-toluenesulphonic acid in refluxing acetic acid, both isomers (*cis* and *trans*) were observed even after 1 hr (table 3). The alkene **27** occurs in steadily greater proportions, becoming the main component after 10 hrs. The figures from the last column (table 3) correspond to small amounts of starting alcohol (1–2%) besides 2–3 unidentified components. The *cis*- isomer was found te behave similarly; large amounts were recovered after short time as *trans*-isomer.

The practically quantitative formation of the alcohol *trans*-**28** during the buffered acetolysis of **14a** indicates that the reaction is highly stereospecific. An explanation of this behaviour must certainly be sought in the structure of the intermediates through which the rearrangement **14a** → *trans*-**28** occurs. The phenyl group assists from the back-side the ionization of the $-CH_2OTs-$group, situated in the favourable pseudoaxial position. The nucleophilic attack on the phenonium ion **31** which

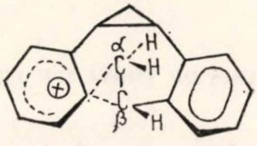
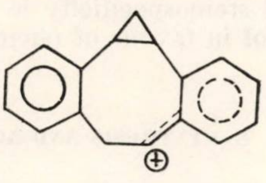
* *p*-TsOH in AcOH at 118°.

results could be realized only from the side originally occupied by the tosyl group.



31



32

The examination of models indicated that the β-attack leads to a ring-enlarged product in which the substituent (—OAc) occupies a pseudoaxial position (*trans*-configuration), in agreement with the observed results.

The preferred β-attack could be due to the fact that the final eight-membered ring product is less strained than the seven-membered ring compound, which might result through α-attack.

The ring-enlargement could also occur through a benzylic ion **32**, resulted from **14a** by a simple Wagner-Meerwein rearrangement with phenyl migration. However, such an intermediate would yield a mixture of the two epimeric acetates *trans*- and *cis*-**28**-**OAc** (as the reduction of the ketone **30** gives rise to a 4 : 6 mixture of both alcohols).

The stereochemistry of the reaction product *trans*-**28** may be regarded as evidence for the intervention of phenonium ion.

The subsequent transformation of the primary solvolytic product *trans*-**28** is consistent with the intermediacy of a benzylic ion. In the presence of *p*-toluenesulphonic acid (unbuffered acetolysis) or formic acid (buffered formolysis), reionization of *trans*-**28**-**OAc** leads to the benzylic cation **32** which can subsequently yield both *trans*- and *cis*-**28** epimers.

This SN1 reaction is accompanied by an irreversible elimination reaction affording the alkene **27** which becomes, after a few hours, the main reaction product. The latter reaction makes difficult the determination of the equilibrium ratio of the two epimers.

The small amounts of *cis*-**28** alcohol and alkene **27** which appear even in the buffered acetolysis suggest also a rearrangement **31** → **32**. This rearrangement would proceed with a smaller rate than the collapse with $^{-}$OAc ion which yields **28-OAc**.

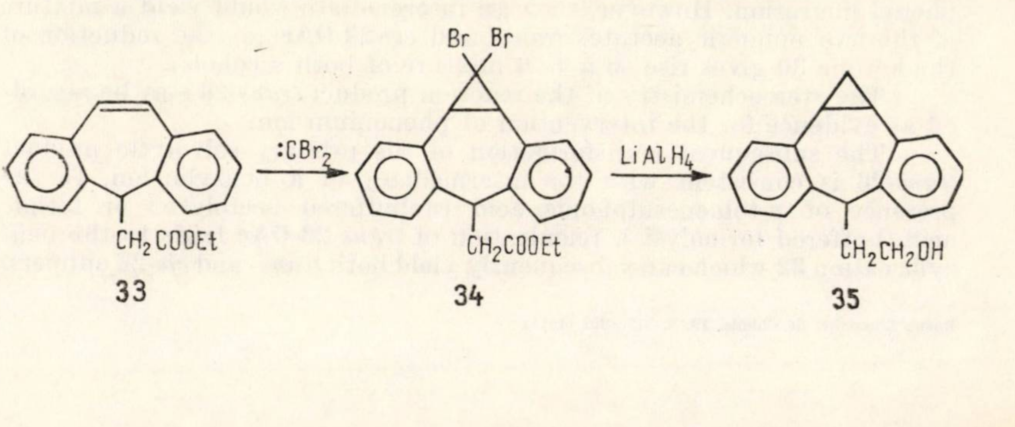
The *trans*-configuration of **14a**, having a pseudoaxial $-CH_2OTs$ group, is favourable to a cyclopropyl ring participation and the opening of this ring would diminish the ring strain in the skeleton. Nevertheless, the analysis of the solvolysis products indicates that this participation, if it occurs, is very feeble (some products of cyclopropyl participation could be found among the unidentified minor components — table 1, last column). It must be mentioned here that even in the case of the related tosylate **13a** the double bond assistance is limited.[10a]

The stabilizing influence provided by the aromatic ring is more important than that of the cyclopropane ring and the formation of the phenonium ion **31** is favoured over that of other possible intermediates. The observed stereospecificity in the buffered acetolysis could be considered as a proof in favour of phenonium ion intervention.

B. SYNTHESIS AND ACETOLYSIS OF TOSYLATE 14b

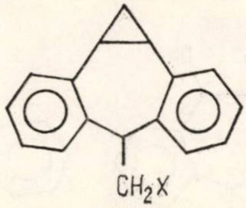
Previous work carried out in this laboratory [11] showed that in the tosylate **13b** favourable conditions for interaction between cationic center and the median double bond exist; the ionization is assisted by the double bond, the bridged products representing 85% of the reaction products. By analogy, the lengthening of the side-chain could also have a favourable effect in the case of **14**. To substantiate this hypothesis the solvolytic behaviour of tosylate **14b** was examined.

The synthesis of dibenzobicyclo[5.1.0]octadien-4-yl-ethanol(**35**) by a similar method as that applied for **15** (the addition of $:CBr_2$ to dibenzocycloheptatrien-7-yl-ethylacetate (**33**) [11a]) proceeds with a low yield (18%).



33 34 35

Better results (65%) were obtained by lengthening the side-chain of the tosylate **14a**, by usual procedures.



a) X = — CN
b) X = — COOH
c) X = — COOEt

36

The conversion of tosylate **14a** to the nitrile **36a** was effected on treatment with NaCN in DMSO. The hydrolysis of this compound and the subsequent esterification of **36b** and LiAlH$_4$-reduction of **36c** affords the alcohol **35**. The tosylate **14b** was obtained from **35** by a standard procedure. All the above compounds, including the tosylate **14b**, present the *trans*-configuration, as it results from the synthetic way.

The kinetic determination of the acetolyses of **14b** indicated rate constants of the order of magnitude 10^{-5}:

	14b	**13b**	**37**
$k^{110°}_{AcOH}$	$1.25 \times 10^{-5} s^{-1}$	$2.04 \times 10^{-4} s^{-1}$	$1.34 \times 10^{-5} s^{-1}$
$k^{110°}_{AcOH+AcONa}$	$1.87 \times 10^{-5} s^{-1}$	$2.17 \times 10^{-4} s^{-1}$	$1.47 \times 10^{-5} s^{-1}$

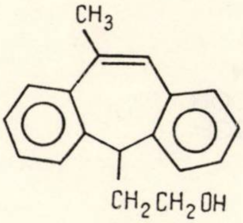
These rate constants are nearly equal to those of the saturated tosylate **37**, but visibly smaller than those of the unsaturated tosylate **13b**[25] or of other systems in which the double bond assistance was demonstrated.

The composition of the reaction mixture in the unbuffered acetolysis of **14b** (reflux for 60 hrs, about 10 half-lives) was v.p.c. determined after the LiAlH$_4$-reduction of the crude reaction product. Three major components were evidenced : the starting alcohol **35** (48%), the alcohol **38** (37%) and the diol **39** (12%), the remaining 3% representing unidentified components.

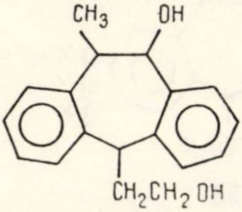
---

[25] M. Voicu and F. Badea, *Rev. Roumaine Chim.*, **14**, 929 (1969).

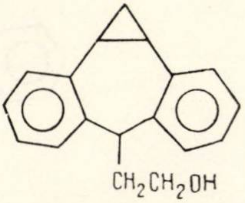
The compounds **38** and **39** were separated by preparative v.p.c. and their structures were tentatively assigned on the basis of NMR spectra in the presence of the shift reagent $Eu(DPM)_3$.



38

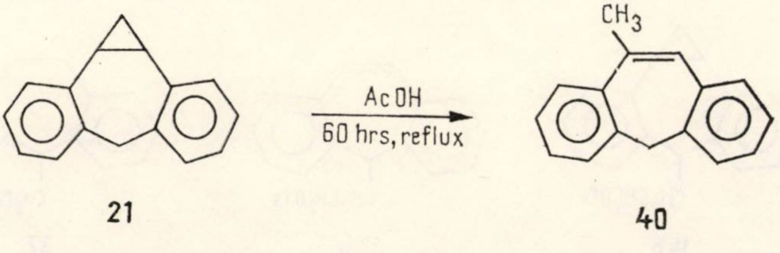


39



35

The compounds **38** and **39** were probably formed by the opening of the cyclopropane ring under the reaction conditions and not by cyclopropyl participation during solvolysis. Additional evidence was provided by the fact that the known [26] hydrocarbon **40** was formed on treating the hydrocarbon **21** under the same conditions as in the solvolysis of **14b**.



The acetolysis of **14b** using shorter reaction times (approx. 5 half-lives) yields the acetate of the unrearranged alcohol **35** in 93% yield.

In the buffered acetolysis of **14b** (5 or 10 half-lives) the same acetate of the starting alcohol was obtained in more than 90% yield.

The first question which may arise concerning the above mentioned solvolyses is why the tosylates **13b** and **14b** differ so significantly in their solvolytic behaviour; if in the first case, the double-bond assistance was proved by rate constants as well as by products, in the second case the elusive cyclopropyl participation could not be demonstrated by either of these criteria. Two explanations are available in this respect: (a) the more strict steric conditions necessary for cyclopropyl participation [4-6] as compared with double bond assistance and (b) the impossibility of the two carbon atom side-chain of tosylate **14b** to reach the conformation required for assistance. Indeed, in compound **14b** the two H-atoms dotted in the formulas are more oriented towards the median ring than the vinyl hydrogens of **13b**; it is thus plausible that the cyclopropane ring is not easily accesible to the$-CH_2OTs$ group.

13b

EXPERIMENTAL

Melting points are uncorrected. IR spectra were recorded with a double-beam UR-20 Carl Zeiss Jena spectrophotometer. NMR spectra were obtained on a Varian A-60 A spectrometer using TMS as internal standard. The v.p.c. analyses were performed on a Carlo Erba model D gas chromatograph using Neopentylglycol succinate columns (3% on Chromosorb W), 2 m, at 205°, with a hydrogen rate-flow of 35 ml/min. The v.p.c. separations were carried out on a preparative Carlo Erba model GV chromatograph using silicone oil OV7 (20% on Chromosorb W), 1.25 m, 210°, with a hydrogen rate-flow of 100 ml/min.

The acetate of 2:3.5:6-dibenzo-8.8-dibromobicyclo[5.1.0]octa-2.5-dien-4-yl-methanol (**16**). A mixture of acetate **18** (6.6 g; 25 mmoles) and phenylmercuric tribromomethane (16 g; 30 mmoles)[16] in anhydrous benzene (30 ml) was heated with magnetic stirring at 85° for 3 hrs. The starting materials were rapidly dissolved and a precipitate of phenylmercuric bromide (m.p. 285–286°) was formed. The reaction mixture was cooled, then filtered and anhydrous ether (100 ml) was added to the filtrate. The solution was left overnight in a refrigerator and evaporated *in vacuo* after further filtration of some phenylmercuric bromide. The remaining material was easily crystallized by adding a few drops of methanol. The acetate **16** (6.5 g; 60%), m.p. 151–3° (methanol). (*Found*: C, 52.46; H, 3.80; Br, 36.71. $C_{19}H_{16}Br_2O_2$ requires C, 52.32; H, 3.69; Br, 36.64%). *IR spectrum* (CS_2; cm^{-1}): 762 vs, 784 vs, 1220 vs, 1742 vs, 3021 m, 3060 m. *NMR spectrum* ($CDCl_3$, δ ppm): 1.85 (s, 3H, $COCH_3$); 3.51 (s, 2H cyclopropyl); 3.90 (1H, Ar$CH$Ar, J = 8.15 Hz); 4.71 (m, 2H, J = 8.15 Hz); 7.1–7.6 (m, 8H arom.).

The phenylmercuric tribromomethane utilized in this reaction was prepared after Seyferth's procedure[17] and phenylmercuric bromide was obtained[18] from phenylmercuric acetate and NaBr.

2:3.5:6-Dibenzo-8.8-dibromobicyclo[5.1.0]octa-2.5-dien-4-yl-ethyl carboxylate (**17**). The addition of $:CBr_2$[16] to the ester **19** was performed in the same way as described for **16**. The ester **17** obtained in a 60% yield showed a m.p. 142–143° (ethanol). (*Found*: C, 52.59; H, 3.87; Br, 36.50. $C_{19}H_{16}Br_2O_2$ requires C, 52.32; H, 3.69; Br, 36.64. *IR spectrum* (CS_2;

cm^{-1}) : 723 s, 752 s, 1030 s, 1201 vs, 1741 vs, 2980 m, 3024 m, 3070 w. *NMR spectrum* ($CDCl_3$; δ ppm) : 1.19 (t, 3H, J = 7 Hz) ; 3.34 (s, 2H cyclopropyl) ; 4.19 (q, 2H, J = 7 Hz) ; 4.49 (s, 1H, ArC*H*Ar) ; 7.1–7.5 (m, 8H arom.).

2 :3.5 :6-Dibenzobicyclo[5.1.0]octa-2.5-dien-4-yl-methanol (**15**). To a suspension of $LiAlH_4$ (1.90 g ; 50 mmoles) in anhydrous tetrahydrofurane [19] (THF ; 15 ml) a solution of acetate **16** (or ester **17**) (4.36 g ; 10 mmoles) in THF (25 ml) was added dropwise with stirring during 1 hr. The reaction mixture was heated for 16 hrs at reflux, then cooled and decomposed with a cold 10% solution of H_2SO_4. After ether-extraction the organic layer was washed with water, dried and evaporated *in vacuo* affording the alcohol **15**, (2.2 g ; 93 %), m.p. 87–89° (*n*-hexane). (*Found* : C, 86.34 ; H, 6.74 ; $C_{17}H_{16}O$ requires C, 86.40 ; H, 6.82). *IR spectrum* (CS_2 ; cm^{-1}) : 770 vs, 1035 vs, 2890 m, 2920 m, 2960 m, 3028 m, 3070 m, 3079 m, 3200–3550 wm, 3600 m. *NMR spectrum* ($CDCl_3$; δ ppm) : 0.66 (m, 1H cyclopropyl, J_{trans} = = 5.5 Hz, J_{gem} = 4 Hz) ; 1.52 (m, 1H cyclopropyl, J_{cis}= 9 Hz, J_{gem} = 4 Hz) ; 2.4 (q, 2H cyclopropyl, J_{cis} = 9 Hz, J_{trans} = 5.5 Hz) ; 3.78 (1H, ArC*H*Ar, J = 7.9 Hz) ; 4.38 (2H, J = = 7.9 Hz) ; 6.9 –7.5 (m, 8H arom.).

The $LiAlH_4$-reduction of acetate **16** in diethyl ether (4 hrs, reflux) gave rise to the corresponding alcohol whose reaction with *n*-Bu_3SnH [27] afforded the same alcohol **15**.

2 :3.5 :6-Dibenzobicyclo[5.1.0]octa-2.5-dien-4-yl-methyl tosylate (**14a**). To a cold solution of alcohol **15** (2.36 g ; 10 mmoles) in 5 ml anhydrous ether and 1.2 ml (15 mmoles) anhydrous pyridine, tosyl chloride (2 g ; 10.5 mmoles) was added in small portions. After keeping for 24 hrs at 0° the reaction mixture was decomposed with cooled water when tosylate **14a** precipitated (3.7 g ; 94.1%), m.p. 151–3° (ethanol). (*Found* : C, 73.97 ; H, 5.78 ; S, 7.93. $C_{24}H_{22}O_3S$ requires C, 73.82 ; H, 5.68 ; S, 8.21). *IR spectrum* (CCl_4 ; cm^{-1}) : 971 s, 1180 s, 1191 s, 1379 s, 2926 w, 3028 w, 3069 w. *NMR spectrum* ($CDCl_3$; δ ppm) : 0.58 (m, 1H cyclopropyl, J_{trans} = 5.5 Hz, J_{gem} = 4 Hz) ; 1.45 (m, 1 H cyclopropyl, J_{cis} = 9 Hz, J_{gem} = 4 Hz) ; 2.18 (q, 2H cyclopropyl, J_{cis} = 9 Hz, J_{trans} = 5.5 Hz) ; 3.91 (t, 1H, ArC*H*Ar, J =7.9 Hz) ; 4.92 (d, 2H, J = 7.9 Hz) ; 6.95–7.7 (m, 12 H arom.).

The unbuffered acetolyses of tosylate **14a**. A solution of tosylate **14a** (3.9 g ; 10 mmoles) in anhydrous acetic acid (80 ml) was heated at 118° for 24 hrs (about 10 half-lives). The reaction mixture was poured into water, neutralized with Na_2CO_3 and ether-extracted. The combined ether extracts were washed with water, dried and the solvent was then removed *in vacuo*. The partially crystallized residue (2.1 g) dissolved in anhydrous ether (50 ml) was added dropwise with stirring to a suspension of $LiAlH_4$ (1 g) in 30 ml anhydrous ether. The reaction mixture was then refluxed for 6 hrs, left overnight and worked-up in the usual manner. The partially crystallized product (1.95 g ; 95.5%) was v.p.c.-analysed, (see table 1). By column-chromatography of the reaction mixture on neutral alumina *2 :3.6 :7-dibenzobicyclo[6.1.0]nona-2.4.6-triene* (**27**) was isolated (1.7 g ; 87%) on elution with petroleum ether. The alkene **27** m.p. 115° (methanol). (*Found* : C, 93.38 ; H, 6.52. $C_{17}H_{14}$ requires C, 93.53 ; H, 6.47). *IR spectrum* (CS_2 ; cm^{-1}) : 760 s, 771 vs, 1031 m, 2986 m, 3006 m, 3021 m, 3068 m. *NMR spectrum* (CCl_4 ; δ ppm) : 0.9–1.6 (m, 2H cyclopropyl) ; 2.26 (q, 2H cyclopropyl, J_{cis} = 8.2 Hz, J_{trans} = 5.5 Hz) ; 6.89 (s, 2H olef.) ; 6.9–7.5 (m, 8H arom.).

By continuing the elution of the chromatography column with diethyl ether — petroleum ether (1 : 1) mixture, a crystallized product with m.p. 131–9° was obtained (0.15 g, 7%). The v.p.c.-analysis of this product indicated the presence of three components which were identified by comparison with authentic samples (*vide infra*) as : alcohol *trans*-**28**, alcohol **15** and alcohol *cis*-**28**.

---

[27] D. Seyferth, H. Jamazaki, D. Alleston, *J. Org. Chem.*, **28**, 703 (1963).

NaOAc buffered acetolysis of tosylate **14 a**. A solution of tosylate **14 a** (3.9 g;10 mmoles) and anhydrous NaOAc (2.46 g; 30 mmoles) in 80 ml anhydrous acetic acid was hoated at 118° for 24 hrs. The reaction mixture afforded 2.8 g (97.8%) of a crystalline product which was subsequently $LiAlH_4$ reduced. The usual work-up gave rise to a white crystalline product (2.2 g; 92%) the composition of which was established by means of v.p.c. (see table 1). No pure compound could be isolated by alumina column chromatography. By recrystallization of the crude acetolysis product (after $LiAlH_4$-reduction) from *n*-hexane, the main component, *trans-2:3.6:7-dibenzobicyclo[6.1.0]nona-2.6-dien-4-ol* (**28**) was obtained. The *trans*-**28** alcohol (structure assigned from $Eu(DPM)_3$–NMR spectra), (95% purity), m.p. 131–3° (*Found*: C, 86.41; H, 7.00. $C_{17}H_{16}O$ requires C, 86.40; H, 6.82). *IR spectrum* (CS_2; cm^{-1}): 753 vs, 763 vs, 1009 m, 3602 m. *NMR spectrum* ($CDCl_3$; δ ppm): 1.1–1.7 (m, 2H cyclopropyl); 2.1 (s, 1H, OH); 2.5 (m, 2H cyclopropyl, $J_{gem} = 13.5$ Hz, $J'_{vic} = 8$ Hz); 5.04 (q, 1H, $J'_{vic} = 8$ Hz, $J_{vic} = 9.2$ Hz); 6.85–7.3 (m, 8H arom.).

Two minor components: the alkene **27** and the alcohol **15** were v.p.c. identified by comparison with authentic samples. The structure of another component, formed in a small amount (2%) during this solvolysis was chromatographically proved, its retention time being identical with that of the alcohol *cis*-**28**. This isomer could be obtained by preparative v.p.c. applied to the mixture of alcohols *trans*-**28** and *cis*-**28** formed in the $NaBH_4$-reduction of the ketone **30** (*vide infra*).

The oxidation of the mixture of alcohols trans-**28** and *cis*-**28**. To an acetone (15 ml) solution of the buffered-acetolysis product of **14a** after $LiAlH_4$ reduction (0.23 g) (which contained 94% alcohol *trans*-**28**) Jones reagent [22] (0.5 ml) was added dropwise with stirring until the yellow colour of the reaction mixture was maintained. After 5 minutes, isopropanol (0.2ml) was added to decompose the excess reagent, then 20 ml water were poured and the reaction mixture was ether-extracted. The organic solution was washed with a conc. solution of Na_2CO_3, dried and evaporated *in vacuo*. *2:3.6:7-Dibenzobicyclo[6.1.0]nona-2.6-dien-4-one* (**30**) was formed (0.2 g; 88%), m.p. 124–4,5° (methanol). *Found*: C. 87.01; H, 6.16, $C_{17}H_{15}O$ requires C, 87.14; H, 6.02). *IR spectrum* (CS_2; CCl_4; cm^{-1}): 768 vs, 775 vs, 1020 m. 1242 m, 1689 vs, 2925 w, 3028 m, 3082 m. *NMR spectrum* (CCl_4; δ ppm): 1.1–1.8 (m, 2H cyclopropyl); 2.40 (q, 2H cyclopropyl, $J_{cis} = 8.5$ Hz, $J_{trans} = 5.5$ Hz); 3.69 (d, 1H, $J_{gem} = 16.5$ Hz); 4.68 (d, 1H, $J_{gem} = 16.5$ Hz); 6.8–7.5 (m, 8H arom.).

The oxime of the ketone **30**, m.p. 235–237° (ethanol). (*Found*: C, 82.10; H, 6.2; N. 5.57.$C_{17}H_{15}NO$ requires C, 81.90; H, 6.06; N, 5.62).

$NaBH_4$ reduction of 2:3.5:6-dibenzobicyclo[6.1.0]nona-2.6-dien-4-one (**30**). To a solution of ketone (0.5 g; 2.13 mmoles) in 30 ml ethanol, a solution of $NaBH_4$ (0.05 g; 13 mmoles) in 15 ml water containing 0.06 ml 2N NaOH was added dropwise at room temperature(evolution of gases), left overnight, then most of the solvent evaporated. Water was added to the residue and the product was isolated by filtration. The v.p.c.-analysis indicated two components: the alcohol *trans*-**28** (39%) (identical with the major product of the buffered acetolysis of **14 a**) and another component (61%) which was preparatively-v.p.c. separated (93% purity), m.p. 145–8°. The NMR spectrum of this compound in the presence of $Eu(DPM)_3$ indicated the configuration of the alcohol *cis*-**28**. IR spectrum (CS_2; cm^{-1}): 756 vs, 766 vs, 1031 m, 3602 m. *NMR spectrum* ($CDCl_3$; δ ppm): 1.1–1.6 (m, 2H cyclopropyl); 2.12 (s, 1H, OH); 2.35 (q, 2H cyclopropyl, $J_{cis} = 8.5$ Hz, $J_{trans} = 5$ Hz); 2.82 (q, 1H, $J_{gem} = 15$ Hz, $J_{vic} = 6.2$ Hz); 4.10 (q, 1H, $J_{gem} = 15$ Hz, $J'_{vic} = 9$ Hz); 6.11 (q, 1H, $J_{vic} = 6.2$ Hz, $J_{vic} = 9$ Hz); 6.8–7.6 (m, 8H arom.).

HCOONa buffered formolysis of tosylate **14a**. A solution of tosylate **14 a** (3.9 g; 10 mmoles) and anhydrous HCOONa (2.04 g; 30 mmoles) in 80 ml 99% formic acid was heated at 100.5° for 24 hrs. The product analysis after 1 hr and 24 hrs was performed by v.p.c. of the reaction mixtures after $LiAlH_4$-reduction (see table 1, entries 3 and 4). The work-up was the same as in the acetolyses of **14 a** (*vide supra*). In the reaction mixture the hydrocarbon **27** and the alcohols *trans*-**28** and *cis*-**28** were identified by comparison with authentic samples.

Reaction of the buffered-acetolysis product of **14 a** *in acid medium.* A solution of the buffered-acetolysis product of **14 a** (after $LiAlH_4$-reduction) (0.23 g, containing approximately 91% *trans*-**28**) and *p*-toluenesulphonic acid (0.172 g; 1 mmole) in 25 ml anhydrous acetic acid was heated at 118°. Samples were extracted at the times registered in table 3. After the usual work-up and $LiAlH_4$-reduction, oily or partially crystallized reaction mixtures were obtained, which were subsequently v.p.c.-analysed (see table 3).

*Reaction of the alcohols trans-***28** *and cis-***28** *in NaOAc—AcOH.* A sample of alcohol *trans*-**28** (0.23 g; 1 mmole) (91% purity) (or *cis*-**28**; 94% purity) and anhydrous NaOAc (0.24 g; 3 mmoles) were heated in 25 ml anhydrous acetic acid for 24 hrs at 118°. After the work-up and $LiAlH_4$-reduction (as in the acetolysis of **14 a**) the product (0.22 g; 96%) was found to be identical with the starting material.

2:3.6:7-Dibenzobicyclo[6.1.0]nona-2.6-diene (**29**).

a) *By Wolff-Kishner procedure* applied to the ketone **30**, the saturated hydrocarbon **29** was obtained (0.15 g; 80%), m.p. 84—6° (methanol). (*Found*: C, 92.60; H, 7.40. $C_{17}H_{16}$ requires: C, 92.73; H, 7.27). *IR spectrum* (CS_2; cm^{-1}): 758 vs, 769 vs, 2891 w, 2940 m, 3021 m, 3062 m, 3074 m. *NMR spectrum* (CS_2; δ ppm): 1.1—1.6 (m, 2H cyclopropyl, J_{cis} = 8.2 Hz, J_{trans} = 5.5 Hz); 2.30 (q, 2H cyclopropyl J_{cis} = 8.2 Hz, J_{trans} = 5.5 Hz); 2.65—3.82 (m, 4H, syst. A_2B_2); 6.75—7.1 (m, 8H arom.).

b) *The reduction of hydrocarbon* **27**. The hydrocarbon **27** (0.22 g; 1 mmole) was hydrogenated in ethanol (25 ml) in the presence of PtO_2 catalyst (room temperature, atmospheric pressure). After usual work-up the saturated hydrocarbon **29** (0.2 g; 98%), m.p. 84—6° was obtained. This hydrocarbon was identical with that obtained from ketone **30**.

2:3.5:6-Dibenzobicyclo [5.1.0] octa-2.5-diene (**21**). A mixture of hydrocarbon **22** (4.75 g; 25 mmoles) and phenylmercuric tribromomethane (16 g; 30 mmoles) in 30 ml anhydrous benzene was heated with stirring at 85° for 3 hrs. After the work-up as in the case of acetate **16**, it was obtained *2:3.5:6-dibenzo-8.8-dibromobicyclo[5.1.0]octa-2.5-diene* (**23**) (3.64 g; 45%), m.p. 138—40° (methanol). (*Found*: C, 52.60; H, 3.20; Br, 43.85. $C_{16}H_{12}Br_2$ requires C, 52.75; H, 3.29; Br, 43.96. *IR spectrum* (CS_2; cm^{-1}): 752 s, 780 s, 1030 m, 2851 w, 2950 w, 3027 m, 3068 m. *NMR spectrum* ($CDCl_3$; δ ppm): 3.33 (d, 1H, ArC*H*Ar, J = 13 Hz); 3.41 (s, 2H cyclopropyl); 4.58 (d, 1H, ArC*H*Ar, J = 13 Hz); 7.10—7.70 (m, 8H arom.).

The dibromoderivative **23** (3.64 g; 10 mmoles) was reduced with $LiAlH_4$ (1.9 g; 50 mmoles) in anhydrous THF (15 ml) for 16 hrs at reflux. After the usual work-up the hydrocarbon **21** was obtained. Elemental analysis, IR and NMR spectra correspond to the literature data.[9b]

2:3.5:6-Dibenzobicyclo[5.1.0]octa-2.5-dien-4-yl-acetonitrile (**36 a**) was synthesized in 89% yield from tosylate **14 a** and NaCN after a procedure described [28] for 4-cyanocyclopentene. The nitrile **36 a** m.p. 99—100.5° (methanol). (*Found*: C, 87.98; H, 6.30; N, 5.93. $C_{18}H_{15}N$ requires C, 88.16; H, 6.13; N, 5.71). *IR spectrum* (CCl_4; cm^{-1}): 931 m, 1120 m, 1493 s, 2251 w, 2928 s, 2980 m, 3021 s, 3068 s. NMR spectrum ($CDCl_3$; δ ppm): 0.68 (m, 1H cyclopropyl, J_{gem} = 4 Hz, J_{trans} = 5.5 Hz); 1.59 (m, 1H cyclopropyl, J_{gem} = 4 Hz, J_{cis} = 8.2 Hz); 2.47 (q, 2H cyclopropyl, J_{cis} = 8.2 Hz, J_{trans} = 5.5 Hz); 3.42 (2H, J = 8.3 Hz); 3.91 (1H, J = 8.3 Hz); 6.9—7.6 (m, 8H arom.).

---

[28] C. E. Johnson, J. E. Keiser and J. C. Sharp, *J. Org. Chem.*, **34**, 860(1969).

2:3.5:6-Dibenzobicyclo[5.1.0]octa-2.5-dien-4-yl-acetic acid (**36 b**). The hydrolysis of nitrile **36a** in alkaline solution as described [29] for 5-carboxymethyl bicyclo[2.2.2]oct-2-ene affords the acid **36 b** in 95% yield, m.p. 194–5° (methanol). (*Found*: C, 81.75; H, 6.20. $C_{18}H_{16}O_2$ requires C, 81.79; H, 6.10). *IR spectrum* (CCl_4; cm^{-1}): 940 w, 1120 w, 1410 m, 1713 s, 2400–3300 associated OH absorption. *NMR spectrum* ($CDCl_3$; δ ppm): 0.66 (m, 1H cyclopropyl, $J_{trans} = 5.5$ Hz, $J_{gem} = 4$ Hz); 1.52 (m, 1H cyclopropyl, $J_{gem} = 4$ Hz, $J_{cis} = 8.5$ Hz); 2.48 (q, 2H cyclopropyl, $J_{cis} = 8.5$ Hz, $J_{trans} = 5.5$ Hz); 3.48 (2H, $J = 7.9$ Hz); 4.16 (q, 1H, $J = 7.9$ Hz); 6.85–7.5 (m, 8H arom.); 10.1 (s, 1H, COOH).

2:3.5:6-Dibenzobicyclo[5.1.0]octa-2.5-dien-4-yl-ethylacetate (**36c**) was obtained in 90% yield by direct esterification of the acid **36 b**. The ester **36 c** m.p. 60–61.5° (ethanol). (*Found*: C, 82.34; H, 7.05. $C_{20}H_{20}O_2$ requires C, 82.19; H, 6.85). *IR spectrum* (CS_2; cm^{-1}): 751 s, 761 s, 811 s, 1176 vs, 1186 vs, 1376 vs, 2922 m, 2981 m, 3046 m, 3062 m. *NMR spectrum* (CCl_4; δ ppm): 0.64 (m, 1H cyclopropyl, $J_{gem} = 3.5$ Hz, $J_{trans} = 5$ Hz); 1.03 (t, 3H, $J = 7$ Hz); 1.5 (m, 1H cyclopropyl, $J_{cis} = 8.2$ Hz, $J_{gem} = 3.5$ Hz); 2.48 (q, 2H cyclopropyl, $J_{cis} = 8.2$ Hz, $J_{trans} = 5$ Hz); 3.3 (d, 2H, $J = 7.9$ Hz); 3.91 (q, 2H, $J = 7$ Hz); 4.1 (t, 1H, $J = 7.9$ Hz); 6.7–7.5 (m, 8H arom.).

2:3.5:6-Dibenzobicyclo[5.1.0]octa-2.5-dien-4-yl-β-ethanol (**35**) was obtained (88%) by the reduction of the ester **36c** with $LiAlH_4$, m.p. 83–4.5° (methanol). (*Found*: C, 86.16; H, 7.25. $C_{18}H_{18}O$ requires C, 86.40; H, 7.20. *IR spectrum* (CCl_4; cm^{-1}): 1031 s, 1048 s, 1380 m, 1492 m, 2878 m, 2925 m, 2960 m, 3061 m, 3250–3600 s, 3639 m. *NMR spectrum* ($CDCl_3$; δ ppm): 0.68 (m, 1H, cyclopropyl, $J_{trans} = 5.2$ Hz, $J_{gem} = 3.5$ Hz); 1.56 (m, 1H cyclopropyl, $J_{cis} = 8.2$ Hz, $J_{gem} = 3.5$ Hz); 1.92 (s, 1H, OH); 2.40 (q, 2H cyclopropyl, $J_{cis} = 8.2$ Hz, $J_{trans} = 5.2$ Hz); 2.55 (q, 2H, $J = 7.5$ Hz); 3.59 (t, 2H, $J = 7.5$ Hz); 3.78 (t, 1H, $J = 7.5$ Hz); 6.9–7.5 (m, 8H, arom.).

2:3.5:6-Dibenzobicyclo[5.1.0]octa-2.5-dien-4-yl-β-ethyl tosylate (**14 b**). The treatment of the alcohol **35** with tosyl chloride led to the tosylate **14 b** (99%), m.p. 107–8° (ethanol). (*Found*: C, 74.06; H, 6.05; S, 7.64. $C_{25}H_{24}O_3S$ requires C, 74.22; H, 5.98; S, 7.93). IR spectrum (CS_2; cm^{-1}): 751 s, 761 s, 811 s, 1176 vs, 1186 vs, 1370 vs, 2922 m, 2981 m, 3046 m, 3062 m. *NMR spectrum* ($CDCl_3$; δ ppm): 0.61 (m, 1H cyclopropyl, $J_{gem} = 4$ Hz, $J_{trans} = 5.5$ Hz); 1.52 (m, 1H cyclopropyl, $J_{gem} = 4$ Hz, $J_{cis} = 8.2$ Hz); 2.36 (q, 2H cyclopropyl, $J_{cis} = 8.2$ Hz, $J_{trans} = 5.5$ Hz); 2.42 (s, 3H, CH_3); 2.71 (m, 2H); 3.68 (t, 1H, $J = 8$ Hz); 3.90 (t, 2H, $J = 6.5$ Hz); 6.85–7.9 (m, 12H arom).

Solvolysis of the tosylate **14 b** was carried out under the same conditions as those used for the tosylate **14 a**. After 5 half-lives the unbuffered as well as the buffered acetolyses afforded (after $LiAlH_4$-reduction) the starting alcohol **35** in more than 90% yield. The same result was obtained from the buffered acetolysis after 10 half-lives. The unbuffered acetolysis gave rise after 10 half-lives (and $LiAlH_4$-reduction) to a mixture (93% yield) whose v.p.c.-analysis indicated the presence of three components: the alcohols **35** (48%), **38** (37%) and **39** (12%). These components could be separated by means of v.p.c. affording the starting alcohol **35**, the alcohol **38** (92.8% purity) and the diol **39** (84.2% purity). The alcohols **38** and **39** (uncrystallized viscous oils) were identified by their NMR spectra. In the case of the compound **38** two conformers were evidenced: axial and equatorial (3 : 1 ratio). *NMR spectra* ($CDCl_3$; δ ppm): *axial conformer*: 1.5 (s, 1H, OH); 1.95 (m, 2H, $J_1 = 7.5$ Hz, $J_2 = 6-6.5$ Hz); 2.40 (d, 3H, $J_{allyl} = 1-1.5$ Hz); 3.30 (t, 2H, $J_2 = 6-6.5$ Hz); 4.13 (t, 1H, $J_1 = 7.5$ Hz); 6.90 (q, 1H olef., $J_{allyl} = 1-1.5$ Hz); 6.95–7.6 (m, 8H arom.); *equatorial conformer*:

[29] H. W. WHITLOCK and M. W. SIEFKEN, *J. Amer. Chem. Soc.*, **90**, 4929 (1968

2.45 (d, 3H, $J_{allyl} = 1-1.5$ Hz) ; 2.68 (2H, $J_1 = 7.5$ Hz, $J_2 = 6-6.5$ Hz) ; 3.70 (t, 2H, $J_2 = 6-6.5$ Hz) ; 3.84 (t, 1H, $J_1 = 7.5$ Hz).

The structure of the two isomers was also established using the $Eu(DPM)_3$.

The diol **39** *NMR spectrum* ($CDCl_3$; δ ppm) : 1.30 (3H, CH_3, $J^* = 6$ Hz) ; 1.98 (m, 2H, $J^*_1 = 8$ Hz, $J^*_2 = 6$ Hz) ; 2.05 (s, 2OH) ; 3.3–3.95 (m, 4H) ; 4.17 (t, 1H, $J^* = 8$ Hz) ; 7.2–7.6 (m, 8H arom.). (J^* deduced from NMR spectra with $Eu(DPM)_3$). The structure of the compound **39** was also confirmed by means of NMR spectra with $Eu(DPM)_3$.

Kinetic measurements. The acetic acid had a purity of 99.98 %. The solutions were 0.01 M in tosylate **14 a** or **14 b** and 0.03 M in AcONa. To the sample extracted from the reaction mixture (which contains an excess of AcONa) a known quantity of 0.05 M solution of $HClO_4$ was added and the mixture was titrated with a 0.05 M solution of NaOAc using p-bromophenole blue [30] as indicator.

Acknowledgement. Elemental analyses were performed by Miss E. Şliam and Mrs V. Daniel, to whom our thanks are due.

Elimination of two molecules of water from Ia leads to the linear hydrocarbons Va and VIa and to the angular hydrocarbon VIIa. The VIa : VIIa ratio, as resulted from gas-liquid chromatography, is 7 : 1. Elimination of two water molecules from Ib yields the angular hydrocarbons Vb and VIb and the linear hydrocarbon Xb. The Xb : VIb ratio, calculated from the NMR spectrum, is 1.2 : 1. The decrease of this ratio is explained by the increase of the double bond migration due to the hyperconjugation effect of the methyl group in the position 7 – 8. The formation of the reaction compounds is explained by a mechanism implying classical carbonium ions as intermediates, or by a mechanism with non-classical carbonium ions.

Chemical properties [1–3] and IR spectra [4,5] of 8-R-tricyclo-[7.3.1.$0^{2,7}$]tridecane-2,13-diols (I), where $R = H$, CH_3, C_2H_5, C_3H_7, C_6H_5, lead to the following conformation of these derivatives of bicyclo[3.3.1]nonane (figure 1) : the two fused rings have the conformation of *trans*-decalin, and the third one is situated in a plane approximately perpendicular on the medium plane of the first two rings ; the two hydroxyl groups are 1,3-*cis*, i.e. both are axial.

The tertiary hydroxyl group from C_2 is easily eliminated in acid medium. E_2 eliminations take place in the easiest way when the leaving groups are in *anti*-periplanar conformation.[6] *Anti*-periplanarity of the leaving groups in a six-membered ring system requires that they be diaxial, even if this is the conformation of higher energy. The elimination of the hydroxyl group from C_2 may occur, consequently, both with axial hydrogen atom from C_7, and with hydrogen atom from the neighbouring carbon atom of the fused ring. The formation of the 2–7 double bond is favoured by its localization at the carbon atoms without any hydrogen atoms.

Arguments from orbital-overlap considerations lead to the prediction that the transition state must be coplanar not only for a dihedral angle of 180°, but also for one of 0°. Though *trans*- E_2 elimination is the prevalent one, the elimination was also observed when the leaving groups were in *sin*-periplanar conformation.[7,8] Therefore, theoretically, the elimination could also take place with the equatorial hydrogen atom from C_1. It does not occur in this way not only because the dihedral angle between the two leaving groups is different from 0°, but also because it requires the introduction of the double bond at the bridgehead of the bicyclic system, i.e. it comes into conflict with the Bredt's rule.[9]

The Bredt's rule may be stated in qualitative terms as follows: a double bond cannot be placed with one terminus at the bridgehead of a bridged ring system unless the rings are large enough to accommodate the double bond without excessive strain. The strain results from torsional forces on the double bond which tend to twist the p_z orbitals of the double bonded carbon atoms besides the parallel condition required for maximum overlap.

There were some attempts to determine the limits of the Bredt's rule. Fawcett [10] proposed that the sum of number of atoms in the bridges of a bicyclic system (S number) determines whether that system can accomodate a bridgehead double bond. He concluded from the experimental available data that the compounds with bridgehead double bonds could be isolated for $S \geqslant 9$, and that the transient intermediates with bridgehead double bonds might be possible for $S \geqslant 7$. Bicyclic $[n. 3. 1]$ system can accomodate a bridgehead double bond when $n \geqslant 5$.[11, 12]

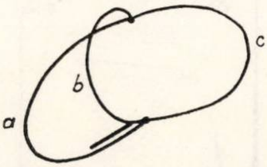
[10] F. S. Fawcett, *Chem. Rev.*, **47**, 219 (1950).

Wiseman[13] suggested another criterion to appreciate the limits of the Bredt's rule applicability. Considering the configuration of a double bond bridgehead bicyclic system, he has shown that the double bond is exocyclic to one of the rings (bc) and endocyclic in the other (ac). The double bond being at the branching point of the two rings, it must be substituted *cis* in one of the rings (ab) and *trans* in the other (ac). Wiseman suggested that the strain of the bridgehead double bonds is closely related to the strain of the corresponding *trans*-cycloalkenes. *Trans*-cyclooctene was the smallest *trans*-cycloaklene isolated ; *trans*-cycloheptene was obtained only as a transient reactive species. According to this criterion, a bicyclic birdgehead alkene can be isolated when the larger of the two rings, containing the double bond, has at least eight atoms, and a transient intermediate with bridgehead double bond is possible when the larger ring containing double bond is seven-membered. Thus, the limits of the Bredt's rule diminish to $S \geqslant 7$ for isolable compounds and to $S \geqslant 6$ for transient intermediates.



This criterion allows to determine whether a double bond can be placed at the bridgehead of a bicyclic system, as well as which branches of the system can contain a double bond.

The preparation of the following bridgehead alkenes confirmed Wiseman's hypothesis : bicyclo[4. 3. 1]dec-1(2)-ene-10-one,[14] bicyclo-[4. 2. 1]non-1(2)-ene and bicyclo[4. 2. 1]non-1(8)-ene,[15] ethyl-9-oxobicyclo.[4. 2. 1]non-6-ene-1-carboxilate,[16,17] bicyclo[3. 3. 1]non-1-ene, [13,18–20] bicyclo[3. 2. 2]non-1(2)-ene and bicyclo[3. 2. 2]non-1(7)-ene.[21] The last two, which require the introduction of the *trans*-double bond in a seven-membered ring, exist only as dimers.

RESULTS AND DISCUSSIONS

Examination of the hydroxyl group elimination products (position 2) from diols (I), where R = H and CH_3, leads to the conclusion that the elimination takes place with hydrogen atom from C_7. Thus, the

NMR spectrum of tricyclo [7. 3. 1. $0^{2,7}$] trideca-2-ene-13-acetates (IIa), obtained by dehydration and acetylation with zinc chloride and acetic anhydride, has the following peaks (figure 2): one triplet at δ 4.74, with an area corresponding to one hydrogen atom, assigned to the hydrogen atom from C_{13}, one singlet at δ 1.96 due to the methyl of acetate

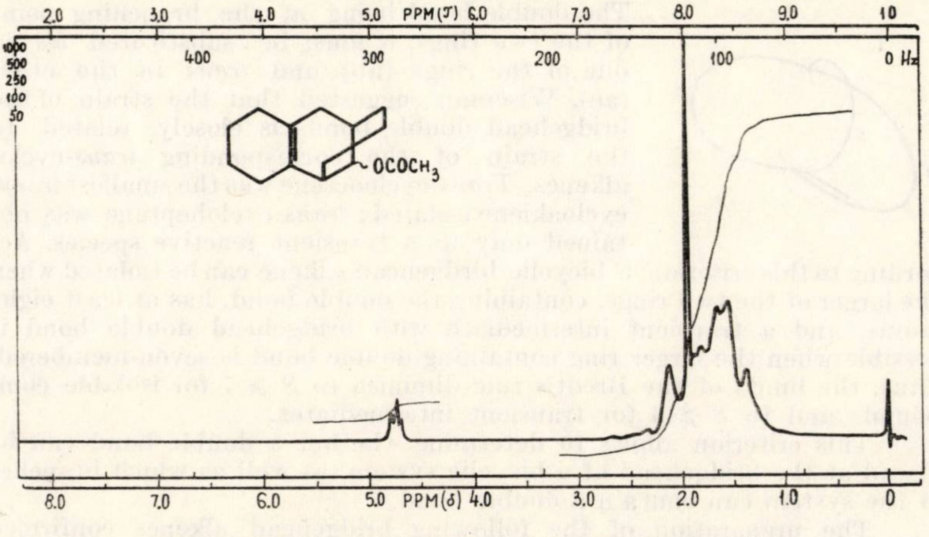

Fig. 2. — NMR spectrum of the unsaturated acetate IIa.

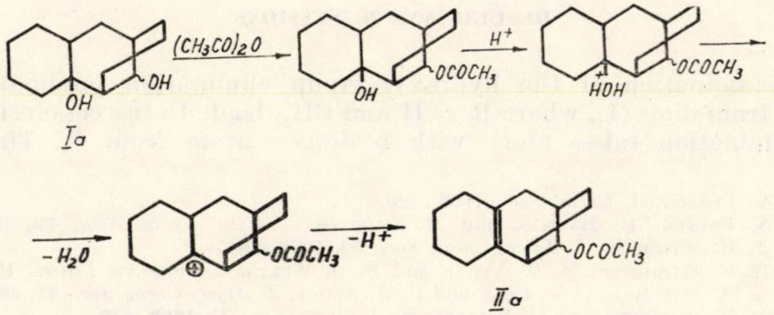
group and a complex absorption at δ 1.03—2.29 due to the other 18 hydrogen atoms. There is no peak for ethylene hydrogens, therefore, the double bond is in the position 2—7. This is confirmed by 2941 cm $^{-1}$ band of the IR spectrum, assigned to the bridgehead CH group. The elimination scheme is then:



In the reaction medium it is also possible, first, the dehydration reaction followed by acetylation of the secondary hydroxyl group. The acetate group of unsaturated acetate IIa may be axial or equatorial. Their separation by gas-liquid chromatography on SE-30 and carbowax 20 M was not possible.

The NMR spectrum of 8-methyl-tricyclo[7.3.1.0^{2,7}]tridecene-13-acetates (IIb) (figure 3), which can also exist as two isomers due to the position of the acetate group, has one triplet at δ 4.88 assigned to the hydrogen from C_{13}, one singlet at δ 2.00 for methyl from acetate group, one doublet at δ 1.00 due to the methyl group from C_8, one complex absorption from δ 0.76 to 2.50, with an area corresponding to 17 hydrogen atoms, on which one singlet is superposed at δ 1.70, assigned to the methyl group attached to an ethylene carbon atom (from C_8). It follows that the acetate IIb can exist as two isomers due to the double bond position : the acetate with the double bond in the position 2–7 and the other one with double bond in the position 7–8. The formation of the first isomer is explained by the above scheme, and of the second one by the migration of the double bond in the position 7–8, due to the hyperconjugation effect of the methyl group :

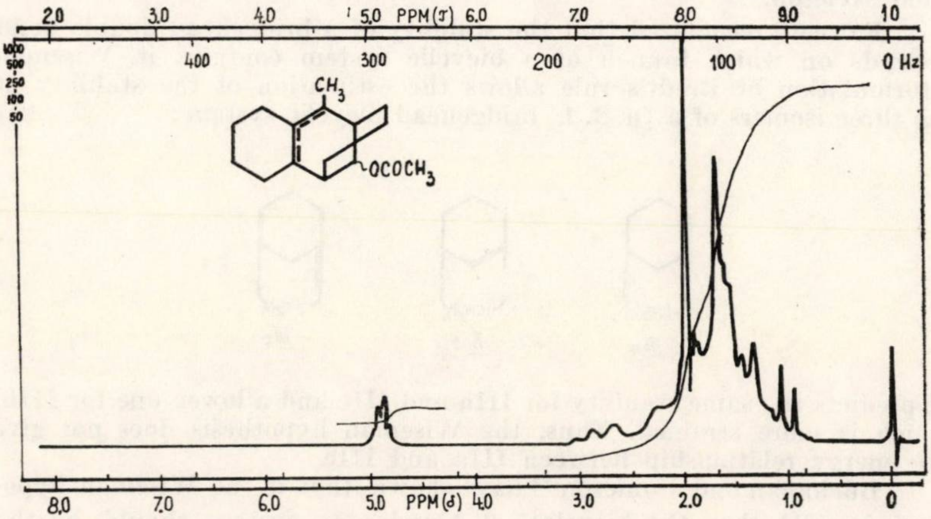


Fig. 3. – NMR spectrum of the unsaturated acetate IIb.

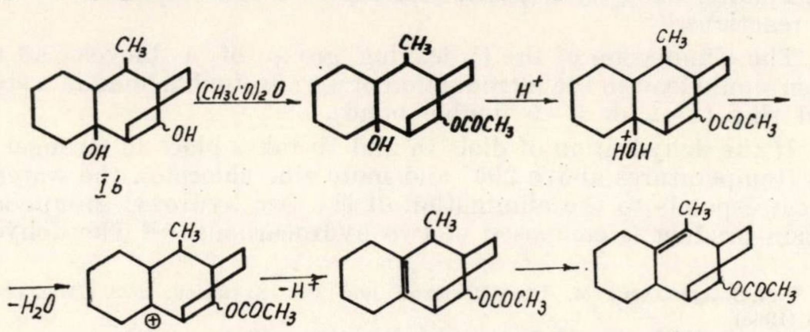
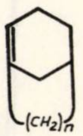


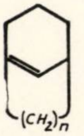
The calculation of the two isomers ratio from the integral curves of the NMR spectrum is not possible. The gas-liquid chromatograms on SE-30 and carbowax 20 M do not allow also the separation of the acetate (II b) isomers.

The elimination of the secondary hydroxyl group (from C_{13}) occurs in more energic conditions, taking place a rearrangement of the carbon atom skeleton.[3,22]

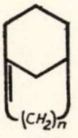
Fawcett recognized that the stability of a bridgehead double bond depends on which branch of a bicyclic system contains it. Wiseman reformulation of Bredt's rule allows the estimation of the stability of the three isomers of a [n. 3. 1] bridgehead bicyclic system :



IIIa



IIIb



IIIc

It predicts the same stability for IIIa and IIIc and a lower one for IIIb, which is more strained. Thus, the Wiseman hypothesis does not give the energy relationship between IIIa and IIIc.

Buchanan and Jamieson [23] have shown that if the Wiseman hypothesis is valid, then the bicyclo[5. 3. 1]undecane system should be the smallest one which can tolerate bridgehead double bonds in all three possible positions. They obtained these isomers [23,24] and from NMR, IR and UV spectra and chemical properties concluded that bicyclo[5. 3. 1]-undec-7(11)-ene-8-one is really more strained than bicyclo[5. 3. 1]undec-7(8)-ene-11-one.[24]

It is a lack of information about the elimination reactions of [n. m. 1] bicyclo compounds having the leaving group in one-membered bridge. The elimination of the hydroxyl group from C_9 is studied by two papers. [22,25] It is also known a paper about the solvolysis of bicyclo-[3. 3. 1]nonyl-9-tosylate [26]; the solvolysis is accompanied by elimination reactions.

The elimination of the C_9 leaving group of a bicyclo[3.3.1]nonyl system would lead to the introduction of a *trans*-double bond in a six-membered ring (1–9 or 5–9 double bond).

If the dehydration of diols Ia and Ib takes place in stronger conditions (temperatures above 200° and more zinc chloride), the water quantity corresponds to the elimination of the two hydroxyl groups and the reaction product is composed of two hydrocarbons. [3,22] The dehydration

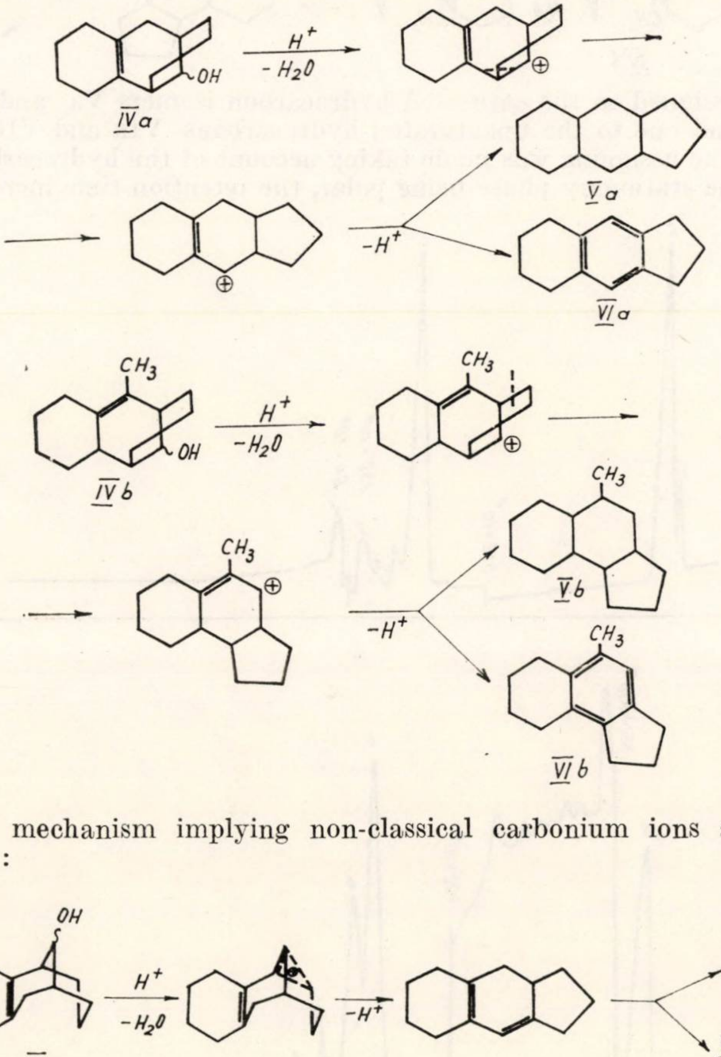
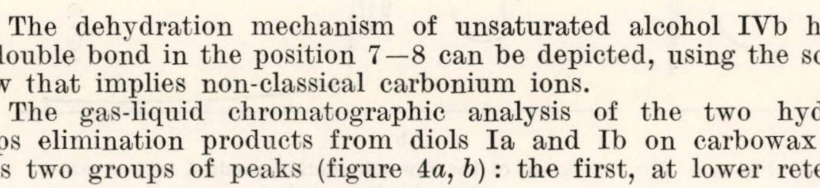
of unsaturated alcohols IVa and IVb zinc chloride yields the same hydrocarbons. Their formation can be explained by the reaction mechanism given above [22] :

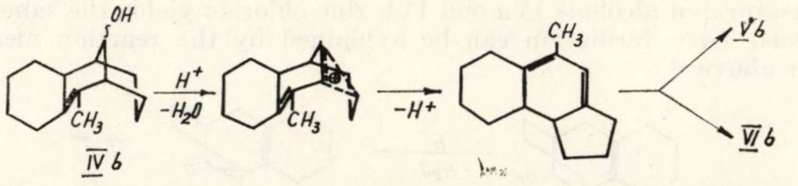


or by a mechanism implying non-classical carbonium ions as intermediates :



The dehydration mechanism of unsaturated alcohol IVb having the double bond in the position 7—8 can be depicted, using the scheme below that implies non-classical carbonium ions.

The gas-liquid chromatographic analysis of the two hydroxyl groups elimination products from diols Ia and Ib on carbowax 20M shows two groups of peaks (figure 4*a*, *b*) : the first, at lower retention



times, assigned to the saturated hydrocarbon isomers Va and Vb, and the second one to the unsaturated hydrocarbons VIa and VIb, respectively. The assigning was made taking account of the hydrocarbon structures (the stationary phase being polar, the retention time increases with

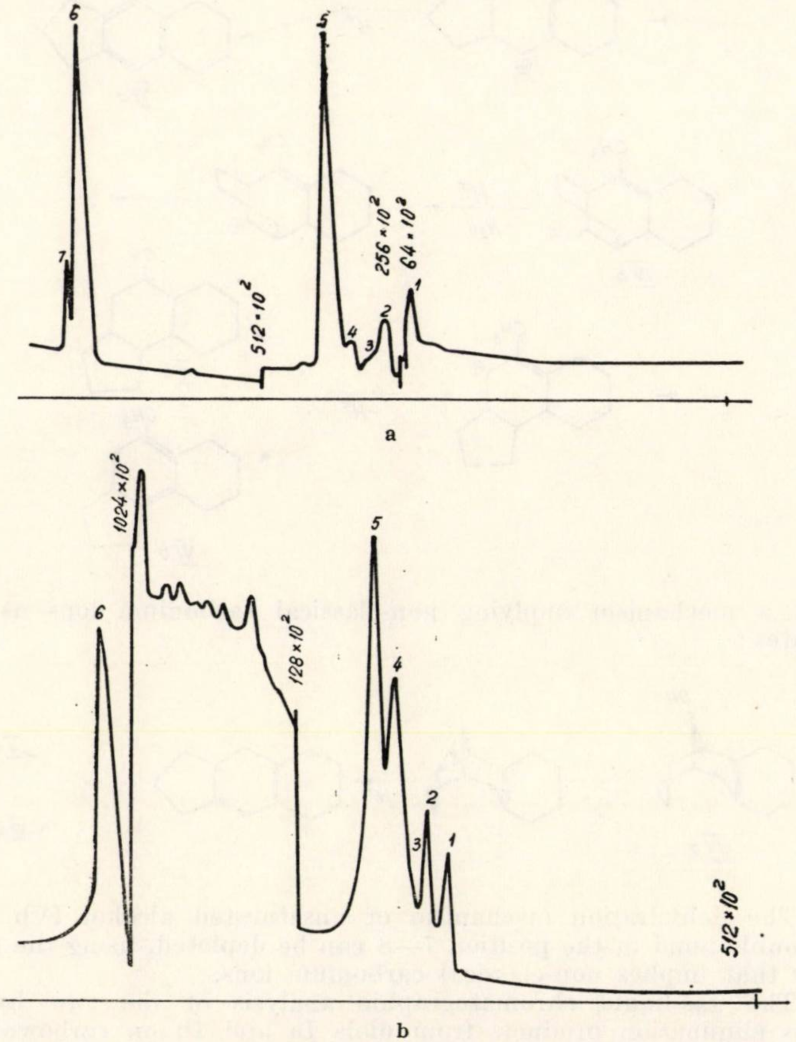


Fig. 4. — Chromatogram of the raw elimination product of two water molecules from diols :

a) Ia; *b*) Ib.

the polarity of the substance) as well as on the basis of NMR and IR spectra of the fractions separated by preparative gas-liquid chromatography on the same stationary phase.

The first group of peaks of the dehydration products of diol Ia is composed of five resolved peaks (figure 4 *a*). The hydrocarbon Va can exist as five isomers, like perhydroanthracene. The main peak is probably due to the most stable isomer *trans-anti-trans*. The second group is built up from two peaks, the first one due to the hydrocarbon VIa, and the second one due to the angular isomer VIIa. Therefore, angular isomers of the hydrocarbon Va can also exist in the first group of peaks. Percentage composition of this mixture, as calculated from the chromatogram recorded using the flame ionization detector, starting from the lowest retention times, is : 1.04, 5.02, 3.17, 27.71, 0.66, 54.53 and 7.87 per cent. The ratio between the areas of the peak 4 and 6 is 1 : 2, that corresponds to the theoretical ratio of the saturated hydrocarbon Va and unsaturated hydrocarbon VIa. The VIa : VIIa ratio is about 7 : 1.

The NMR spectrum of the main peak from the first group (peak 4) (figure 5 *a*) has a complex absorption at δ 0.60—2.65 corresponding to the saturated hydrogen atoms from the five- and six-membered rings of the compound Va. The complex absorption of the mixture of peaks 3 and 4 (figure 5 *b*) has the same limits, but different appearance.

The NMR spectrum of the peak 6 (figure 6 *a*) has the following signals : one complex absorption from δ 1.39 to 2.25, with an area corresponding to six hydrogen atoms, assigned to the two equivalent methylene groups of the six-membered ring and to the methylene group of the five-membered ring which are not attached to the benzene ring; one asymmetrical triplet at δ 2.76 ($J = 6.5$ Hz) for eight hydrogen atoms due to the four methylene groups from six- and four-membered rings attached to the benzene ring; one singlet at δ 6.77 corresponding to two hydrogens for the two equivalent aromatic hydrogen atoms. Therefore, this spectrum corresponds entirely to the structure of the compound VIa.

The peaks 6 and 7 are no longer well resolved on the carbowax 20M preparative column, so that the peak 7 could not be separated. On the other hand, the NMR spectrum of the mixture of peaks 6 and 7 were recorded, hoping that by difference the contribution of the peak 7 could be established. The spectra are completely identical, as we can see from figure 6 *a*, *b*. As a matter of fact, the two aromatic hydrogen atoms must be equivalent in practice, considering the structure of the angular isomer.

The structure of the hydrocarbon VIa was also proved by dehydrogenation with platinized asbestos. The main product was 5,6-benzindane (VIIIa), a crystalline substance — melting point 94°, picrate melting point 118° — described by McQuilin and Robinson [27] and by Sen-Gupta.[28] An oily compound was obtained in small quantity in addition to the hydrocarbon VIIIa, this being probably the angular isomer IXa

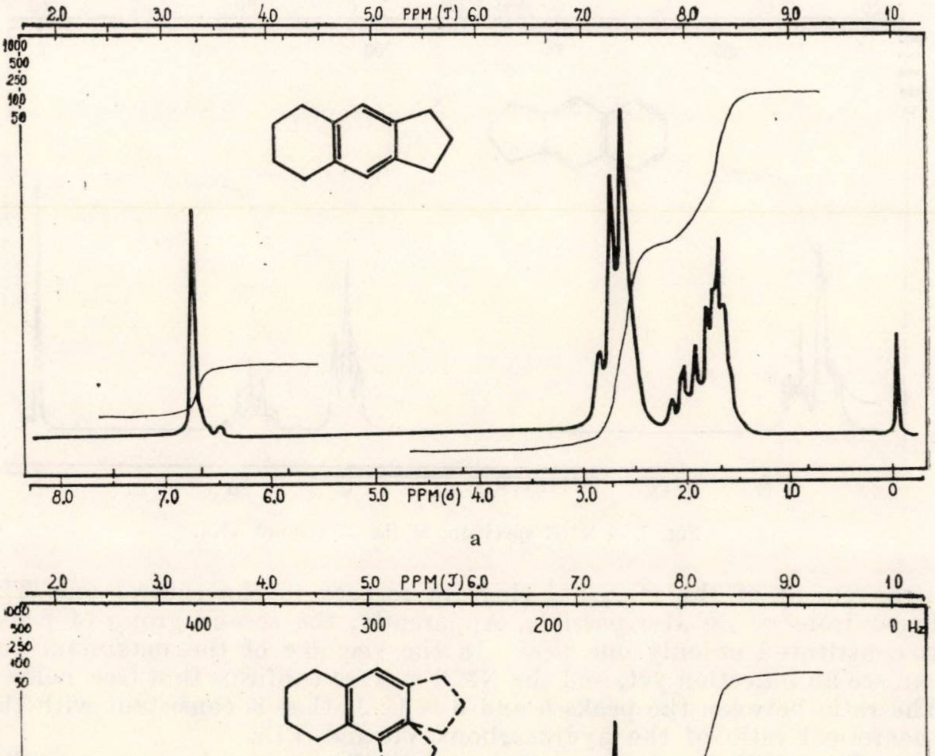
The NMR spectrum (figure 7) is entirely consistent with the assigned structure : one quintet at δ 2.08 ($J = 7$ Hz), with an area corresponding to two hydrogen atoms, assigned to the methylene group of the five-membered ring nonattached to the naphtalene nucleus ; one asymmetrical triplet at δ 2.98 ($J = 7$ Hz) for four hydrogen atoms due to the two methylene groups of the five-membered ring attached to the naphtha-



b

Fig. 6. — NMR spectra of the second group of peaks of the dehydration product of diol Ia :

a) peak 6 ; *b*) peak 6 + peak 7

lene nucleus; one complex absorption from δ 7.10 to 7.90 for the six aromatic hydrogen atoms. The gas-liquid chromatographic analysis on carbowax 20M shows only one peak.

The first group of peaks of the dehydration products of diol Ib is also composed of five peaks: four resolved and one unresolved. The hydrocarbon Vb has five isomers too, resulting from ring fusion and the arrangement of the marginal rings in respect to the central one. The linear isomers are also possible. Apparently, the second group of peaks is constituted of only one peak. In the vecinity of the maximum one can see an inflection yet, and the NMR spectra confirms that (see below). The ratio between the peaks 5 and 6 is 1 : 2, that is consistent with the theoretical ratio of the hydrocarbons Vb and VIb.

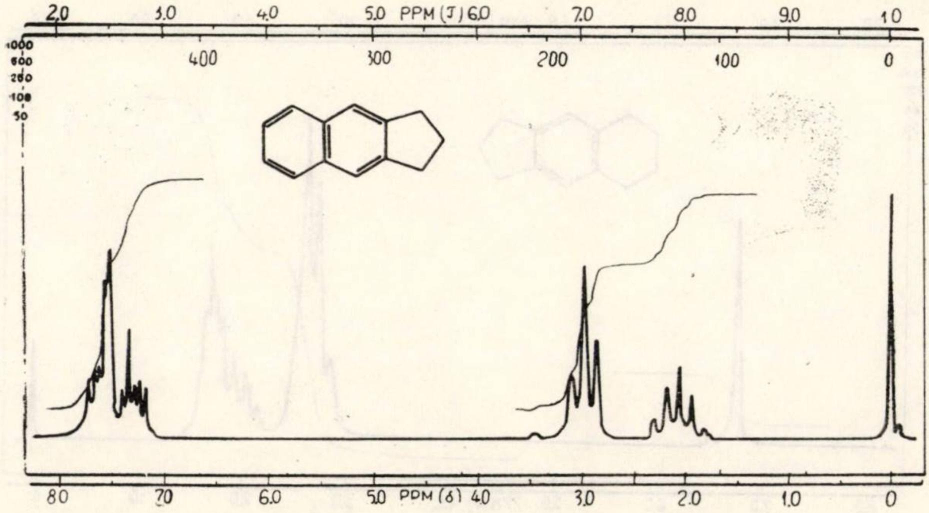


Fig. 7. – NMR spectrum of the compound IXa.

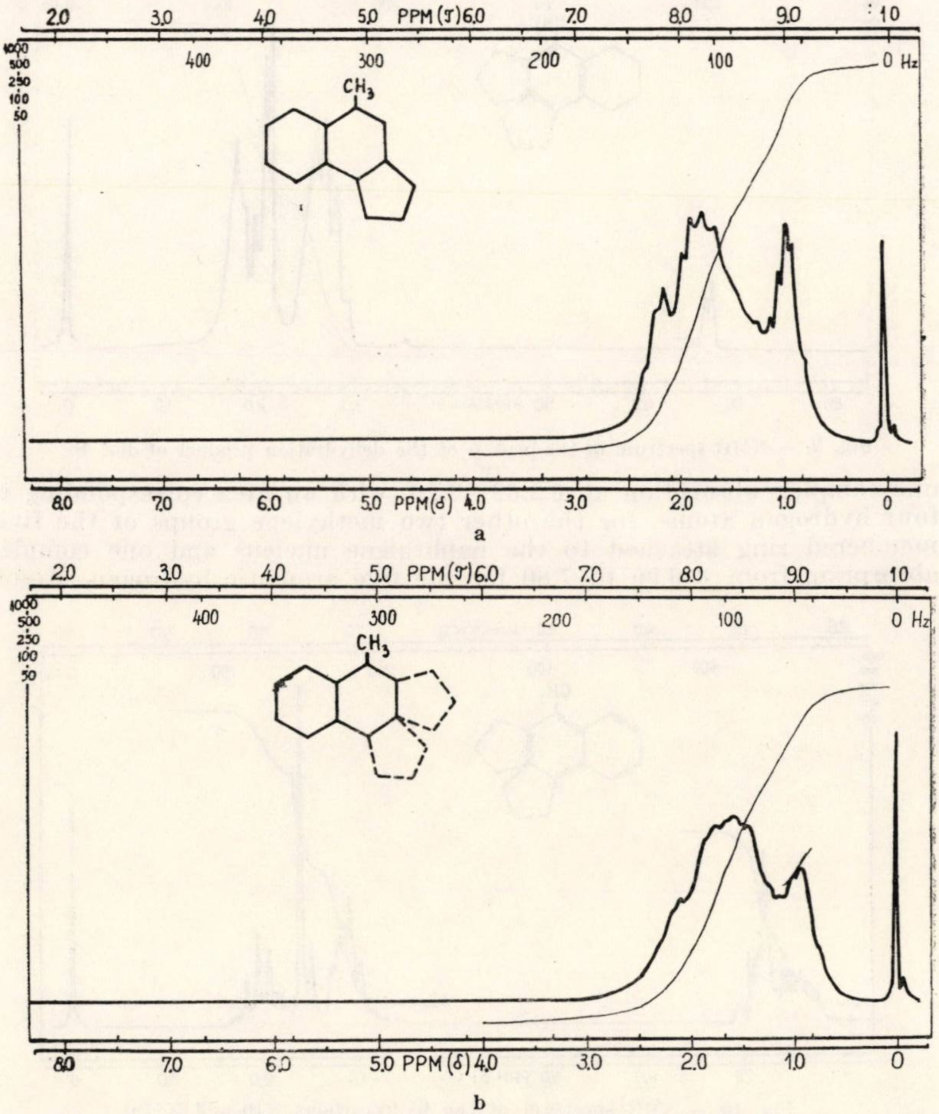
The NMR spectrum of the peak 5 (figure 8 *a*) has one complex absorption at δ 0.40–2.90 and the NMR spectrum of the peaks 2, 3, 4 and 5 (figure 8*b*) one modified complex absorption ranging the same limits.

The NMR spectrum of the peak 6 (figure 9) has a complex absorption from δ 1.37 to 2.26, with an area corresponding to 9 hydrogen atoms, assigned to the three methylene groups of the six- and five-membered rings nonattached to the benzene nucleus and to the methyl group attached to the benzene nucleus; one triplet at δ 2.58 ($J = 7$ Hz) for eight hydrogen atoms due to the four methylene groups of the five- and six-membered rings attached on the benzene ring and one apparent doublet centered at δ 6.68 for one aromatic hydrogen atom. This is not a doublet, but two closed singlets: one at δ 6.71 assigned to the aromatic hydrogen atom of the linear isomer Xb of the hydrocarbon VIb, which gives a peak at a lower field, and the other one at δ 6.64 for the aromatic hydrogen atom of VIb. The ratio VIb : Xb is about 1 : 1,2, as results from the integral curve. The splitting of the methyl group signal attached to the benzene nucleus is also observed. The methyl group of Xb gives a peak at δ 2.06, and the methyl group of VIb at δ 2.13. The integral curves are not clear enough, so that the ratio of isomers cannot be verified.

The dehydrogenation of the mixture of hydrocarbons VIb and Xb, using platinized asbestos, result in the formation of the corresponding mixture of hydrocarbons XIb and XIIb. Their NMR spectrum (figure 10)



a

b

Fig. 8. — NMR spectra of the first group of peaks of the dehydration product of diol Ib :
a) peak 5; *b*) peak 2 + peak 3 + peak 4 + peak 5.

corresponds to the $C_{14}H_{14}$ formula and has one quintet at δ 1.95 ($J = 7$ Hz) assigned to the methylene group of five-membered ring nonattached on naphtalene nucleus; one doublet from δ 2.32 to 2.62 for the methyl group attached to the naphtalene nucleus (the first at δ 2.40 for the linear isomer XIIb and the second at δ 2.51 for the angular isomer XIb);

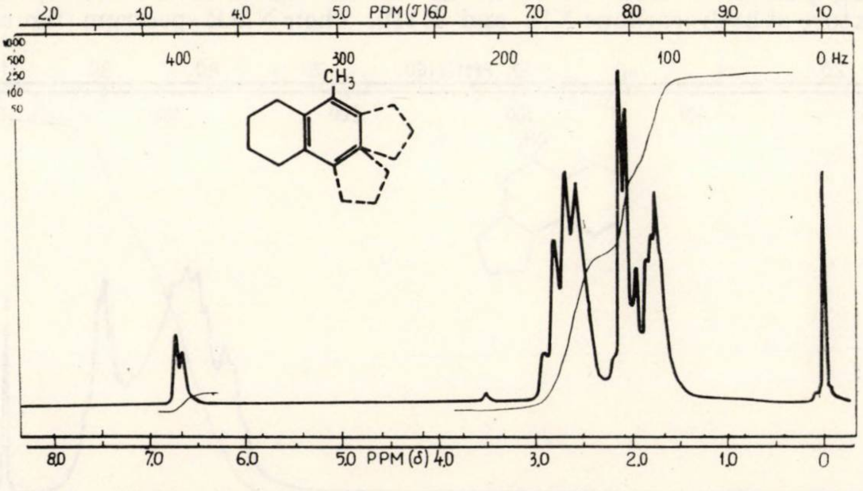


Fig. 9. — NMR spectrum of the peak 6 of the dehydration product of diol Ib.

one complex absorption at δ 2.62—3.20, with an area corresponding to four hydrogen atoms, for the other two methylene groups of the five-membered ring attached to the naphtalene nucleus and one complex absorption from δ 6.90 to 7.80 for the five aromatic hydrogen atoms.

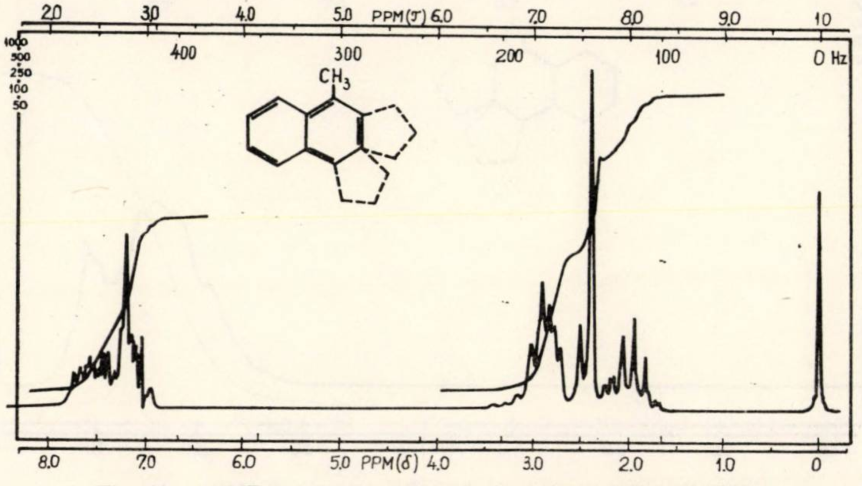

Fig. 10. — NMR spectrum of the hydrocarbons XIb and XIIb.

Therefore, the methyl groups of XIb and XIIb give characteristic signals. The XIb : XIIb ratio is about 1 : 3 as resulted from integral curve and 1 : 3.4 as resulted from gas-liquid chromatography on carbowax 20M.

CONCLUSIONS

Elimination of two water molecules from diol Ia leads to the formation of the hydrocarbons Va and VIa as main products. In addition to these linear hydrocarbons, the corresponding angular hydrocarbons may also arise. Gas-liquid chromatographic analysis on carbowax 20 M reveals the conclusion that the ratio between the linear hydrocarbon VIa and the angular one VIIa is 7 : 1, i.e. the linear isomer prevails. The existence of isomer VIIa is explained by the migration of the double bond in the position 7–8.

Elimination of the two molecules of water from diol Ib results in the formation of the hydrocarbons Vb, VIb and Xb and, probably, of the corresponding saturated linear hydrocarbons. The Xb : VIb ratio is 1,2 : 1. The decreasing of this ratio is explained by the migration of the double bond in the position 7–8 due to the hyperconjugation effect of the methyl group. The migration of the double bond is also observed in the NMR spectrum of the unsaturated acetate IIb, the methyl group giving one doublet with smaller chemical shift for the methyl attached to the saturated C_8, as well as one singlet with larger chemical shift for the methyl attached to the ethylene C_8. The spectrum does not allow the calculation of the isomers ratio.

EXPERIMENTAL PART

The preparation of diols Ia and Ib has been described in the earlier papers.[3,22]

TRICYCLO[7. 3. 1. $0^{2,7}$]TRIDECA-2-ENE-13-ACETATES IIa

98 g (0.4667 mole) of diol Ia, 241.5 g (2.367 mole) of acetic anhydride (the ratio diol Ia : acetic anhydride was 1 : 5.07) and 10 g of zinc chloride were heated gradually in an air bath in an experimental equipment consisting of a 500 ml two necks round-bottomed flask, a 80 cm Vigreux column and a distillation head leading to a graduated separating funnel for the collecting of the acetic acid resulting from the reaction. The temperature was raised after $2\frac{1}{2}$ hr of refluxing and the acetic acid began to distillate. The distillation ceased after $1\frac{3}{4}$ hr. There were collected 101 ml distillate between 116 and 124° (theoretically 80.1 ml of acetic acid). The removing of acetic anhydride was continued and another 86 ml were collected. The remaining acetic anhydride was removed using the water-jet pump. The reaction mixture was cooled and extracted with ether (4 × 200 ml). The etheric extracts were washed with water and dried with natrium bicarbonate. The solvent removal gave 104 g of raw oil, which was distilled *in vacuo* (b. p. 110–111°/2 mm Hg) to give 72.6 g (66.5%) of colourless liquid, $n_D^{20} = 1.5083$; IR (CCl_4) : 2943, 2868, 2840, 1726, 1450, 1377, 1272, 1095, 1042, 992 and 974 cm^{-1}; NMR (CCl_4) : δ 1.03–2.29 (complex absorption), δ 1.96 (singlet), δ 4.74 (triplet).

8-METHYL-TRICYCLO[7. 3. 1. $0^{2,7}$]TRIDECENE-13-ACETATES IIb

100 g (0.446 mole) of diol Ib, 228.6 g (2.241 mole) acetic anhydride and 10 g of zinc chloride were heated and worked as above. There were obtained 106.7 g raw oil, which

was distilled *in vacuo* (b.p. 112–113°/1.5 mm Hg) to give 62.9 g (56.8 %) light yellow liquid, $n_D^{20} \times 1.5118$; IR(CCl_4) : 2943, 2868, 1726, 1451, 1377, 1272, 1110, 1042 and 986 cm^{-1}; NMR (CCl_4) : δ 0.76–2.50 (complex absorption), δ 1.00 (doublet), δ 2.00 (singlet), δ 4.88 (triplet).

DEHYDRATION OF THE ALCOHOL Ia

50 g (0.238 mole) of diol Ia were heated with 25 g of zinc chloride in a Dean-Stark apparatus in an air bath. 8.6 ml of water were collected in 2 hrs (theoretically 8.6 g of water).

35.5 g of dehydration product were obtained, $n_D^{20} = 1.5521$, which were analysed by gas-liquid chromatography on carbowax 20 M.

DEHYDRATION OF THE ALCOHOL Ib

30 g (0.134 mole) of diol Ib and 6 g zinc chloride were heated in an air bath in a Dean-Stark apparatus. 4.7 ml of water were collected in 2 hrs (theoretically 4.8 g of water). 26 g of dehydration product were obtained, which were analysed by gas-liquid chromatography on carbowax 20 M.

The dehydrogenation of the hydrocarbon VI a and of the mixture of hydrocarbons VIb and Xb using platinized asbestos was made in the same conditions as the dehydration using palladium.[22]

The chromatographic analysis was performed by employing a Becker 401 type gas-liquid chromatograph, using a 6 mm o.d. copper column, 4 m in length. Packing material was 16 % carbowax 20M on 60–80 mesh celite C_{22}. The flame ionization detector was used, with nitrogen as carrier gas. The conditions were as follows :

injection temperature	210°
column temperature	100–200°, with 6°/min programing
detector temperature	240°
gas flow rate	40 ml/min
injected quantity	0.5–1µl.

The preparative gas-liquid chromatography was carried out on a Carlo Erba GT type preparative chromatograph by employing a 10 mm o.d. stainless steel column, 2 m in length, and 20 % carbowax 20M on 30–60 mesh chromosorb W as packing material. The thermal conductivity detector was used, with hydrogen as carrier gas. The conditions were :

injection temperature	280°
column temperature	195°
detector temperature	280°
gas flow rate	500 ml/min
auxiliary gas flow rate	60 ml/min
injected quantity	150µl.

The purity of fractions was verified using a 4 mm o.d. aluminium column, 2 m in length and 20 % carbowax 20M on 60–80 mesh chromosorb W as packing material, on an analytical Carlo Erba GT chromatograph in the following conditions :

injection temperature	260°
column temperature	115–170°, with 4°/min programing
detector temperature	260°
hydrogen flow rate	25 ml/min
injected quantity	0.2–0.4µl

thermal conductivity detector.

ÜBER 1,2,3,4-TETRAHYDROACRIDIN-9-CARBOXYLSÄURE DERIVATE II[1]

ESTER UND THIOESTER

M. CÂRJE

Physiologisches Institut „D. Danielopolu", Bukarest, Bd. 1 Mai, nr. 11

Eingegangen am 23. Juni 1973

Wir bemühten uns einige Ester- und Thioester - abkömmlinge der im Titel angegebenen Säure zu synthetisieren, um ihre Wirkung auf das Nervensystem studieren zu können.

Das Säurechlorid der 7-R-1,2,3,4-Tetrahydroacridin-9-Carboxyl-Säure (R = H, Cl, OCH_3) reagiert mit Äthanol, Äthylen Glykol, Athylen Chlorhydrin oder Diäthylamin-Äthanthiol, wobei die entsprechenden Ester und Thioester entstehen.

Die neusynthetisierten Ester und Thioester wurden auch durch I.R.-Spektren charakterisiert.

Von der Tatsache ausgehend, daß die Acridinstrukturen, die einen teilweise oder gänzlich gesättigten Ring besitzen, eine Wirkung auf das Nervensystem ausüben könnten, setzten wir die Synthese von Abkömmlingen der 1,2,3,4-Tetrahydroacridin-9-Carboxyl-Säure (THA-Säure) fort. Wir nahmen die Synthese einiger Ester und Thioester der Abkömmlinge der THA-Säure mit H, Cl, oder OCH_3 in Stellung 7 vor.

Die Synthese der THA-Säuren erfolgte[1], indem wir von Anilin, *p*-Chloranilin und *p*-Anisidin ausgingen, die mit Chloralhydrat und Hydroxilamin reagieren und die entsprechenden Isonitrosoacetanilide, die in Gegenwart von Schwefelsäure zu dem Isatinring führen, ergeben. Die Isatine reagieren in basischem Milieu mit Cyclohexanon, wobei die THA-Säuren entstehen. Unter Einwirkung von Phosphorpentachlorid werden die entsprechenden Säurechloride erhalten. Die Ester sind von den nachstehenden Alkoholen abgeleitet: Äthanol, Äthylenglykol und Äthylenchlorhydrin, während die Thioester von Diäthylaminäthanthiol ausgehen.

Das Säurechlorid reagiert mit den entsprechenden Alkoholen und dem Thioalkohol, wobei als Reaktionsmilieu Azeton, Dichloräthan oder auch der entsprechende Alkohol verwendet wurde. Die Thioester isolierten wir unter Form von Chlorhydraten, da die freien Basen keine Stabilität aufweisen.

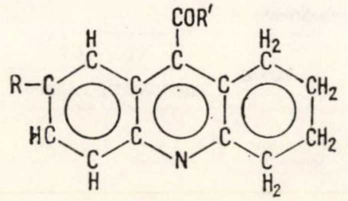
* Die Schm.p. wurden nicht korrigiert.

Von den synthetisierten Ester ist ein einziges im Schrifttum [2] – und zwar das Äthylester der THA-Säure – verzeichnet, wobei sein Schmelzpunkt angegeben wird.

Die synthetisierten Ester und Thioester sind in Tab. 1 enthalten. Zur Charakterisierung der Substanzen und zur Identifizierung der verschiedenen Funktionsgruppen wurden die Infrarotspektren der neusynthetisierten Ester und Thioester bestimmt. Die Absorptionsbreite, die einer Frequenz von $\nu C = O$ entsprach, verhielt sich (siehe Tab. 2) zwischen 1714–1734 cm^{-1}, wobei sie dem in der Literatur für die Ester der aromatischen Säuren [3] angegebenen Bereich entsprach. Die Zwischenwirkung mit dem Schwefelatom in den Thioester 10–12 führte zur Minderung der Absorptionsfrequenz der Verbindung $C = O$ bis zu 1671–1678 cm^{-1} (im Schrifttum [3] 1680 $\pm$ 10 cm^{-1}). Der gesättigte Teil des dreizyklischen Systems konnte wegen Überlagerung mit dem Hydrokarbonatrest der Esterfunktion nicht nachgewiesen werden.



R

H,Cl, OCH_3

R'

$O-CH_2-CH_3$

$O-CH_2-CH_2-OH$

$O-CH_2-CH_2-Cl$

$S-CH_2-CH_2-N\ (C_2H_5)_2$

Die OH-Gruppe der Verbindungen 4–6 wurde durch die Frequenz $\nu O-H$ dargestellt. Es wurden breite Bänder bei cca 3200 cm^{-1} (durch Wasserstoffverbindungen) erreicht. Die Frequenzen der Auszugbreite der Verbindung $C-Cl$ ermöglicht die Identifizierung der „trans" – (700–760 cm^{-1}) und „gauche" – 650–690 cm^{-1})[4] Conformer. Die schwache Intensität dieser Bänder und die Überlagerung mit den Deformierungsbreiten der $C-H$ - Verbindungen des aromatischen Systems, lassen die Zuschreibung der dem „trans" - Conformer charakteristichen Frequenz bei den studierten Verbindungen als unsicher erscheinen.

Die Chlorhydrate der tertiären Amine 10–12 weisen ein sehr breites charakteristisches Band, um etwa 2500 cm^{-1} Frequenz auf, wie auch ein Spaltband mittlerer Intensität, bei etwa 2000 cm^{-1}, kennzeichnend für die Gruppe $C = \overset{+}{N}H$.[4] (Literatur [4]).

EXPERIMENTELLER TEIL

Äthylester der THA-Säuren. Zu 0,01 Mol. Chlorhydrat des Säurechlorids der entsprechenden THA-Säure werden 12 ml. absolutes Äthanol hinzugefügt. Es wird eine Stunde lang refluirt. Es wird anschließend mit 200 ml Wasser verdünnt, Kohle hinzugegeben und filtriert. Die entsprechenden Ester werden mit NaOH 2 N ausgefällt. Es wird filtriert und mit Wasser gewaschen.

2-Chloräthylester der THA-Säuren. Zu 0.01 Mol. Chlorhydrat des Säurechlorids der entsprechenden THA-Säure werden, 2,1 ml Athylenchlorhydrin hinzugegeben. Das Reaktionsgemisch wird eine Stunde lang auf 100–110°C über einem Ölbad erhitzt. Zubereitung wie oben.

N,N-Diäthylamino-2-Thioäthylester der THA. 2HCl.-Säuren. Zu 0,01 Mol. Chlorhydrat des Säurechlorids der entsprechenden THA-Säure in 20 ml Dichloräthan werden, 0,015 Mol. Diäthylaminoäthanthiol (aus Thioharnstoff und Diäthylamin-Chlor-2-Äthan präpariert [5]) hinzugefügt. Es wird eine Stunde lang refluiert, worauf Dichloräthan an der Wasserstrahlluftpumpe distilliert wird. Die Reaktionsmasse wird in 200 ml Wasser aufgelöst, Kohle hinzugefügt und filtriert. Die entsprechenden Thioester werden mit NaOH 2 N ausgefällt. Der Niederschlag, in Form einer schleimigen Masse, wird aus der Lösung durch Zentrifugieren abgesondert. Er wird 2—3 mal mit Wasser gewaschen und dies wieder durch Zentrifugieren entfernt. Die dickflüssige Masse wird in Azeton aufgelöst und mit wasserfreiem Na_2SO_4 ausgetrocknet. Nach Filtrieren wird dieser Lösung eine HCl Gas — in Azeton — Lösung beigefügt. Das Dichlorhydrat des Thioesters fällt aus. Es wird filtriert und mit Azeton gewaschen.

SYNTHESIS BASED ON FORMYL FURO (2,3-*b*) BENZOTHIACHROMONE

NICOLAE RĂȘANU * and OVIDIU MAIOR**

* Laboratory of Organic Chemistry, Pedagogic Institute of Constantza, Romania
** Laboratory of Organic Chemistry, University of Bucharest, Romania

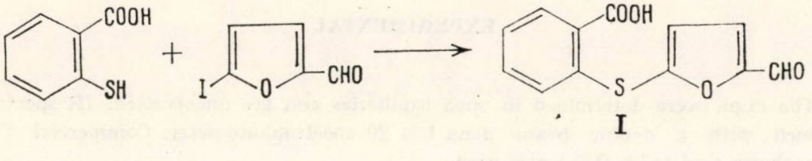
Received April 24, 1973

In this work the cyclodehydration reaction has been applied to 2-carboxyphenyl-5′-formyl furylthioether in the purpose of obtaining 2-formyl furo (2,3-*b*) benzothiachromone. Chemical and IR evidences for the structure of the cyclization product are given.

One of the best methods for the synthesis of thioxantone, is orthocarboxydiphenylthioether acides cyclodehydration with different reagents such as polyphosphoric acid,[1, 2] concentrated sulphuric acid,[3] and so forth.

In order to obtain 2-formyl furo (2,3-*b*) benzothiachromone, a thioxantone analog in which one benzene ring is substituted by a furane nucleus, the cyclodehydration reaction was applied to 2-carboxyphenyl-5′-formyl furylthioether (I).

The starting material (I) was synthesized through an Ullmann reaction from thiosalicylic acid [4] and 5-iodfurfurol,[5] in the presence of potassium hydrogen carbonate and copper bronze. The yields in 2-carboxyphenyl-5′-formyl furylthioether are in the range 60–68%.



Polyphosphoric acid cyclization of (I) afforded 2-formyl furo (2,3-*b*) benzothiachromone, in 68% yield.

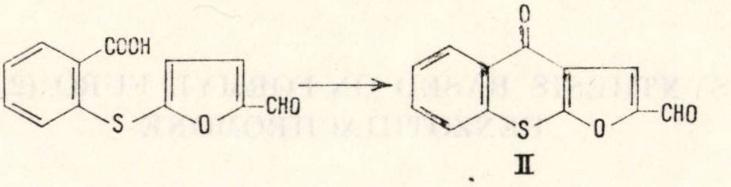
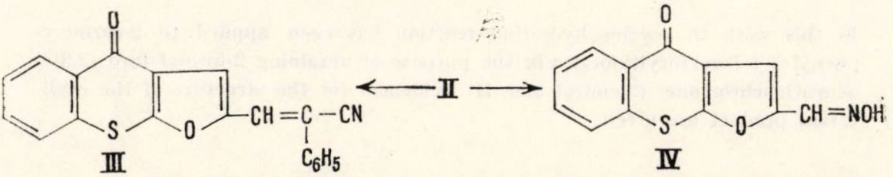
[5] Z. N. Nazarova, *Zhur. obshchei. Khim.*, **25**, 539 (1955).

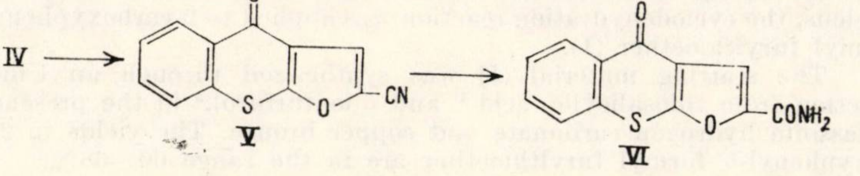


The temperature range 115—125° proved to be critical for the reaction; above this temperature non-unitary products were obtained.

The carbonyl groups in (II) have different reactivities, as evidenced by the formation of monoderivatives (IV) and (III) in the reaction with hidroxylamine and benzyl cyanide, respectively.



The oxime (IV) was converted into the nitrile (V) by means of acetic anhydride. Polyphosphoric acid is an excellent reagent for the hydrolysis of aromatic unhindered nitriles to amides.[6] The nitrile (V) through hydrolysis with polyphosphoric acid gave the expected amide (VI).



EXPERIMENTAL

The m.ps. were determined in open capillaries and are uncorrected. IR spectra were determined with a double beam Jena UR 20 spectrophotometer. Commercial "Merck" polyphosphoric acid (84 % P_2O_5) was used.

2-CARBOXYPHENYL-5-FORMYL FURYLTHIOETHER (I)

A mixture of thiosalicylic acid (5.5 g), 5-iodofurfurol (8 g), potassium hydrogen carbonate (7 g) and copper bronze (0.1 g) in 150 ml dioxan was heated under reflux for 4 hours.

---

[6] L. F. Fieser and M. Fieser, "Reagents for Organic Synthesis", John Wiley New York, 1967, p. 903.

After cooling, the mixture was diluted with 1000 ml water, filtered and the solution was acidified with dilute hydrochloric acid. The precipitate was collected by filtration. Recrystallization from methanol gave white crystals, m.p. 203--205°. 68% yield.

Found : S, 12.25 $C_{12}H_8O_4S$ requires : S, 12.51%

IR (KBr) cm^{-1} 750 (4H), 1680 (formyl), 1710 (carboxy)

2-FORMYL FURO(2,3-b) BENZOTHIACHROMONE (II)

The foregoing acid (6 g) was heated between 115–125° for 2 hours, under vigorous stirring, with polyphosphoric acid (54 g). The mixture was cooled and poured into an excess of ice-water. The resulting precipitate was collected on a Büchner funnel and washed successively with water, potassium hydrogen carbonate solution, and again with water. The crude material was recrystallized from dioxan, giving the desired product (II) 3.2 g (58%) m.p. 242–243°.

The product (II) with conc. H_2SO_4 give a brown-red colour with a slight green fluorescence.

Found : C, 62.83 ; H, 2.85 ; S, 14.16 $C_{12}H_6O_3S$ requires : C, 62.59 ; H, 2.62 ; S, 13.92

β-[FURO (2,3-b) BENZOTHIACHROMONE]-α-PHENYLACETONITRILE(III)

The compound (II) (0.7 g) was dissolved under slightly heating in a mixture of dioxan (20 ml) and methanol (20 ml). Benzyl cyanide (0.1 ml) and a drop of 10% NaOH was added, and the mixture was kept at room temperature for 7 hours.

Extraction of the resulting solid with dioxan, and then with glacial acetic acid for moving off impurities, gave crystalline residue (0.7 g), m.p. 265–266°. This compound with conc. H_2SO_4 give a yellow colour with green fluorescence.

Found : S, 9.90 $C_{20}H_{11}O_2SN$ requires : S, 9.73%.

IR(KBr) cm^{-1} 740 (4H), 1215 (C–O–C), 1630 (CO), 2215 (CN)

2-FORMYL FURO (2,3-b) BENZOTHIACHROMONE OXIME (IV)

A mixture of compound (II) (2 g), hidroxylaminehydrochloride (2 g) and anhydrous pyridine (30 ml) was boiled on water bath for 3 hours.

After cooling the reaction mixture was diluted with water, and the resulting precipitate after filtration and recrystallization from methanol yielded (IV) (2 g) m.p. 248–249°. This compound with conc. H_2SO_4 give a blue fluorescence.

Found : S, 13.27 $C_{12}H_7O_3SN$ requires :S, 13.07%.

SYNTHESES OF NEW POLYMERS BY DESTRUCTIVE METHODS. II [1]

MECHANOCHEMICAL COMPLEXATION AND COMPLEXATION BY IRRADIATION USING ^{60}Co γ-RAYS IN THE SYSTEM: POLY(ETHYLENETEREPHTHALATE), ETHYLENEDIAMINE AND METALLIC SALTS

CRISTOFOR SIMIONESCU, CLEOPATRA VASILIU OPREA and CLAUDIA NEGULIANU

Polytechnical Institute of Iassy, Department of Organic and Macromolecular Chemistry,
Str. 23 August N° 11, Romania

Received April 7, 1973

Destruction of the heterochain polymers, of the nature of poly-(ethyleneterephthalate), achieved under the action of the mechanical energy and that of γ-rays, is accompanied by the accumulation of an increasing number of functional end groups, able to react with suitable condensation agents existing in the working medium and where metallic salts are also present in system, the fragments synthesized by polycondensation act as macromolecular ligands. Processes of polycondensation and complexation activated by destructive methods are decisively influenced by some factors, as: processing time, ratio of reactants (polymer : diamine : metallic salt), temperature and atmosphere (inert, oxygen, etc.) in which the reaction occurs. The such obtained polycondensation and polycomplexation products exhibit sensibly different properties from those of the support polymers: increased thermal stability, permanent magnetic moment and chemical resistance against some aggressive media (acids, bases and solvents).

INTRODUCTION

Experimental observations registered at mechanochemical polycondensation showed the ability of such synthesized fragments to react with the building material of the apparatus in which the mechanical processing was achieved, suggesting a new sort of synthesis, namely mechanochemical complexation.[2–4] On the other hand, the achieving of polycondensation by means of a destructive factor in condition of $^{60}Co\gamma$-rays energy instead of mechanical energy, reported in the first note of this work, created complexation premises for the destruction fragments of poly (ethyleneterephthalate) in the presence of ethylenediamine and some metallic salts.

The aim of the present paper is to describe comparatively the complexation methods under the action of the two kinds of energy (i.e., mechanical and γ-irradiation) on the principle of satisfying the electron vacancy of some metallic elements at the expense of electrons unparticipant in the chemical bond of electronegative elements (e.g., O and N) disposed along the macromolecular backbone. The complexation reaction takes place in the presence of polycondensation fragments, simultaneously synthetized, which finally act as macromolecular ligands.

We must mention that intermediate active centres are important for process achieving, and we also suppose that the complexation reaction starts only after the accumulation of a sufficient number of $-CO-NH-$ groups by chain which will become the future ligand; the $-CO-NH-$ group has two electronegative atoms carrying free electrons which will occupy vacancies of metallic elements.

The mechanochemical complexation and that by irradiation were verified in the system: poly(ethyleneterephthalate): ethylenediamine (forming the ligand): different metallic salts (e.g., Fe^{3+}, Mn^{2+}, Co^{2+}, Ni^{2+}, etc., acetates and chlorides).

EXPERIMENTAL

1. METHODS OF INVESTIGATION

The components of the polycondensation reaction, i. e., poly(ethyleneterephthalate) and ethylenediamine, were purified as previously described [5] and metallic salts were used without purification as "pro analysis" derivatives.

The mechanochemical complexation was processed in a laboratory vibrating mill LS-60, VEB Kefama Kotzhutte/Thuringer DDR equipped with stainless-steel milling bodies and vessels, gas admission and exhaust valves and thermostating jacket. Polymer powder, metallic salt and the balls were introduced into milling vessels ensuring the desired filling ratio (i.e., $\alpha = 0.4\,\%$). After vessel sealing and their cleaning by 3 or 4 vacuum — nitrogen cycles the reaction was carried out in nitrogen atmosphere. The amount of required ethylenediamine was introduced in the last vacuum cycle through a calibrated pipette fixed at a cover valve. The reaction temperature was $18 \pm 2°$. Vibration frequency was that of motor number of revolution (i.e., 1450 r.p.m.) and vibration amplitude was of 4 mm.

The complexation reaction by irradiation was carried out in glass ampoules equipped with a sealing system and means to make vacuum or to change the inert atmosphere. After homogeneous mixing of poly-(ethyleneterephthalate), ethylenediamine and metallic salt, the ampoules were cleaned by a vacuum — nitrogen cycle and after nitrogen cycle and nitrogen filling were sealed and exposed to ^{60}Co γ-rays action of 231 rad/hour. The irradiation time was constant (i.e. 18 hours) and corresponded to a dose of 15 Mrad.

---

[5] CL. VASILIU OPREA, CL. NEGULIANU and CR. SIMIONESCU, *Makromol. Chem.*, **126**, 217 (1969).

In the case of the mechanochemical method the complexation was achieved using the following systems :

a) poly(ethyleneterephthalate) (10 g) + ethylenediamine (30 g) + $FeCl_3.6H_2O$ (6.5 g).

b) poly(ethyleneterephthalate) (10 g) + ethylenediamine (30 g) + $Mn(CH_3COO)_2.4H_2O$ (6 g).

c) poly(ethyleneterephthalate) (10 g) + ethylenediamine (30 g) + $MnCl_2.4H_2O$ (6 g).

A wide range of factors was pursued in this reaction, e.g., polymer : diamine ratio, influence of the amount of metallic salt or of its anion and reaction time.

A systematic study and the obtained data were in detail reported earlier. [3,4]

When γ-rays energy was used, the main question lay in practical verification of this possibility of synthesis. For this purpose, all the parameters considered at mechanochemical degradation and the irradiation dose were kept constant and the influence of the amount of metallic salt, which is the provider of complexing agents, was mainly followed.

The reaction products obtained under the action of these two energies, i.e. mechanical and of γ-rays, were purified by methanol extraction in a Soxhlet apparatus with a view to removing the unreacted ethylenediamine and metallic salt.

In all cases two fractions were obtained by extraction, one soluble in methanol and another insoluble in methanol. The first fraction was considered to be purified when the material from the extraction cartridge did not vary its weight and the washing liquid had not chlorine anions (at least for metallic chlorides). After separation, this part of the reaction product was dried in vacuum at 40° and analysed. The obtained extract consists in a mixture of micromolecular derivatives, i.e. ethylenediamine and metallic salt, which represent the unreacted part of the reactants taken in excess and of some complexes synthesized on the above discussed principle, but methanol soluble.

We suppose that this part of the extraction mixture results either by polycondensation of oligomers (obtained by mechanochemical destruction or by irradiation of the support — polymers) with ethylenediamine and, subsequently, complexation with metallic elements or by the reaction of polycondensate with the complexing centre.

In order to separate this part of the extract it was concentrated, precipitated with ethylether, filtered and washed with large amounts of ether up to a complete removing of micromolecular components (i.e., ethylenediamine and metallic salts). After this treatment the product was dried in vacuum at room temperature and was considered as soluble fraction. Two specifications must be made :

1 — Solubility was for the moment verified only for a limited number of solvents.

2 — The discussed fraction does not solve as a matter of fact in methanol but in a methanolic solution of ethylenediamine (after purification, this fraction becomes insoluble in ethylenediamine free methanol).

2. INFLUENCE OF SOME FACTORS ON THE COMPLEXATION REACTION IN DESTRUCTIVE CONDITIONS

2.1. Reaction time

The influence of this factor on the mechanochemically conducted reaction was followed choosing as criterion for its evolution the percentage of chemically linked nitrogen, determined by the Kjeldahl method.

The obtained results are comparatively presented together in fig. 1. We can see that metal inserting in the structural unit of the new compound obtained determines a sensible lowering of the percentage of chemically linked nitrogen by polycondensation; the more weakly linked is the metallic element in the metallic salts which provide it, the lower is this percentage.

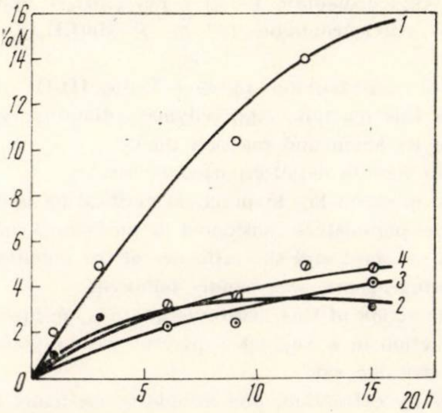

Fig. 1. – Dependence of chemically linked nitrogen on the reaction time for complexation products mechanochemically synthesized.

1, Witness polycondensation process; *2*, Complexation with $FeCl_3 . 6H_2O$; *3*, Complexation with $MnCl_2 . 4H_2O$; *4*, Complexation with $Mn(CH_3COO)_2 . 4H_2O$.

Examining curves *2* and *3* obtained using metallic chlorides salts of a strong acid – it is obvious that the content of chemically-fixed nitrogen is, for each moment of the reaction, lower than that corresponding to acetic salts (curve *4*) in which the metallic element is less bound. Owing to this fact the metallic centre is more easily attracted in the ligand sphere, the formation in the same period of several chelate centres being possible, in this last situation. At the same time, in every complexation case, the chemically linked nitrogen is lower than that corresponding to polycondensation products, proving formation of new structural units.

2.2. *Quantity of metallic salt*

The amount of ferric chloride, provider of complexing centres, is another decisive factor of reaction. In order to point out its influence, a succession of milling processes were achieved maintaining at constant values duration (3 hrs.) and diamine quantity (30 g) and varying metallic salt (i.e. ferric chloride) from 1.5 g to 15 g; the percentage of chemically linked nitrogen decreases gradually with the increase of the amount of complexing agent (fig. 2).

2.3. *Quantity of diamine*

The polycondensation process, in fact that of synthesis of the macromolecular ligand, is intimately determined by the amount of diamine introduced. The ratio between the reactants introduced represents a significative parameter of the reaction development as it regulates the proportion between the reaction of ligand synthesis and that of polycondensation.[2,5] This ratio was modified by introducing in the reaction medium variable amounts of ethylenediamine (10 – 15 ml), keeping unchanged the amounts of poly (ethylenterephthalate) and of metallic salt. The syntheses were carried out for a constant time of 9 hrs and the results are presented in fig. 3. For all investigated cases the curves are ascensive and have a flattening tendency for large diamine quantities (i.e., about 50 ml).

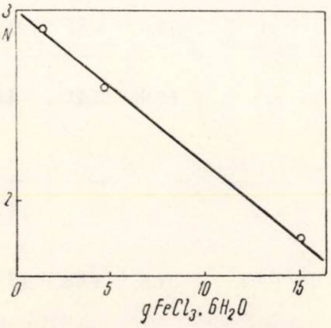

Fig. 2. Dependence of complexation reaction of poly (ethylenterephthalate) with ethylenediamine and $FeCl_3.6H_2O$ on the amount of metallic salt (iron chloride).

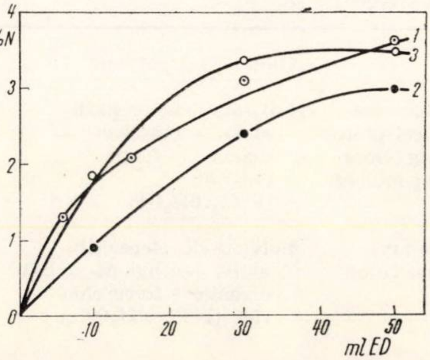

Fig. 3. Influence of amount of ethylenediamine on the process of mechanochemical complexation :

3. CHARACTERIZATION OF COMPLEXATION PRODUCTS SYNTHESIZED BY DESTRUCTIVE METHODS

3.1. Elementary analysis

One of the methods used for the characterization of complexes achieved by one of the two discussed routes, which allows for establishment of chemical composition, was the thermal decomposition of products in a combustion furnace at 700° and in nitrogen stream. The obtaine results are presented in tables 1 and 2.

Both at complexes based on iron and on manganese we can see a sensible modification of the elementary composition of the support polymer owing to its transformation by polycondensation and fixation of the metal as complexing centre.

Thus, it was found that the percent content of hydrogen and carbon is sensibly changed and a new element, namely nitrogen, is inserted,

Table 1

Comparative data of the chemical composition of the complexes synthesized (by mechanochemical processing and by γ-rays irradiation) from poly(ethyleneterephthalate), ethylenediamine and ferric chloride

The way in which the reaction is activated	Complex	Reaction time (hrs)	Amount of metallic salt (g)	Elementary analysis		
				%C	%H	%N
—	Unmodified polymer	0	0	63.6	4.81	0

which increases quantitatively with the processing time or with the amount of condensation agent.

Analysis of the products obtained changing different reaction parameters showed also corresponding changes of residuum, undecomposed during pyrolysis. The amount of residuum increases with the reaction time. The attempts to establish analytically (i.e., by colorimetric, gravimetric or volumetric analysis) the chemically bonded metal failed; the obtained values were anomalously increased. Consequently, the obtained residuum cannot be identified as one of the inorganic oxidate states of the metal to be used for its percent content calculation. In our opinion, this residuum represents in fact a macromolecular compound resulted by thermal transformation of the complex synthesized by the described methods, which remains unchanged up to high temperatures (i.e. near 1000°) and is characterized by chemical resistance (solvents, acids and bases).

Analysing the elementary composition of the products obtained at the limit degree of transformation by γ-rays irradiation and mechanochemically, it has been ascertained that, in the last case, the decrease of carbon or hydrogen content is more intense but the values of chemically linked nitrogen are greater in the first case.

It can be supposed that under mechanochemical conditions for long processing time, the reaction of ligand synthesis and complexation is accompanied by pronounced decarboxylation effects, more limited under irradiation conditions.

3.2. Infrared analysis

Infrared spectroscopy was another method used in order to obtain some information regarding the ligand structure and mechanism of its synthesis eventually. This method was indeed useful since the IR spectra of products synthesized in different working conditions are also different. The characterization of polycomplexes can be realized on the basis of their chemical composition which changes with the reaction time and the amount of complexing agent in the reaction medium.

Depending on these parameters, which condition the bonding of larger or smaller amounts of diamine, the complexation products are soluble or insoluble in extraction solvents (methanol or water) with the same remark, made at polycondensation, that the solubility does not refer to pure extraction solvents but to diluted solutions of ethylenediamine used for removing of the reactant excess (i.e., ethylenediamine or metallic salt) and their IR spectra show characteristic differences. Soluble products, containing high nitrogen percentages, (about 15%) exhibit a succession of common bands comparatively with IR spectra of the witness polymers, e.g., that corresponding to the aromatic ring or to the glycolic rest $-CH_2-CH_2-O-$, but other bands are quite new, corresponding to aminic groups, at 1560 cm^{-1} or 1640 cm^{-1} or to iminic groups, at 3300 cm^{-1}, which were formed by the reaction of destruction fragments with ethylene-diamine. In addition, these spectra are void of the band from 1720 cm^{-1}, corresponding to the most peculiar group of polyesteric support, namely the esteric carboxyl (fig. 4).

The IR spectra recorded in the case of insoluble products mechanochemically obtained ascertain the same structure of the ligand and of the corresponding polycondensation products, keeping the rule that

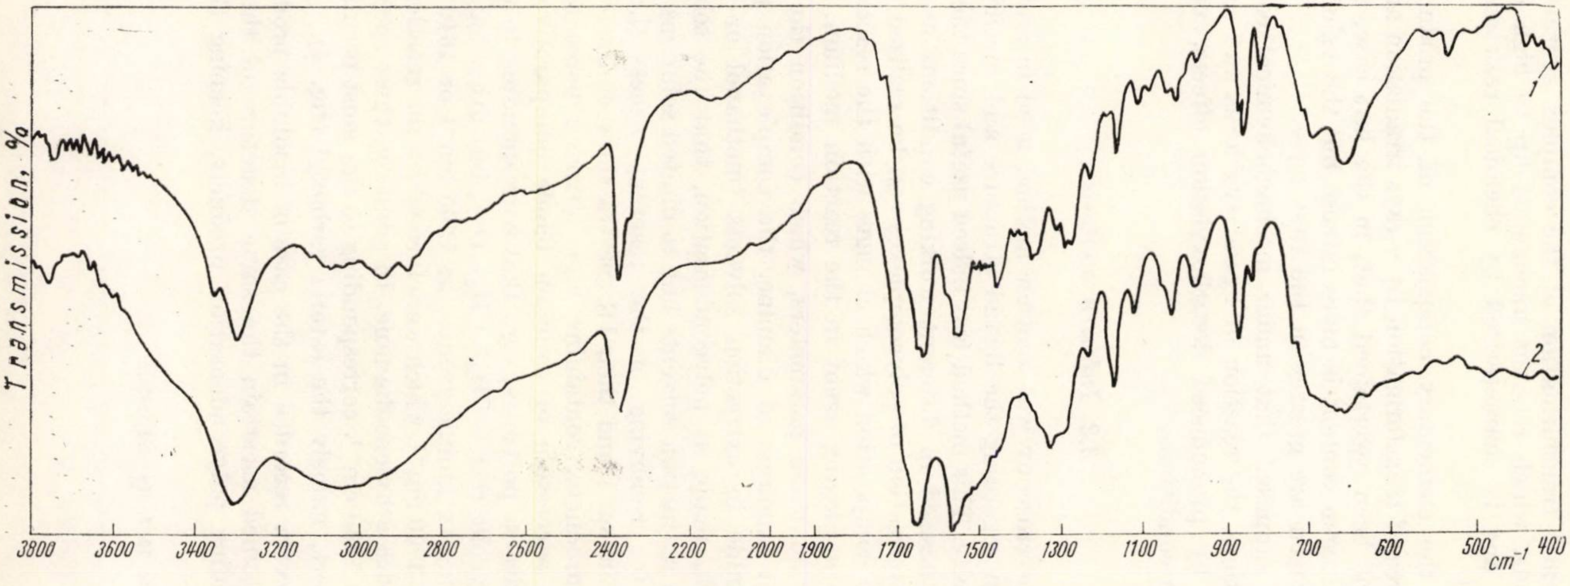

Fig. 4. — Comparative IR spectra of soluble complexes obtained by irradiation: *1*, Soluble product obtained from poly(ethyleneterephthalate), ethylenediamine and ferric **chloride**; *2*, Soluble **product** obtained from poly(ethyleneterephthalate), ethylenediamine and manganese **chloride**.

only for short reaction times the band of esteric carboxyl appears, it disappearing for long intervals of time (figs. 5, 6).

On the other hand, making a comparison between complexes characterized by limit degrees of transformation (e.g., 96 hours for mechanochemical synthesis and 18 hours for γ-rays irradiation process), we

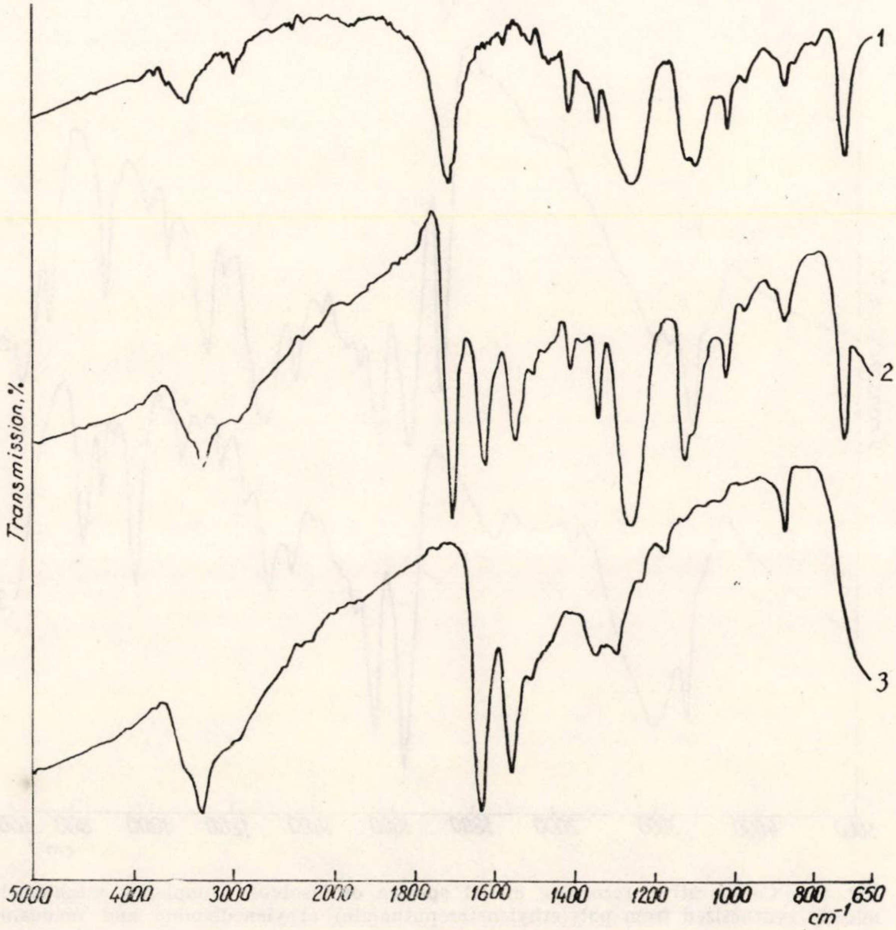

Fig. 5. — Comparative IR spectra of insoluble complexes mechanochemically obtained from poly(ethyleneterephthalate), ethylenediamine and ferric chloride:
1, Witness sample of poly(ethyleneterephthalate); *2*, Complex synthesized for a milling time of 15 hrs; *3*, Complex synthesized for a milling time of 96 hrs.

can see that, unlike the IR spectra of mechanochemical products which are void of band from 1720 cm^{-1}, the spectra of irradiation products still keep a small absorption at this wave number (fig. 7). This fact

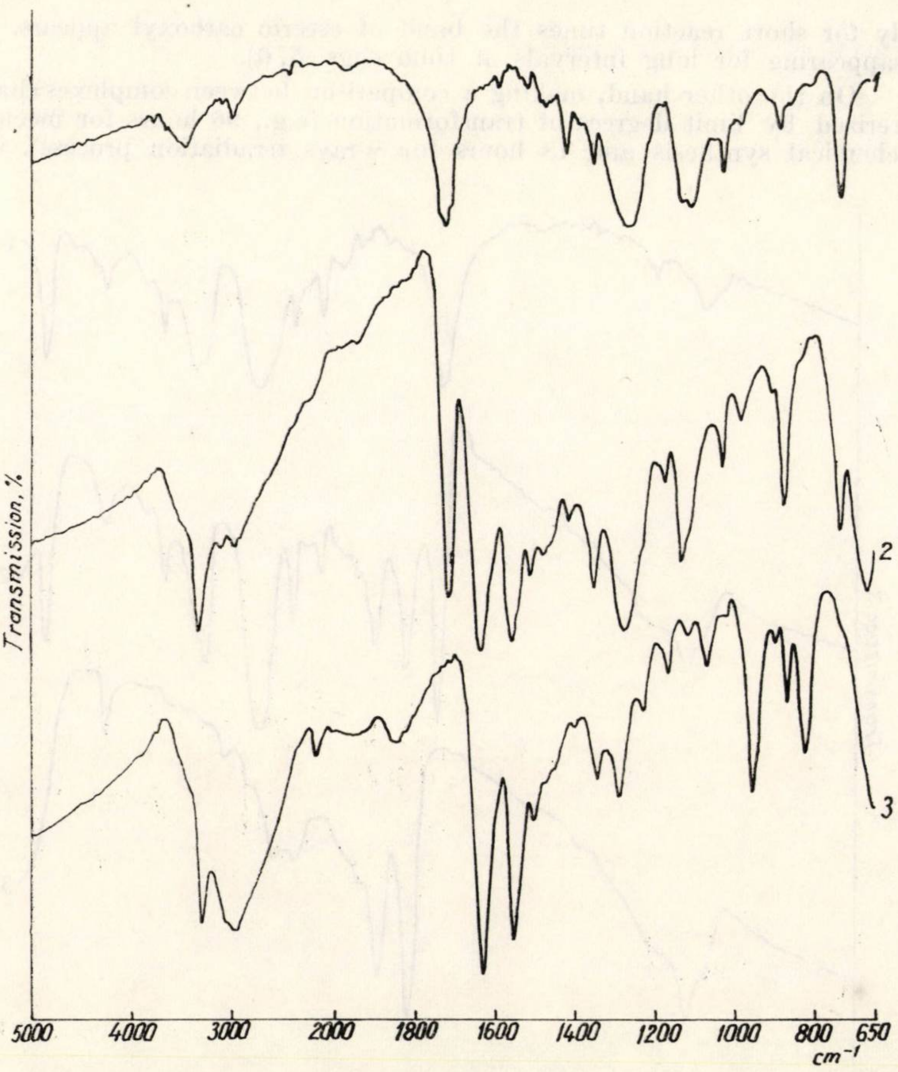

Fig. 6. — Comparative recording of IR spectra of insoluble complexes mechanochemically synthesized from poly(ethyleneterephthalate) ethylenediamine and manganese acetate;

1, witness polymer; *2*, complex synthesized for a milling time of 15 hrs.; *3*, complex synthesized for a milling time of 96 hrs.

may be explained by a more intense decarboxylation of the support for long durations of mechanochemical processing or by more intense effects of tautomer transformations $-CO-NH- \rightarrow -C=N-$, already discussed in our paper referring to polycondensation by destructive methods.

3.3. *ESR data*

The method of electron spin resonance has been used in order to point out the paramagnetic properties of the synthesized complexes.

These properties are justified on the one hand by the ligand structure (in ligands there are unparticipant electrons of electronegative elements, i.e. oxygen, nitrogen, from —CO—NH— groups formed by polycondensation) and, on the other hand, by the presence of metallic elements used as complexing centres (i.e. Fe^{3+}, Mn^{2+}). ESR spectra of samples synthesized mechanochemically or by irradiation containing variable amounts of metallic salts, were recorded using a Varian E-12 spectrometer.

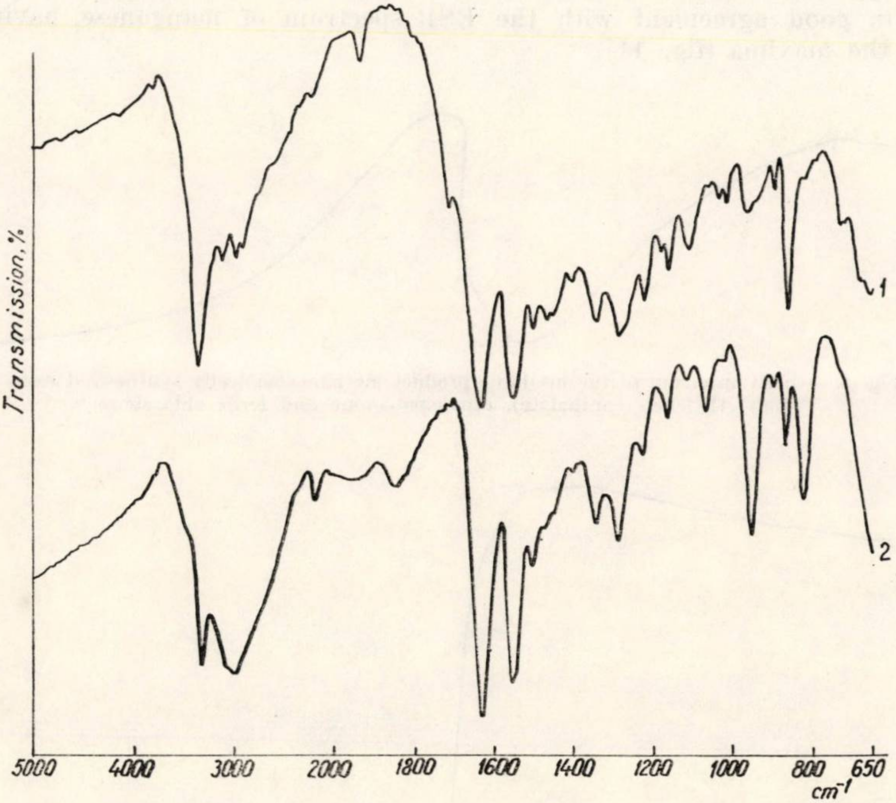

Fig. 7. — Comparative IR spectra of insoluble complexes of poly(ethyleneterephthalate), ethylenediamine and manganese acetate synthesized by irradiation (*1*) or by mechanochemical processing (*2*).

One can see that the number of complexing centres, respectively the metal amount of the polymer, has a decisive importance regarding the shape of ESR spectrum. It is well known that ESR spectra of paramagnetic metals are constituted from a number of bands which are characteristic for each element. Thus, in the case of manganese, ESR spectrum has six maxima, but,[6] in order to achieve this shape, the amount of metal has to be less than 10^{-1} g. Over this limit the bands overlap giving broader signals. In the case of the described complexes the metal amount in them exceeds almost in every case the said limit preventing the obtaining of a well-resolved spectrum. The high concentration of unpaired spins, owing to large amounts of metal, caused the overlap of the bands (figs. 8—10) both in the case of the samples mechanochemically synthesized and in the case of those obtained by irradiation. Nevertheless, in order to have a characteristic spectrum for synthesis of a complex by irradiation were used only 0.02 g of metallic salt (instead of 6.5 g, amount used in all cases). The ESR spectrum of this complex is in good agreement with the ESR spectrum of manganese, having all the maxima (fig. 11).

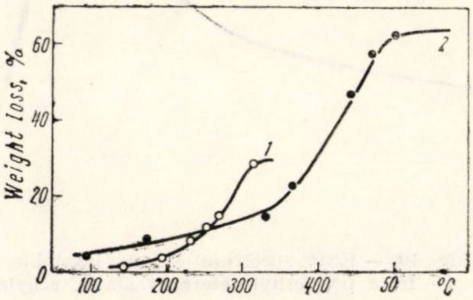
4. SOME PROPERTIES OF COMPLEXATION PRODUCTS SYNTHESIZED BY DESTRUCTIVE METHODS

4.1. Thermal stability

The thermal stability of the products synthesized in destructive conditions (i.e., by mechanochemical processing or γ-rays irradiation) was followed by thermogravimetric and thermodifferential analysis using a Paulik-Erdely thermobalance working over temperature intervals of 20—700° in inert medium and with a heating rate of 12.4°/min.

The thermal properties were studied choosing samples characterized by limit degrees of transformation obtained both by mechanochemical processing and by γ-rays irradiation using ferric and manganese acetates and chlorides as complexing agents. Some useful conclusions have been reached, as follows : making a comparison between mechanochemically synthesized samples representing complexes of iron or manganese, it has been found that the thermal stability of the products increases with the milling time (fig. 12); the complex achieved by vibrating milling for 12 hours of a reaction mixture of poly(ethyleneterephthalate), ethylenediamine and manganese acetate looses at 500° about 62 % of its weight, while that obtained for a reaction time of 96 hrs looses only 28.8 % of its weight at 310° and after that shows no more loss (fig. 13).

Fig. 12. — Dependence of weight loss percentage on the decomposition temperature; mechanochemical complex synthesized from poly(ethyleneterephthalate), ethylenediamine and manganese acetate by vibrating milling for 96 hours (*1*) and 12 hours (*2*).



If a comparison is made between complexes of the same metallic element but for synthesis for which different sorts of salts were used, e.g. manganese chloride and acetate, we can see that the complex of manganese chloride is more thermal resistant; perhaps the acetic ion is more easily decomposed thermally by temperature rising (fig. 14). At last, from this point of view a comparison is needed between mechanochemical and irradiation products. Fig. 15 shows that the weight loss is quite smaller in the case of the product mechanochemically synthesized for 96 hours from poly(ethyleneterephthalate), ethylenediamine and ferric chloride eaching only 29 % at 440° and remaining constant up to 1000° (fig. 15, rcurve *2* and fig. 16) while the product achieved by γ-rays irradiation and characterized by a limit degree of transformation (18 hours), is totally decomposed up to 600° (fig. 15, curve *1* and fig. 16). The same conclusion arises making a comparison between manganese complexes (fig. 17).

The high thermal stability of the complexes mechanochemically synthesized as compared with that of irradiation products must be related to the reaction times required for achieving the limit degree of transformation, which are quite different: 96 hours for mechanochemical processing and only 18 hours for γ-rays irradiation. This condition has as a consequence an intense side reaction of decarboxylation in the first case which is more limited in the second case. The same conclusion was drawn analysing the IR spectra of these complexes, as it was above emphasized.

On the other hand, the high thermal resistance of some complexes is justified in addition by another structural element, namely the nature of chelate cycles which are formed between the ligand and complexing center. In the investigated case, when ethylenediamine was used as condens-

ng agent, the cycles have five terms and it is well known that these cycles are the most stable[7] as compared with the cycles constituted from six terms.

4.2. *Chemical resistance*

The complexes synthesized by the described methods are coloured powders : dark-red (ferric complexes) or yellow-brown (manganese complexes), the intensity of colour depending on the amount of complexed metal. The fractions which we call "insoluble" are infusible and thermostable ; the "soluble" ones have melting points slightly smaller than those of the corresponding supports. The fractions which are insoluble in extraction solvents used for purification, are frequently insoluble also in the solvents of the support-polymer.

---

[7] P. Spacu and M. Brezeanu, "Chimia combinaţiilor complexe", Ed. didactică, 1969, p. 246.

Some data regarding the behaviour of ferric and manganese complexes in the presence of different chemical agents are listed in table 4 and patent [8]. In the first case it has been found that the polymer is only partially soluble, its solubility increasing with temperature rising. The most active solvent was ethanolamine, used at 50° and, respectively, at 100° (table 4). In the second case, that of manganese complexes, the most reactive agents are sulfuric and hydrochloric acids.

Table 3

Dependence of procentage thermostable residuum on the reaction time of the complexes with iron and manganese mechanochemically synthesized

Polymer	Reaction time hrs	Thermostable residuum %
Unmodified poly(ethyleneterephthalate)	0	0.00

Pyridine	2.10	3.60	5.50
Ethanolamine	13.90	39.00	49.50

4.3. Electric conductivity

It is known that insertion of metallic elements in different polymeric structures by complexation confer them properties of electric conductivity, many a time more marked for trivalent than for bivalent complexing centres [9].

In the case of complexes synthesized in destructive conditions, the electric conductivity is indeed changed in this sense, and close relations between this property and the reaction conditions (i.e., reaction time and reactant ratio), or strictly speaking between electric conductivity and the chemical composition of the resulted complex, have been ascertained. Analysing for example the dependence of electric conductivity on the reaction time, we can see that it gradually rises with the reaction development (table 5).

Polymer	Parameter of the mechanochemical synthesis	Electric conductivity, $\sigma(\text{ohm}^{-1}\ \text{cm}^{-1})$
Complex based on Fe^{3+}	Milling time ; hrs ; 0.25 15.00 96.00	$\sigma_{30} = 2.66\times10^{-13}$; $\sigma_{106} = 1.03\times10^{-9}$ $\sigma_{30} = 2.24\times10^{-10}$ $\sigma_{108} = 5.60\times10^{-7}$ $\sigma_{30} = 3.85\times10^{-10}$ $\sigma_{106} = 1.6\ \times10^{-6}$
	Amount of diamine, ml 15 30	$\sigma_{30} = 1.59\times10^{-10}$; $\sigma_{121} = 2.60\times10^{-7}$ $\sigma_{30} = 2.24\times10^{-10}$; $\sigma_{108} = 5.60\times10^{-7}$
Polychelate based on Mn^{2+} : poly(ethyleneterephthalate) + ethylenediamine + manganese acetate	Milling time, hrs 96	$\sigma_{12} = 1.15\times10^{-10}$; $\sigma_{96} = 5.41\times10^{-8}$
Poly(ethyleneterephthalate) + manganese acetate	96	$\sigma_{34} = 1.15\times10^{-14}$; $\sigma_{119} = 1.50\times10^{-1}$

The activation energy, E_A, changes with the percentage of chemically linked nitrogen in the ranges 2.09–1.03 eV, for polychelates based on iron and manganese, respectively, mechanochemically obtained. Plotting the change of nitrogen percentage *versus* milling time (fig. 17) or the amount of diamine used in reaction (fig. 18), it is seen that besides the corresponding change of activation energy (i.e., E_A decreases with nitrogen percentage increase) the semiconductor character becomes more prominent. As a matter of fact, the importance of diamine participation in the complexation process results in addition, making a comparison between electric conductivity of a complex synthesized by one of the discussed routes and of a witness product obtained in the same reaction conditions but only from a mixture of poly(ethyleneterephthalate) and the respective metallic salt. Following the data of table 5 regarding comparatively the electric conductivity of a complex based on manganese obtained mechanochemically for a milling time of 96 hrs and that of poly (ethyleneterephthalate) sample milled for the same time and in the presence of the same amount of metallic salt but without diamine, we can see, for the second case, negligible values of the studied parameters, while in the case of complexes this change varies as a function of reaction conditions.

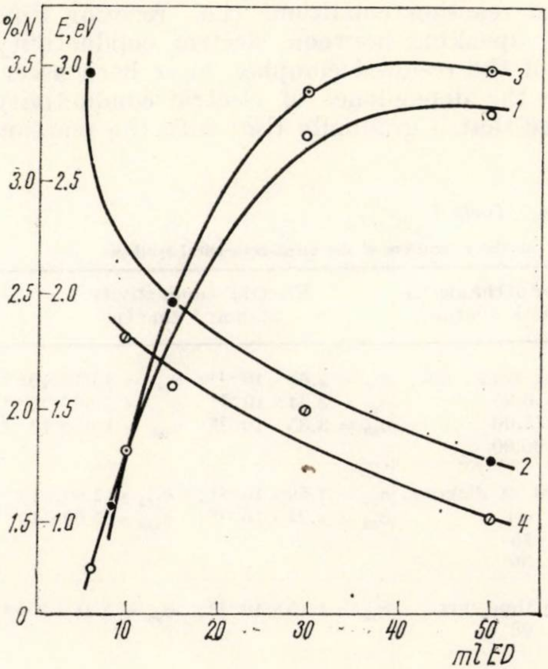

Fig. 18. — Dependence of activation energy of electric conductivity on the amount of ethylenediamine used in reaction and the chemical composition of the complex, respectively : *1*, dependence of percentage of chemically linked nitrogen on the amount of ethylenediamine for a complex with Fe^{3+} ; *2*, dependence of activation energy on the amount of ethylenediamine for a complex with Fe^{3+} ; *3*, dependence of procentage of chemically linked nitrogen on the amount of ethylenediamine for a complex based on Mn^{2+} (from manganese acetate) *4*, dependence of activation energy on the amount of ethylenediamine for a complex based on manganese.

4.4. *Dielectric constant*

Insertion of electropositive elements (i.e. Fe^{3+} and Mn^{2+}) on macromolecular backbones containing electronegative elements (i.e., oxygen and nitrogen) determines sensible changes in value of the dielectric constant and the parent polymer is transformed from an insulator into a semiconductor. Some data, referring to the dielectric constant and tangent of loss angle for different frequencies and temperatures, are given in figs. 19 and 20.

RESULTS AND DISCUSSION

The correlation of the experimental data obtained by application of different physical and chemical methods (e.g. elementary analysis, infrared spectroscopy, electron spin resonance, thermogravimetric and thermodifferential analysis, etc.), regarding the characterization of the polymers synthesized by the two already discussed destruction methods, namely mechanochemical processing and γ-rays irradiation, shows, on the one hand, that the polymers are not identical from the point of view of their structure and properties and, on the other hand, argues for the possibility of generalization of the working method used by the extension of the principle on which it is based, to other working systems: polymer — an energy source.

Polycondensation reactions carried out in systems containing poly (ethyleneterephthalate), ethylenediamine and different metallic salts con-

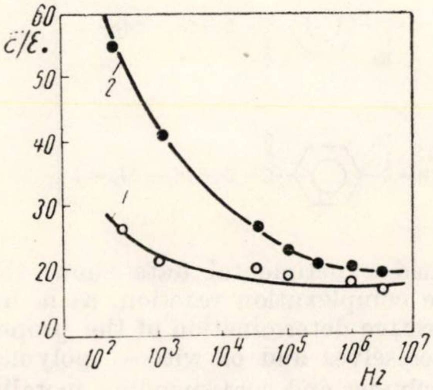

Fig. 19. — Dependence of dielectric constant on frequency for a poly(complex)based on Fe^{3+}:
1, at 20°; *2*, at 40°.

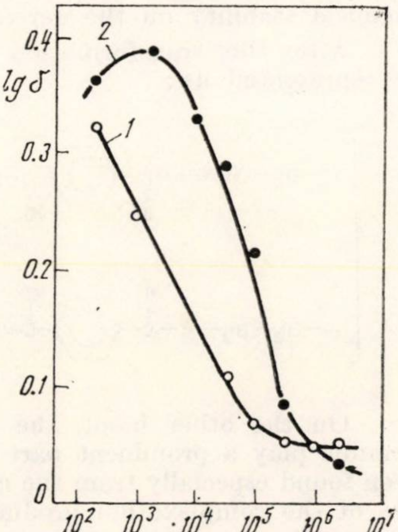

Fig. 20. — Dependence of tangent of loss angle for a complex based on Fe^{3+}
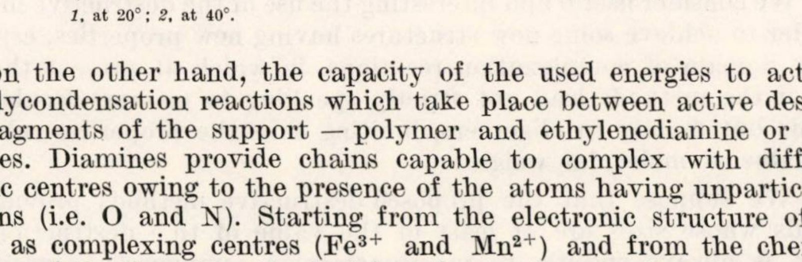
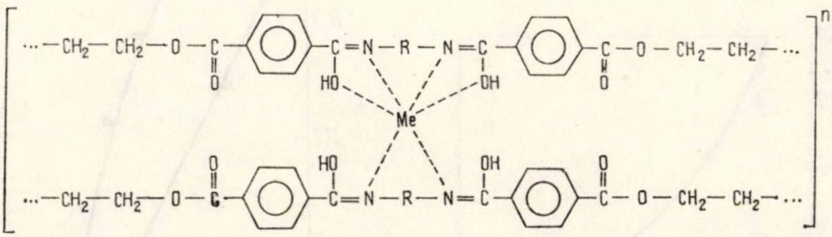
1, at 20°; *2*, at 40 °.

firm, on the other hand, the capacity of the used energies to activate the polycondensation reactions which take place between active destruction fragments of the support — polymer and ethylenediamine or other diamines. Diamines provide chains capable to complex with different metallic centres owing to the presence of the atoms having unparticipant electrons (i.e. O and N). Starting from the electronic structure of the metals as complexing centres (Fe^{3+} and Mn^{2+}) and from the chemical structure of the ligand synthesized just during the complexation reaction, the structural unit of such polymers can be depicted as follows:



The IR data prove, especially for mechanochemical processing, that by increasing the working time the ligand undergoes a tautomeric change :  $-\underset{\underset{O}{\|}}{C}-\underset{\underset{H}{|}}{N} \rightleftarrows -\underset{\underset{OH}{|}}{C}=N-$ which confers an additional thermal and chemical stability on the derivatives formed.

After this transformation the structural unit of the complex can be represented as :



On the other hand, the obtained experimental data show that diamine play a prominent part in the complexation reaction, as it has been found especially from the comparative determination of the properties of the complexation products themselves and of witness polymers achieved by processing of support — polymer and corresponding metallic salt. The witness polymers are not sensibly different from parent polymers from the point of view of the data of structural analysis.

We consider useful and interesting the use of the destructive methods, in order to achieve some new structures having new properties, especially in the domain of complexation reactions, in which at present the great part of the methods lead not strictly speaking to macromolecular compounds but mainly to oligomers, limiting thus the properties related to the value of molecular weight.

We suppose that the proposed destructive methods provide with ligands whose sizes are at least of the value of the destruction limit which is always specific to macromolecular compounds, especially in the case of mechanochemical methods.

CONCLUSIONS

1. Mechanochemical destruction and destruction by γ-rays irradiation of some heterochain polymers, as poly(ethyleneterephthalate), achieved in the presence of diamines and metallic salts, promote complexing reactions.

2. The chemical composition of the synthesized polymers is sensibly dependent on the reaction conditions : duration, ratio of reactants and the amount of metallic salt.

3. The synthesis of the ligand takes place by destructive polycondensation occurring at the same time with complexation; the ligand undergoes simultaneously decarboxylation reactions and a tautomeric change, leading to chain stabilization.

4. Complexes synthesized by mechanochemical processing and γ-rays irradiation exhibit properties which are sensibly different from those of the support: electric conduction, increased thermal stability and increased chemical resistance at the action of acids, bases and solvents.

5. The complexation process carried out in destructive conditions represents a direct application of that of polycondensation which is activated on the same principles and occurs in the same conditions.

ВЛИЯНИЕ УСЛОВИЙ РАСПЫЛИТЕЛЬНОЙ СУШКИ НА СВОЙСТВА ПАСТООБРАЗУЮЩЕГО ПОЛИВИНИЛХЛОРИДА

СООБЩЕНИЕ I.

ЭКСПЕРИМЕНТАЛЬНАЯ ЧАСТЬ

ВАЛЕНТИНА БОЙЕШАН

Промышленный нефтехимический комплекс, Борзешть
Исследовательская лаборатория

ДОРЕЛ ФЕЛЬДМАН

Политехнический институт, Яссы

Получена 30 декабря 1972 г.

Изучалось влияние режима сушки латекса поливинилхлорида в распылительной сушилке на свойства получаемых порошков и их способность к образованию паст. Было найдено, что основным параметром сушки является температура, которая влияет на размеры частиц порошка ПВХ, седиментацию паст и их реологические свойства.

Пластизоли, или пасты, являются коллоидными дисперсиями порошкообразного поливинилхлорида в пластификаторе, которые находятся в жидком или почти жидком состоянии. Для облегчения переработки и в зависимости от назначения в них добавляется ряд вспомогательных материалов: стабилизаторы, красители, наполнители и т.п.[1,2].

Пасты готовятся смешиванием при комнатной температуре порошка ПВХ в пластификаторе. При этом заботятся о том, чтобы полученная паста обладала следующими свойствами:

— имела высокую концентрацию полимера (50—65%);
— имела хорошую текучесть (относительно низкую вязкость);
— была устойчивой при хранении.

Под этим подразумевается сохранение постоянной вязкости во времени и устойчивость коллоидная, т.е. неразделение на фазы. Способность порошка ПВХ образовывать пасты с определенными свойствами зависит от ряда факторов, из которых наиболее важными считаются следующие:

— технология полимеризации;

---

[1] O. Berger и W. Braun, *Plaste u. Kautschuk*, **14**, 663 (1967).
[2] F. Böhme и K. Müller, *Plaste u. Kautschuk*, **7**, 124 (1960).

— условия сушки;

— вид и количество эмульгатора;

— размеры частичек ПВХ, их гранулометрическое распределение и морфология.

Поскольку строение и размеры частиц ПВХ формируются во время полимеризации, сушки и, в некоторых случаях, во время размалывания, считаем, что главными и определяющими факторами являются первые три, а последний — их производное.

Авторы настоящего сообщения занимались исследованием влияний условий распылительной сушки на физические свойства порошкообразного поливинилхлорида и его способность образовывать пасты, объясняя различное поведение порошка в контакте с пластификатором через отличия в строении частиц порошка.

1. СЫРЬЕ, АППАРАТУРА И МЕТОДИКА РАБОТЫ

1.1. СЫРЬЕ

Исследования проводились используя латекс, полученный из установки непрерывной эмульсионной полимеризации хлористого винила, с применением анионно-активного эмульгатора и пероксидного инициатора.

Латекс имел содержание сухого остатка $C = 40—42$ вес %, поверхностное натяжение $\tau = 3—5$ дин/см, удельный вес $\gamma = 1{,}13$ г/см, среднюю величину латексных частиц, определенных методом электронной микроскопии — 700—1100 Å.

1.2. СУШИЛЬНАЯ УСТАНОВКА

Сушка латекса производилась в лабораторной распылительной сушилке объемом в 1 м^3, в среде нагретого воздуха. Производительность сушильной установки 5 кг воды/час. Распыление латекса осуществлялось посредством двухжидкостной форсунки воздух/латекс при помощи сжатого воздуха $P = 4$ атм.

Подвергались изменению:

— расход латекса, соответственно отношение — воздух/латекс при распылении (в пределах 3,6—9,6 л. латекса/час на форсунку, соотв. воздух/латекс = 4750—1750), сохраняя постоянным расход воздуха.

— температура сушки ($T_1 = 100—140°$ — температура воздуха на входе в сушилку; $T_2 = 60—100°$ — температура воздуха на выходе).

1.3. МЕТОДЫ АНАЛИЗА

— Средняя величина чстиц ПВХ и их гранулометрическое распределение определялись по методу седиментации в воде, описанному Шубертом и Штреллер;[3]

— Способность образовывать пасты проверялась путем смешивания в ступке в течение 15 минут порошка ПВХ с диокитилфталатом (ДОФ) в весовом отношении 60/40. У полученных таким образом паст определялась вязкость начальная, через 24 часа и через 7 дней на реовискозиметре Гепплера.

— Течение паст при различных скоростях сдвига исследовалось на реовискозиметре Ротовиско-Гааке,

---

[3] W. Schubert и H. Streller, *Plaste u. Kautschuk*, **15**, 252 (1968).

— коллоидная устойчивость паст оценивалась путем наблюдения за оседанием частиц ПВХ в пасте и измерением диаметра « пятен », образованных отделившимся из пасты пластификатором по методике, данной Рисави.[4]

2. РЕЗУЛЬТАТЫ ЭКСПЕРИМЕНТОВ

Изучая условия распыления и сушки, пришли к выводу, что только изменяя вышеуказанные параметры, из одного и того же латекса можно получить порошкообразный ПВХ с совершенно различными свойствами: порошки, которые не образуют пасты совсем или образуют пасты с различным реологическим поведением.

С точки зрения влияния, оказываемого на вязкостные свойства паст, наиболее важным фактором оказалась температура сушки; тонкость распыления имеет меньшее значение.

2.1. ВЛИЯНИЕ СТЕПЕНИ РАСПЫЛЕНИЯ

От степени распыления зависят размеры частиц сухого порошка ПВХ, поскольку в сушилке из каждой капли латекса образуется твердая частица полимера шарообразной формы. Может считаться, что капля или твердая частичка столкнутся с другой такой же и тогда, в зависимости от состояния их сухости, произойдет слияние капель или слипание зерен. Но это — случаи более редкие и в основном величина сухих зерен пропорциональна диаметру распыляемых капель.

Степень распыления зависит от конструкции форсунок и отношения воздух/жидкость при распылении. Для типа форсунки, принимаемой в этой работе, средний размер капель рассчитывался по формуле[5]

$$dm = \frac{585\sqrt{\tau_1}}{Vr\sqrt{\gamma_1}} + 597\left(\frac{\eta_1}{\gamma_1\tau_1}\right)^{0,45}(1000R_{1/2})^{1,5}, \qquad (1)$$

где

dm — средний размер капель в микронах,

τ_1 — поверхностное натяжение латекса (35 дин/см),

$Vr = V_1 - V_2$ — относительная скорость между газом (V_2) и жидкостью (латексом) (V_1), в м/сек,

η_1 — динамическая вязкость латекса (0,035 пуаз),

γ_1 — плотность латекса, $\gamma_1 = 1{,}13$ г/см^3,

$R_{1/2} = \frac{V_1}{V_2}$ — объемное отношение жидкость/газ в форсунке, рассчитанное при минимальном сечении на выходе.

---

[4] D. Ryšavy, *Kunststoffe*, **48**, 108 (1958).

[5] A. Dăscălescu, « Uscarea », Ed. tehnică, Bukarest, 1964, p. 277.

При различных отношениях $R_{1/2}$ в форсунке и различных Vr были подсчитаны средние теоретические величины диаметров капель, представленные кривой 1 на рис. 1.

Во время сушки, благодаря испарению воды из латекса, происходит сжимание капель и сближение латексных частиц в капле. В идеальном случае, если бы из каждой капли латекса образовывалась монолитная частица полимера с плотностью 1,4 г/см^3, при концентрации сухого вещества в латексе в 40% произошло бы уменьшение размеров капель в 1,46 раз, как это выходит из уравнения

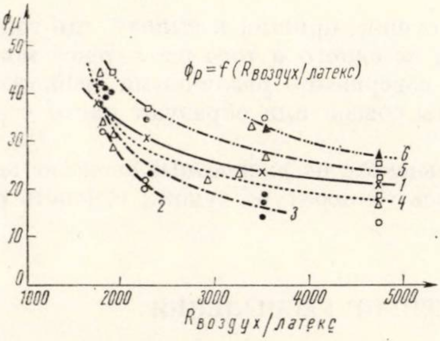

Рис. 1. — Изменения величины сухих частиц ПВХ в зависимости от соотношения воздух/латекс:
кривая *1* — средние рассчитанные размеры диаметров латексных капель (в микронах), кривые *2—6* — средние размеры (в микронах) сухих частиц ПВХ высушенных при температурах: *2* —70°, *3*—80°, *4*— 90°, *5*—10 0°, *6*—110°.

$$\frac{\pi d_1^3 \gamma_1}{6} = \frac{\pi d_2^3 \gamma_2}{6} + G, \qquad (2)$$

где

d_1 и d_2 — диаметры капель латекса и соответственно частиц ПВХ,

γ_1 и γ_2 — плотности латекса и ПВХ,

G — вес испаренной воды.

В действительности из-за быстрого испарения воды латексные частицы не успевают перегруппироваться в капле в плотную сетку и образуют пористое зерно с плотностью $< 1,4$ г/см^3. Пористость неоднородна и зависит от первоначальных размеров капли и температуры сушки.

На рис. 1 представлены практические данные изменения величины сухих частиц полимера, полученных при различных температурах сушки T на выходе из сушилки, в зависимости от степени распыления. Для сравнения тут же приведена и теоретическая кривая 1 для невысушенных капель латекса, рассчитанная по формуле (2). Видно, что:

— величина высушенных частиц изменяется пропорционально величине исходных капель;

— частицы, высушенные при более низких температурах, имеют средние размеры меньшие, чем те, что были высушены при более высоких температурах;

— при температурах сушки выше 100° вместо уменьшения размеров капель наблюдается, наоборот, увеличение средних размеров частиц.

Эти различия можно объяснить различной пористостью частиц. Ряд авторов [6-8] придают большое значение абсолютным размерам и гранулометрическому составу частиц при образовании паст из ПВХ. Считается, что вязкость паст будет тем меньше, чем шире гранулометрическое распределение частиц, или что должно существовать оптимально соотношение между большими и маленькими частицами таким образом, чтобы мелкие частици заполняли пространство между большими, оставляя минимальным объем пустот между ними. В этом случае уменьшается количество пластификатора, необходимого для заполнения пустот между частицами полимера, и при том же объеме употребляемого пластификатора оказывается свободным большее количество жидкости.

Эти соображения верны, если все частицы имеют одинакую структуру и в контакте с пластификатором не происходит разрушение частиц. На самом же деле частицы с одинаковым гранулометрическим составом, но полученные в различных условиях сушки, ведут себя неодинаково по отношению к пластификатору. Так, нами были проверены пастообразующие свойства нескольких проб поливинилхлорида со сходным гранулометрическим составом, но полученных в разных температурных условиях (см. рис. 2 a) и проб с различным гранулометрическим составом, но полученных в одинаковых условиях (см. рис. 2 b). Видно, что изменение вязкости паст во времени не зависит от размеров зерен порошков и следует за изменением температуры сушки.

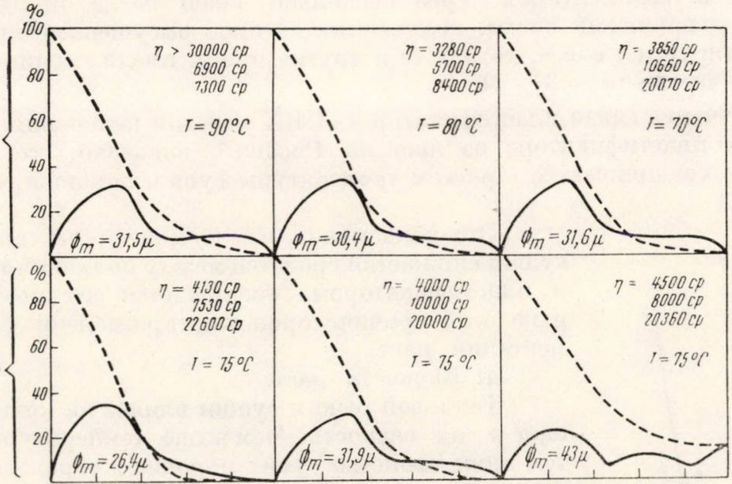

Рис. 2. — Гранулометрический состав, средний размер частиц (Ø в микронах) и изменение вязкости паст во времени (через 1 час, 24 часа и 7 дней) для проб, полученных:

а) при разных температурах сушки T_j:

б) при разных расходах латекса при распылении.

---

[6] T. Hugosson, *Kunststoffe*, **46**, 341 (1956).

[7] H. Koch и W. Sommer, *Kunststoffe*, **47**, 153 (1957).

[8] G. Wick, *Österr. Chem. Ztg.*, **62**, 5 (1961).

Выходит, что одно гранулометрическое распределение без учета условий получения порошка не может быть определяющим фактором в получении паст ПВХ определенной вязкости.

2.2. ВЛИЯНИЕ ТЕМПЕРАТУРЫ СУШКИ

Исследовалась температура воздуха на выходе из сушилки, поскольку сушилка работает в адиабатическом режиме и сразу же после входа нагретого воздуха в сушилку происходит снижение его температуры благодаря расходу тепла на испарение воды. Температура нагретого воздуха на входе в сушилку поддерживалась на необходимом уровне согласно тепловому балансу, определяемому количеством испарившейся воды.

Было замечено, что температура воздуха на выходе из сушилки (сокращенно названная температурой сушки) оказывает многочисленные влияния на свойства полихлорлвинильного порошка. От нее зависят:

а) Величина зерен сухого порошка, как показывает рис. 1.

б) Седиментация паст во времени.

С повышением температуры увеличивается склонность частиц ПВХ к седиментации в пасте, из которой начинает выделяться пластификатор даже в случае частиц небольших размеров.

Так, например, у проб, высушенных при температуре 90°, в пастах начинается седиментация через несколько часов после приготовления пасты, в то время как пасты, полученные из проб высушенные при 70°, не седиментируются вовсе, хотя и те и другие пробы имели сходные средние размеры частиц ($d = 31-80$).

Изучение связи пластификатор — ПВХ методом измерения диаметра « пятен » пластификатора из паст по Рисави[4] показало, что диаметр « пятна » увеличивается с ростом температуры сушки порошка, что видно из рис. 3.

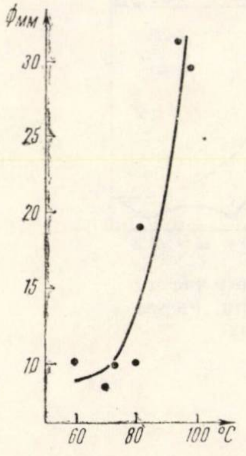

Рис. 3. — Диаметр «пятен» в зависимости от температуры сушки.

Это доказывает, что по мере роста температуры сушки снижается сродство между поливинилхлоридом и пластификатором, уменьшается его лиофильность и по этой причине происходит разделение фаз и седиментация паст.

в) Вязкость паст.

Тепловой режим сушки влияет на консистенцию паст и их вязкость. Чем выше температура сушки, тем ниже свойство сухих порошков образовывать пасты, их первоначальная вязкость растет до полного несвязывания частиц в пасты. В то же время, стабильность вязкости паст во времени улучшается с повышением температуры сушки порошка.

Эти различия видны из графиков рис. 4, где представлены изменения вязкости паст, измеренной на реовискозиметре Гепплера, во времени (начальная, через 24 часа и через 7 дней) и в зависимости от температуры сушки (T_2) порошков ПВХ.

Характер изменения вязкости во времени виден еще лучше из рис. 5—6, на которых кривые были построены на основании математических расчетов вязкости при программировании и обработке результатов по методу Бокса-Вильсона. [9–11]

Были обработаны средние данные экспериментов на 3 уровнях программирования с двумя переменными (температура и расход), получив $\eta = 3^2 = 9$ величин принятых в расчет. Были решены уравнения 2-ой степени, по которым были построены кривые.

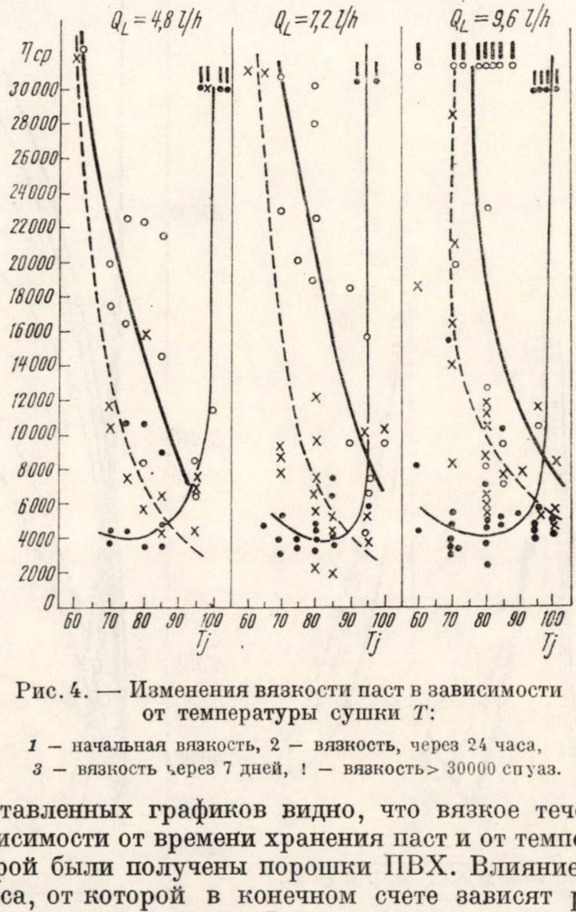

Рис. 4. — Изменения вязкости паст в зависимости от температуры сушки T:

1 — начальная вязкость, 2 — вязкость, через 24 часа,
3 — вязкость через 7 дней, ! — вязкость> 30000 спуаз.

Из представленных графиков видно, что вязкое течение паст различается в зависимости от времени хранения паст и от температуры сушки (T_j), при которой были получены порошки ПВХ. Влияние тонкости распыления латекса, от которой в конечном счете зависят размеры сухих частиц, заметно в меньшей степени. Все же, более мелкие частицы образуют более устойчивые пасты.

На рис. 7 представлены реологические кривые $\eta = f(Ds^{-1})$ (вязкость в зависимости от скорости сдвига) для паст, приготовленных из порошков, высушенных при различных температурах, но при одинаковых условиях распыления.

---

[11] A. Glück, « Metode matematice în industria chimică », Ed. tehnică, Bukarest, 1971.

Видно, что снижение температуры сушки способствует псевдопластичному течению, в то время как повышение температуры ведет к дилатансии, что было замечено и другими исследователями.[1,4,12,13]

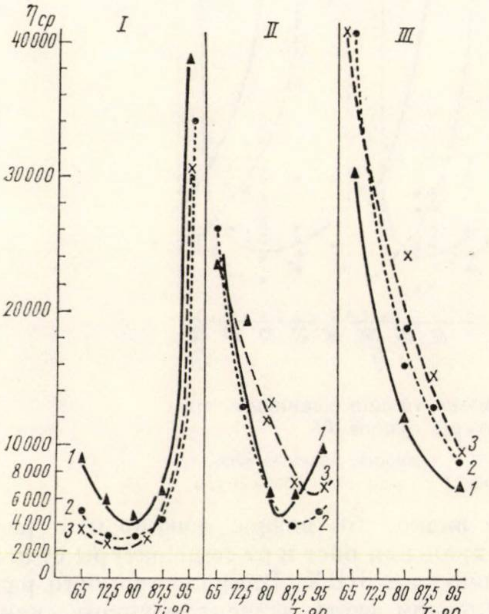

Рис. 5. — Изменения вязкости паст во времени (I — начальная, II — через 24 часа, III — через 7 дней) в зависимости от температуры T сушки ПВХ при различных расходах латекса на форсунку:

1 – 4, 8 л/час, 2 – 7, 2 л/час, 3 – 9, 6 л/час.

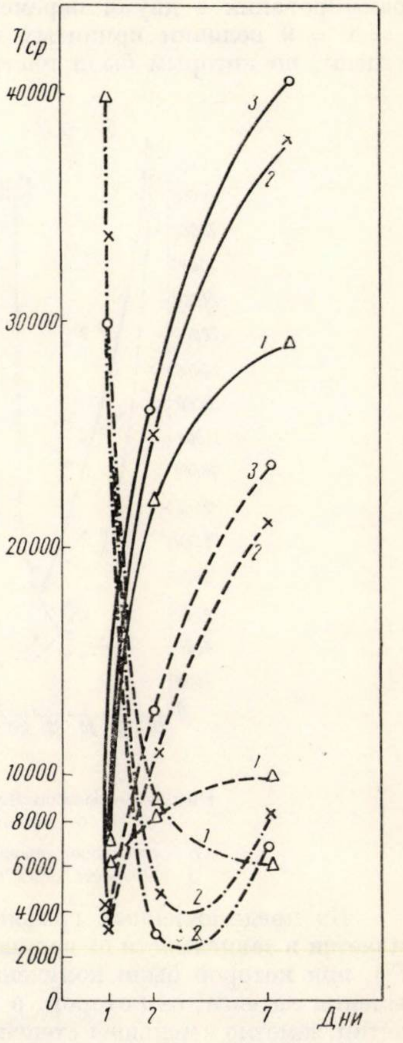

Рис. 6. — Изменение вязкости паст во времени в зависимости от температуры сушки T_j и соотношения воздух/латекс Rв/л при распылении:

——— $T_j = 65°$; 1 – R в/л = 3850;
– – – – – – $T_j = 80°$; 2 – R в/л = 23.8;
– · – · – · – $T_j = 95°$; 3 – Rв/л = 1790.

---

[12] Б. П. Штаркман и И. А. Мухина, *Пласт. массы*, **31**, 50 (1969).

[13] Б. П. Штаркман, И. А. Мухина и Л. И. Шарикова, *Коллоид. журнал*, **31**, 611 (1969).

Порошки, которые не связываются в пасты сначала, через 24 часа контакта с пластификатором образуют сильно дилатантные пасты. Влияние тонкости распыления латекса при сушке менее заметно в реологии паст. На рис. 8 представлены реологические кривые проб, полученных при 70° и различных расходах латекса при распылении, т.е. различных тонкостных распыления. Все порошки, полученные при этой температуре, образуют пасты с псевдопластичным течением, но у более крупных частиц снижения вязкости при больших скоростях сдвига выражено более ярко.

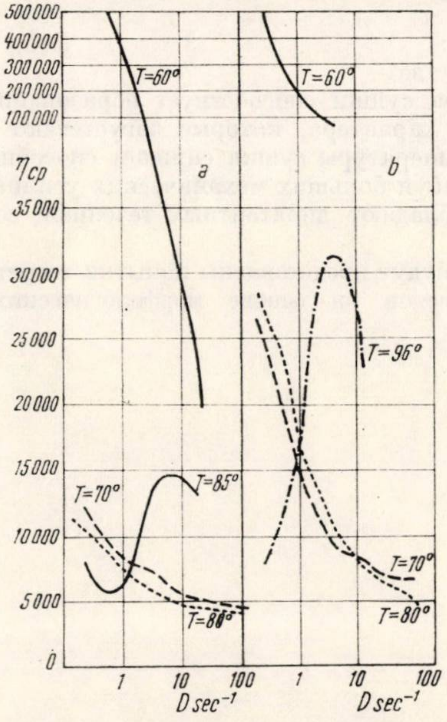

Рис. 7. — Реологические кривые паст $\eta_{cp}=f(Ds^{-1})$ в зависимости от температуры сушки ПВХ:

а) начальная вязкость; б) вязкость через 24 часа.

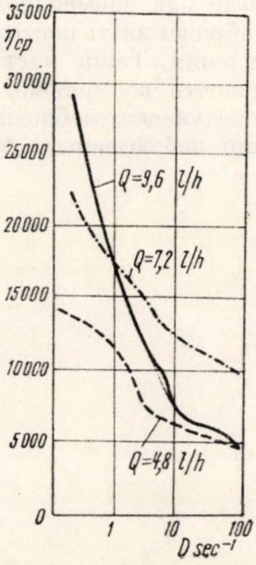

Рис. 8. — Реологические кривые паст $\eta_{cp} = f(Ds^{-1})$ в зависимости от расхода латекса форсунку, л/час. Температура сушки $T_j = 70°$.

ВЫВОДЫ

Изучалось влияние режима сушки латекса ПВХ в распылительной сушилке на свойства порошков и их способности к образованию паст.

Было найдено, что основным параметром сушки является температура; тонкость распыления можно считать вторичным фактором, который все же оказывает влияние на стабильность паст во времени.

Температура сушки оказывает следующие влияния:

— на величину частиц порошка ПВХ;
— на седиментацию паст;
— на консистенцию паст;
— на реологические свойства.

Более низкая температура сушки способствует образованию текучих паст псевдопластического характера, которые загустевают во времени, тогда как повышение температуры сушки снижает способность порошков образовывать пасты, требуя больших механических усилий для их приготовления. Такие пасты обладают дилатантным течением, со снижением вязкости во времени.

В следующем сообщении будут представлены попытки теоретических объяснений наблюдаемых феноменов на основе морфологических исследований.

QUELQUES REMARQUES SUR LES PROPRIÉTÉS DES BÉTONS AUX RÉSINES SYNTHÉTIQUES SANS LIANTS MINÉRAUX. II[1]

I. IONESCU

Laboratoires des Bétons, Mortiers et Armatures pour Bétons — I.C.M.P.C. — Bucarest

Reçu le 18 Avril 1973

On présente les résultats des recherches sur l'influence de certaines propriétés physiques-chimiques des types de résines synthétiques et des facteurs de composition sur les principales propriétés physiques-chimiques des bétons à base de résines synthétiques sans liants minéraux.

Les propriétés des bétons de résines synthétiques sans liants minéraux sont modifiées par de très nombreux facteurs, et les tentatives d'explications scientifiques sont rares encore et limitées.[1–5] En ce qui concerne les propriétés des bétons de monomère FA, nos recherches ont porté sur :

— les propriétés de la résine, du durcisseur et du solvant utilisés et leur dosage ;

— la nature, la provenance et la rugosité de l'agrégat (y compris le filler) ;

— la méthode de travail adoptée, la température et l'humidité de l'air pendant la période de préparation et dans l'intervalle préparation-essai ;

— l'âge et le milieu d'essai, etc.

1. RÉSISTANCE À LA TRACTION PAR FLEXION ET À LA COMPRESSION

Les résistances à la traction par flexion pour les bétons de monomère FA, conservés dans l'intervalle confection-essai à l'ambiance du laboratoire, ont des valeurs comprises entre 64,7 et 168 kgf/cm^2 à 1 jour et continuent à augmenter jusqu'à atteindre de 84,6 à 203 kgf/cm^2 à 7 jours, de 98,3 à 214,6 kgf/cm^2 à 28 jours de 129,8 à 256,8 kgf/cm^2 à un an, de 140,8 à 252,0 kgf/cm^2 à 3 ans. Les bétons de monomère FA et résine LS. 1 (compositions 34 à 39 tableau 1), conservés dans les mêmes conditions, ont, à un jour, des résistances de 28,5 à 29,0 kgf/cm^2, qui continuent à augmenter, de sorte qu'à 28 jours ils atteignent des valeurs de 82,4 à 126,4 kgf/cm^2 ; à un an de 122,6 à 143,1 kgf/cm^2 et de 128,9 à 149,5 kgf/cm^2 à 3 ans, augmentation sensible si on la compare à celle des bétons à résine phénol-formaldéhyde — LS.1 (composition 33, tableau 1), qui est de 42,6 kgf/cm^2 à 7 jours de 67,4 kgf/cm^2 à un an.

Les résistances à la compression, pour les bétons de monomère FA, conservés dans les mêmes conditions, ont des valeurs comprises entre 308 et 760 kgf/cm^2 à 1 jour, qui continuent à augmenter atteignant 339 à 959 kgf/cm^2 à 7 jours, de 529 à 1042 kgf/cm^2 à 28 jours, 682 à 1249 kgf/cm^2 à un an, 706 à 1288 kgf/cm^2 à deux ans, etc. Les bétons de monomère FA et résine LS.1 (compositions 34 à 39, tableau 1) conservés dans les mêmes conditions, ont, à un jour, des résistances de 118 à 174 kgf/cm^2 qui continuent à augmenter et qui atteignent 479 à 628 kgf/cm^2 à 7 jours, 702 à 834 kgf/cm^2 à un an, 716 à 842 kgf/cm^2 à 2 ans, etc, alors qu'on obtient 207 kgf/cm^2 à 7 jours et 448 kgf/cm^2 à 2 ans pour les bétons de résine phénol-formaldéhyde — LS.1 (composition 33, tableau 1).

Les résistances à la traction par flexion et à la compression pour les bétons de monomère FA immergé dans l'eau durant l'intervalle décoffrage-essai (fig. 1 *a* et *b*) augmentent elles aussi dans le temps, mais assez lentement, de sorte qu'aux essais effectués entre 28 et 730 jours, elles représentent de 40 à 65% des résistances des éprouvettes conservées tout le temps à l'atmosphère du laboratoire, ce qui confirme les résultats des recherches préliminaires.[1,6-10] Les résistances des bétons de monomère FA conservés les 28 premiers jours depuis la coulée à l'atmosphère au laboratoire et ensuite immergés dans l'eau potable jusqu'à 365 jours, ont d'abord une légère tendance à décroître jusqu'à 90 à 180 jours, et augmentent ensuite lentement (fig. 1*c*).

Si les résistances des bétons de monomère FA augmentent jusqu'à 1 à 3 ans, leur principale augmentation est enregistrée dans les 7 premiers jours, après la coulée ; la résistance représente alors, en moyenne, 75% de la résistance à un an, puis augmente de plus en plus lentement, pour atteindre, à 28 jours, généralement plus de 90% de la résistance à un an ; celle-ci est pratiquement du même ordre de grandeur que la résistance à 3 ans. Pour les bétons de monomère FA et résine LS.1, l'augmen-

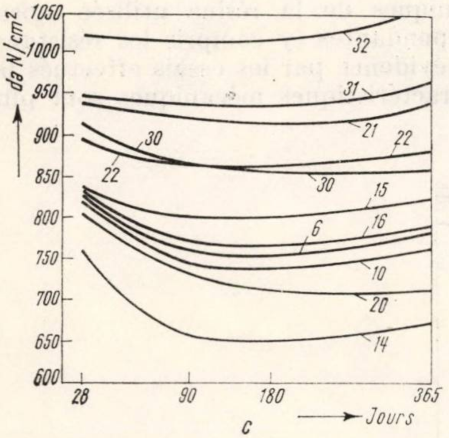

Fig. 1. — a) Variation dans le temps de la résistance à la traction par flexion pour quelques bétons à monomère FA, ou à monomère FA et résine LS.1, pour des éprouvettes conservées à l'atmosphère du laboratoire et des éprouvettes conservées dans l'eau pendant l'intervalle 24 h — âge d'essai (séries d'éprouvettes à 6′, 7′, 10′, 13′, 20′) (pour les compositions, voir tableau 1) ; b) Variation dans le temps de la résistance à la compression pour quelques bétons à monomère FA, ou à monomère FA et résine LS. 1, pour des éprouvettes conservées dans l'eau de 24 h à l'âge d'essai (séries d'éprouvettes 6′, 7′, 10′, 13′, 20′) (pour les compositions, voir tableau 1) ; c) Variation des résistances à la compression pour quelques types de béton à monomère FA lors de l'immersion dans l'eau potable, après une conservation de 28 jours à l'atmosphère du laboratoire (pour les compositions, voir tableau 1).

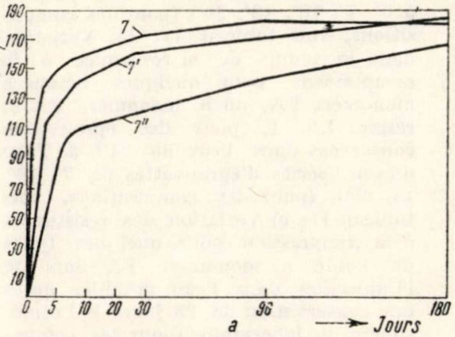
tation des résistances dans la période initiale est un peu plus faible. A 7 jours, on obtient des valeurs qui représentent en moyenne 55 à 65% et à 28 jours, 85 à 90% de la résistance à un an. Le rapport entre la résistance à la compression et la résistance à la traction par flexion des bétons de monomère FA se tient souvent entre 1/4,4 et 1/5,3, de sorte que pour les essais à 28 jours on peut établir avec assez de précision la relation :

$$\sigma_{ti} = 0{,}20\ \sigma_c \qquad (1)$$

Ce rapport, pour les bétons de monomère FA et résine LS.1, varie entre 1/5 et 1/7. Dans ce cas, la variation du rapport R_{ti}/R_c dans des limites plus larges est due à des modifications accusées des propriétés du liant organique utilisé (la résine LS.1 entre dans la composition du liant pour 33 à 67%).

Dans des conditions identiques de confection et d'essai, les résistances mécaniques sont sensiblement affectées, jusqu'à 180 jours, par le taux de durcisseur utilisé (fig. 2 *a* et *b*). Une petite quantité de durcisseur (ABS) dans le mélange est la cause de faibles résistances, du fait du délai prolongé de polymérisation de la résine et en même temps, d'une sensibilité beaucoup plus grande du béton à l'action prématurée de l'eau ou à d'autres actions néfastes pour la résine. Une forte quantité de durcisseur (au-delà du taux considéré comme optimal) détermine un béton de grande fragilité, cassant, de faible résistance au choc mécanique, etc. [1-10]

Les propriétés physico-mécaniques de la résine utilisée agissent elles aussi sur les propriétés correspondantes (y compris les résistances) du béton. Cet aspect a été mis en évidence par les essais effectués pour utiliser la résine LS.1 (dont les caractéristiques mécaniques sont plutôt faibles) dans différentes proportions avec le monomère FA (fig. 1 *a* et *b*). L'augmentation du dosage de la résine, entre certaines limites, pour une quantité constante d'agrégat, n'a pas pour effet un gain de résistance mécanique. Une plus forte proportion de liant peut même entraîner une diminution de résistance par l'accroissement de l'épaisseur du film de résine (matériau de faible rigidité), entre les grains de l'agrégat. Donc, pour chaque composition d'agrégat, il y a un dosage optimal de résine, qui détermine des résistances mécaniques optimales. Une modification du dosage de résine de ±5 à 7 % autour du dosage optimal affecte davantage la consistance du béton que les résistances. Des résistances mécaniques élevées pour de forts dosages peuvent être obtenues avec des agrégats adéquats, par exemple les compositions aux n°s 30 à 32 (tableau 1), préparées avec du filler de concassage (F_2 et F_3) ou avec du filler spécial (F_4) et 24 % de résine.[1-10]



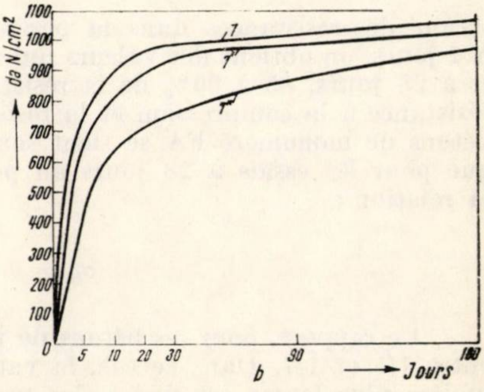


Fig. 2. a) Variation de la résistance à la traction par flexion ; b) Variation de la résistance à la compression pour la composition 7 du tableau 1, pour différents pourcentages de durcisseur (7= 100 %, 7' = 67 %, 7'' = 33 %) et pour une conservation à l'atmosphère du laboratoire à *t* = 20 à 22°.

2. RÉSISTANCE SUR PRISME

Les recherches effectuées sur différentes compositions de béton de monomère FA, à différents âges d'essai (fig. 3 *a* à *d*) indiquent que le rapport R_{pr}/R_c diminue avec l'augmentation du rapport h/b entre la hauteur du prisme et le côté de la section transversale, la diminution étant plus rapide pour h/b = 0,5 à 2,5 et devenant ensuite de plus en plus lente. Pour des compositions identiques, les valeurs du rapport R_{pr}/R_c sont différenciées selon l'âge d'essai des éprouvettes, le dosage

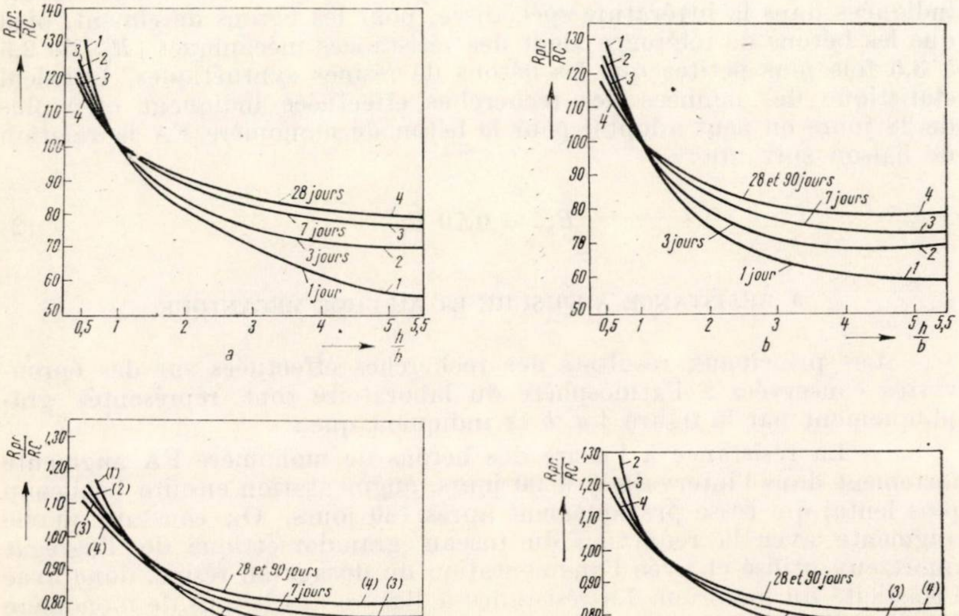

Fig. 3. — a) Variation du rapport R_{pr}/R_c dans le cas du béton fin à agrégats quartzeux broyé 0,02 à 0,30 mm additionné de 24 % de résine, essais effectués entre 1 et 28 jours. b) Variation du rapport R_{pr}/R_c dans le cas du béton fin à agrégats quartzeux 0,02 à 3 mm additionné de 16 % de résine, essais effectués entre 1 et 90 jours ; c) Variation du rapport R_{pr}/R_c dans le cas du béton à agrégats quartzeux 0,02 à 15 mm additionné de 13 % de résine, essais effectués entre 1 et 90 jours ; d) Variation du rapport R_{pr}/R_c dans le cas du béton à agrégats quartzeux 0,1 mm + agrégats basaltiques 1 à 15 mm additionné de 13 % de résine, essais effectués entre 3 et 90 jours.

en résine, la granulométrie et le type d'agrégat utilisé.[8-15] Des différences sensibles sont obtenues surtout pour les essais effectués aux jeunes âges, 1 et 3 jours (fig. 3 *a* à *d*).

A 7 jours, les différences entre les rapports R_{pr}/R_c obtenus par l'essai de bétons de différentes compositions s'atténuent sensiblement, et à 28 et 90 jours, pour la même composition, les valeurs du rapport R_{pr}/R_c sont pratiquement égales, de sorte que dans la représentation graphique les courbes sont superposées (fig. 3 *a* à *d*). Les recherches effectuées jusqu'à l'âge de 3 ans sur des bétons de monomère FA (fig. 3 *d*) ont montré que les valeurs du rapport R_{pr}/R_c sont inférieures aux valeurs indiquées dans la littérature spécialisée, pour les bétons de ciment, bien que les bétons de référence aient des résistances mécaniques (R_c) de 2,5 à 3,5 fois plus petites que les bétons de résines synthétiques. Le calcul statistique des données des recherches effectuées indiquent qu'à plus de 28 jours on peut adopter pour le béton de monomère FA la relation de liaison suivante :

$$R_{pr} = 0{,}70\ R_c \tag{2}$$

3. RÉSISTANCE À L'USURE ET AU CHOC MÉCANIQUE

Les principaux résultats des recherches effectuées sur des éprouvettes conservées à l'atmosphère du laboratoire sont représentés graphiquement par la figure 4 *a*, *b* et indiquent que :

— La résistance à l'usure des bétons de monomère FA augmente fortement dans l'intervalle 7 à 90 jours, augmentation ensuite beaucoup plus lente, qui cesse pratiquement après 180 jours. On constate qu'elle augmente avec la réduction du fuseau granulométrique de l'agrégat quartzeux utilisé et avec l'augmentation du dosage en résine, donc avec l'élasticité du matériau. La résistance à l'usure des bétons de monomère FA à agrégat quartzeux n'est pas sensiblement affectée par le type de filler utilisé (compositions 6, 7, 8, 10, 13, 14, 16, fig. 4 *a*), contrairement à ce qui se produit, dans une certaine mesure, pour les bétons à andésite basaltique, les meilleurs résultats étant dans ce cas obtenus avec les fillers F_3 et F_4. L'explication de ce fait est donnée par les résultats des recherches sur les différents fillers utilisés exposés au.[1] Avec des agrégats spéciaux tels que le carbure de silicium et le corindon, si bons que soient les résultats obtenus (compositions 27 et 28, fig. 4 a), il faut remarquer qu'ils se rapprochent de ceux obtenus pour les compositions 6 à 7 préparées avec des agrégats quartzeux 0 à 3 mm et avec un dosage en

résine plus faible, d'environ 10%. Cette remarque est particulièrement importante du point de vue technique et économique, car l'utilisation de ces agrégats spéciaux, qui sont ordinairement employés comme abrasifs, ne donne de meilleurs résultats que dans certaines conditions, et le liant remplit alors un rôle tout particulier. Ainsi, le monomère FA, par ses propriétés (résistances propres très élevées, bonne adhérence à l'agrégat, etc.) garantit l'augmentation substantielle de la résistance à l'usure par abrasion mécanique du béton et on peut utiliser avec les mêmes résultats techniques les agrégats quartzeux sélectionnés au.[1] La confirmation en est donnée par le fait que les bétons à agrégats 0 à 15 mm et avec 13% de résine (compositions 13 à 23, fig. 4 *a*) ont une résistance à l'usure de 1,5 à 2,8 fois plus grande que les bétons 1 : 4 à ciment RIM 400 et à andésite basaltique 0 à 15 mm (bien que le rapport des résistances à la compression à 28 jours ait été de 1,3 à 1,5), et que les bétons à agrégat fin 0 à 3 mm (compositions 6—7, fig. 4 *a*) et avec 16% de résine ont une résistance à l'usure de 15 à 20 fois plus grande que le béton de ciment pour routes pris comme référence (le rapport des résistances à la compression à 28 jours étant de 1,3 à 1,5). Ceci permet de remarquer que la résistance à l'usure des bétons de résine synthétique dépend des propriétés du liant (résistances mécaniques, élasticité), de l'adhérence dans le système liant-agrégat et, dans une moindre mesure, des propriétés de l'agrégat. Ainsi, avec des agrégats quartzeux judicieusement choisis pour la préparation des bétons de monomère FA, on peut pratiquement obtenir des résultats comparables à ceux que donnent, dans des conditions identiques, le carbure de silicium ou le corindon. L'hypothèse sur le rapport direct entre les résistances mécaniques des bétons et leur résistance à l'usure n'est que partiellement valable et doit être complétée dans le sens suivant : « Dans le cas des bétons à monomère FA, à structure compacte et à résistance à la compression à 28 jours de plus de 700 kgf/cm^2, la résistance à l'usure augmente avec la réduction du module d'élasticité du matériau, c'est-à-dire avec la réduction du fuseau granulométrique et avec l'augmentation du dosage en résine ».[3,8-10,13-15]

La résistance au choc mécanique des bétons de monomère FA et des compositions habituelles augmente principalement dans les 7 premiers jours. Dans l'intervalle de 7 à 28 jours, l'augmentation de la résistance est très lente, puis, pour la plupart des compositions étudiées, cesse pratiquement et se maintient aux environs des valeurs obtenues de 28 jours jusqu'à 1 à 3 ans (fig. 4 *b*). Pour les bétons à agrégats très fins (filler F_2) et contenant 24% de résine (composition 30, fig. 4 *b*), la résistance au choc mécanique continue à augmenter pendant un certain temps, de sorte qu'à un an elle dépasse 200 kgf/cm^2 (résistances de la fonte de soudure); de même, d'importantes augmentations de résistance ont été enregistrées pour les éprouvettes préparées avec le carbure de silicium corrigé comme agrégat (composition 27, fig. 4 *b*), soit à un an plus de 120 kgf/cm^2. La résistance au choc mécanique des bétons préparés avec l'agrégat quartzeux A_2 augmente avec la réduction du fuseau granulométrique et aussi avec le dosage en résine (composition 6, 7, 14, fig. 4 *b*), donc avec la diminution du module d'élasticité, ce qui montre une bonne concordance entre la résistance à l'usure et au choc mécanique et les caractéristiques élastiques du matériau. Pour les mêmes dosages de résine et les mêmes fuseaux granulométriques, les meilleurs résultats sont obtenus avec le filler F2 (provenant du sable quartzeux concassé) et l'agrégat de concassage A4 (compositions 6 à 7 et 14 à 20, fig. 4 *b*).

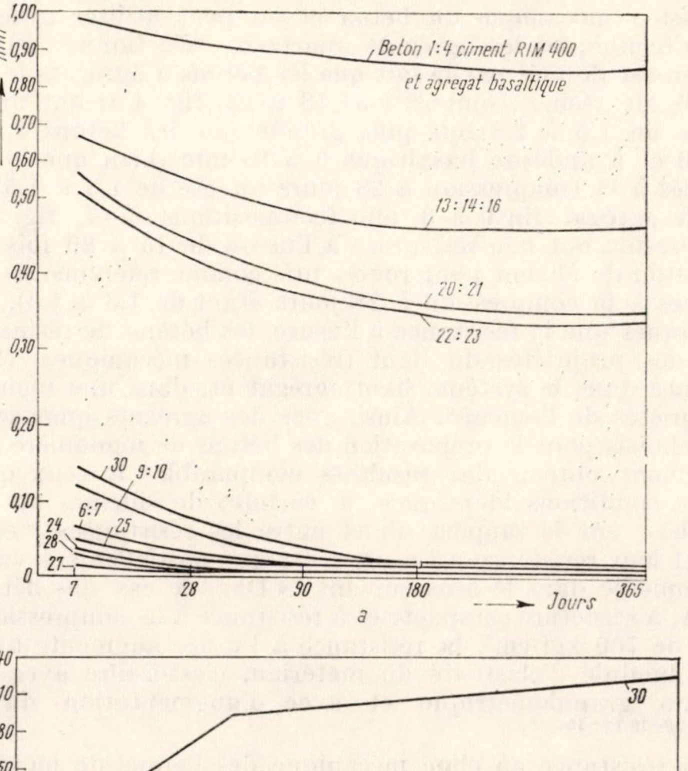

Fig. 4. — a) Variation de la résistance à l'usure dans le temps; b) Variation de la résistance au choc mécanique dans le temps pour différentes compositions de bétons aux résines synthétiques (pour les compositions voir le tableau 1).

Le gain de résistance au choc, de 40 à 50% avec le filler F2 et l'agrégat A4, s'explique par l'augmentation de l'adhérenc dans le système liant-agrégat grâce à la plus grande rugosité de la surface ou du filler de concassage, par rapport à l'agrégat et au filler de carrière.[1] C'est pourquoi il y a également une bonne concordance entre les résistances au choc mécanique et la résistance à la traction par flexion (fig. 1 *a* et 4 *b*). La résistance au choc mécanique des bétons à agrégats A2 et A4, à 28 jours, représente 30 à 55 kgf/cm², c'est-à-dire 5 à 8 fois la résistance du béton pour routes (fig. 4 *b*). L'utilisation de l'agrégat Fc corrigé augmente elle aussi la résistance au choc du béton.[8–10, 15]

4. ADHÉRENCE AU BÉTON ET À L'ARMATURE

Les faits suivants ont été mis en évidence :

— Le béton préparé au monomère FA, ou au monomère FA et à la résine LS.1, a une bonne adhérence au béton et au mortier de ciment sec : 20 kgf/cm² au minimum (*R* traction axiale) à 3 jours, qui augmente légèrement jusqu'à un an, approchant alors 35,1 à 37,6 kgf/cm². Le béton au monomère FA, ou au monomère FA à la résine LS.1, a une faible adhérence au béton et au mortier de ciment humide : 4,0 à 6,2 kgf/cm² à 28 jours, ce qu'on explique comme il suit : le processus de durcissement, dans la zone de contact, est sensiblement affecté par l'humidité du béton (aucune des deux résines ne durcit en présence d'eau, ainsi qu'on l'a déjà montré) et, de plus, il est probable que certaines solutions d'hydroxyde de calcium du béton ou du mortier de ciment, qui migrent vers la surface pendant l'immersion dans l'eau, réagissent avec le durcisseur acide de la résine, contribuant ainsi à la formation, dans la zone de contact, d'une couche de béton de résine, de faible résistance ou non durci (à structure altérée), d'où de mauvais résultats aux essais d'adhérence. De la même manière, s'explique la bonne adhérence du béton de monomère FA ou de monomère FA et de résine LS.1, aux surfaces sèches de béton ou de mortier, car, dans telles conditions, en l'absence d'humidité, la résistance mécanique du béton de résine coulé sur le béton sec augmente rapidement et, en même temps, l'adhérence au béton ou au mortier de ciment ; de même, il est probable que, sur des surfaces sèches de béton, l'action de neutralisation sur le durcisseur de la résine soit très faible ou nulle. L'application sur la surface du béton sec, ou avant l'immersion dans l'eau, d'une couche de peinture bitumineuse (durcissant à froid) semble améliorer l'adhérence du béton de résine dans une certaine mesure, tant sur une surface sèche que sur une surface humide ; dans ce dernier cas, l'adhérence atteint 6 à 12 kgf/cm² à 28 jours, ce qui atteste le rôle de l'eau dans le ralentissement du processus de durcissement du béton de résine, et la prépondérance de ce phénomène négatif.[2, 10, 11, 15]

Les recherches pour déterminer l'adhérence du béton de monomère FA aux armatures et à l'acier montrent que : l'adhérence du béton de résine aux surfaces planes en tôle est sensiblement influencée par leur rugosité : les éprouvettes coulées sur tôle polie atteignent 0,8 % au maximum de l'adhérence des éprouvettes coulées sur des surfaces de tôle brute (respectivement 28,1 et 40,6 kgf/cm² à 28 jours, par rapport à 34,7 et 59,6 kgf/cm²). L'adhérence aux surfaces de tôle brute, pour les mêmes compositions de bétons, représente 0,75 à 0,85 % de l'adhérence à des barres en acier à béton, Ø 10 mm (fig. 5 a) ce qui prouve que pour les bétons de résines synthétiques l'adhérence par collage joue un rôle beaucoup plus important que pour les bétons de ciment où elle atteint 2,7 à 19,2 kgf/cm². L'adhérence augmente, dans certaines limites, avec le dosage en résine (composition 10—14 — tableau 1) mais pour de forts pourcentages de résine, elle tend à baisser ce qui est probablement dû à l'aptitude de ces bétons à subir de fortes déformations (compositions 30).

L'étude de l'adhérence aux différents types de barres d'acier et de treillis métalliques par la méthode directe a pu être effectuée principalement sur des éprouvettes cubiques de 10 × 10 × 10 cm de côté car aux essais sur éprouvettes prismatiques longues de 21 cm et de 32 cm, l'adhérence du béton de résine aux barres d'acier (OL 38 Ø 10) dépassant la résistance à la rupture de la barre, celle-ci cassait. Les résultats des recherches pour déterminer la variation de l'adhérence (effort jusqu'au premier glissement) de certains types de bétons fins et de bétons de résine synthétique aux barres d'acier OL 38 de Ø 10 mm, placées verticalement lors de la coulée, sont représentés graphiquement par la figure 5 *a* et prouvent que l'adhérence augmente dans le temps, ses valeurs étant comprises entre 31 et 64 kgf/cm^2 à 7 jours, 45 et 67 kgf/cm^2 à 28 jours et 57 et 72 kgf/cm^2 à 365 jours. La principale augmentation de l'effort d'adhérence a été enregistrée dans les 7 premiers jours : on obtient alors 52 à 88 % de l'effort d'ahérence à 365 jours ; l'adhérence continue à augmenter légèrement jusqu'à 90 jours, et on a alors des valeurs pratiquement égales à celles obtenues à 365 jours. Si l'on continue à arracher la barre des éprouvettes de béton après le premier glissement, l'effort augmente d'abord puis baisse légèrement (après un temps qui dépend de la vitesse et de l'effort d'arrachement de la barre) pour se stabiliser autour d'une valeur qui correspond à 0,76—0,85 de l'effort exercé jusqu'au premier glissement, pour toutes les compositions de béton essayées entre 7 et 365 jours, exception faite pour les compositions de bétons fins (préparées au filler et avec 24 % de résine) où l'effort d'arrachement sous charge constante augmente de 0,40 à 7 jours, à 0,54 à 28 jours, 0,70 à 90 jours, 0,80 à 180 jours et 0,85 à 365 jours de la valeur de l'effort au premier glissement (fig. 5 *b*, *c*).

Pour des éprouvettes cubiques avec armatures placées horizontalement et verticalement (compositions n°s 7 et 10), le rapport horizontal/vertical a donné des valeurs de 0,88 et 1,10, ce qui indiquerait que pour les bétons de résine synthétique à faible viscosité, telle que le monomère FA, le fait d'avoir placé les barres d'armature parallèlement ou perpendiculairement à la direction du coulage n'exerce pas d'influence particulière. La valeur de l'effort moyen d'adhérence au premier glissement pour les barres d'acier OL de Ø 10 mm, pour les compositions 7, 10, 14, 20 aux essais à 28 et 365 jours est :

$$\tau_{\text{moyen}} = 0{,}072\, \sigma_c \tag{3}$$

et pour les compositions de béton fin (préparé avec du filler et 24 % de résine) aux essais à 28 jours :

$$\tau_{\text{moyen}} = 0{,}050\, \sigma_c \tag{4}$$

Les recherches sur l'adhérence du béton au monomère FA et à la résine LS.1 aux barres crénelées en Pc 52 de Ø 10 mm, ou au fil métallique sigma à adhérence améliorée de Ø 6 mm ont montré que l'adhérence est tellement forte qu'aux essais, d'abord à 7 jours puis à 3 et à 1 jour, la barre en Pc 52 se casse (sans déplacement de son extrémité libre) sous une force de 4 200 à 4 500 kg (c'est-à-dire un effort de 5 500 à 5 700 kgf/cm^2 à la barre), tandis que le fil métallique sigma se rompt sous un effort dans le fil de plus de 6 000 kgf/cm^2 sans déplacement de l'extrémité libre, ce qui indique que l'adhérence dépasse 140 kgf/cm^2 et que la longueur d'ancrage calculée pour de telles barres diminue pour chaque longueur de barre de 5 cm. Ceci s'explique par la grande résistance à la traction et au cisaillement de ce nouveau type de béton et par son aptitude à bien se couler sur la surface des aciers à haute adhérence. Les recherches pour déterminer l'adhérence du béton de monomère FA (compositions 7 et 10, table 1) à une barre de SBP à adhérence améliorée (fig. 5 d) ont prouvé que les barres de SBP commencent à glisser (aux essais à 28 jours) sous des efforts moyens de 180 et 206 kgf/cm², les efforts augmentent ensuite continuellement, jusqu'à ce que l'extrémité libre de la barre glisse de 5 mm (les essais ont alors été arrêtés). L'explication en est donnée par une résistance toujours plus grande grâce au moulage du béton sur la surface des barres de SBP. La détermination de l'adhérence à différents treillis de SBP a exigé des efforts importants, plus de 300 kgf/cm² jusqu'au premier glissement. Il a été constaté que, dans ce cas, l'arrachement du treillis se produit par suite des déformations qu'il subit (sous

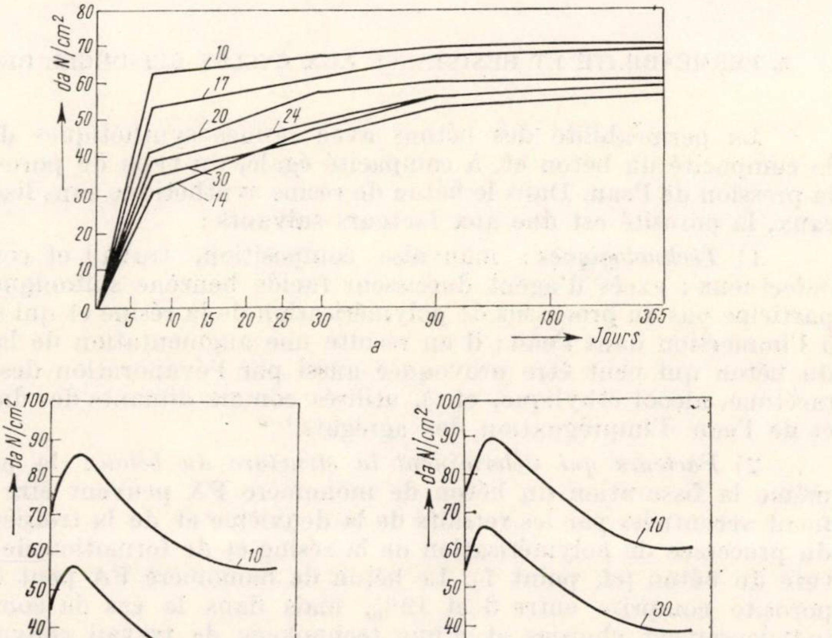

Fig. 5. — a) Variation de l'adhérence, dans le temps, déterminée par arrachement des barres en ØL 38 à profil normal pour différentes compositions de bétons aux résines synthétiques (cf. tableau 1) ; b) Variation de l'effort nécessaire pour déplacer l'extrémité libre d'une barre en OL 38 Ø 10 mm après le premier glissement, pour différentes compositions de béton (cf. tableau 1), essais à 28 jours ; c) Variation de l'effort nécessaire pour déplacer l'extrémité libre d'une barre en OL 38 Ø 10 mm après le premier glissement, pour différentes compositions de béton (cf. tableau 1), essais à 90 jours ; d) Variation de l'effort nécessaire pour déplacer l'extrémité libre de la barre Ø 5 mm en SBP enrobée dans un béton de composition 10 (cf. tableau 1), essais à 28 jours.

charge) et dues à la traction des fils métalliques, ainsi que des déformations qui se produisent sous la couche de mastic de résine autour du treillis. Les observations effectuées jusqu'à présent prouvent que les bétons de monomère FA ou de monomère FA et de résine LS.1 protègent bien l'armature, que les éprouvettes soient conservées à l'air ou dans l'eau durant l'intervalle de 28 à 365 jours ; une fois extraites, les armatures présentent une surface nette, sans aucune trace de corrosion.[10, 11, 15]

5. PERMÉABILITÉ ET RÉSISTANCE AUX CYCLES GEL-DÉGEL RÉPÉTÉS

La perméabilité des bétons avec résines synthétiques dépend de la compacité du béton et, à compacité égale, du type de porosité et de la pression de l'eau. Dans le béton de résine synthétique sans liants minéraux, la porosité est due aux facteurs suivants :

1) *Technologiques* : mauvaise composition, travail et compactage défectueux ; excès d'agent durcisseur (acide benzène sulfonique) qui ne participe pas au processus de polymérisation de la résine et qui se dissout à l'immersion dans l'eau ; il en résulte une augmentation de la porosité du béton qui peut être provoquée aussi par l'évaporation des solvants (acétone, alcool éthylique, etc.), utilisés comme diluants des durcisseurs, et de l'eau d'imprégnation des agrégats.[1–9]

2) *Facteurs qui déterminent la structure du béton* : la porosité et même la fissuration du béton de monomère FA peuvent être sensiblement accentuées par les retraits de la deuxième et de la troisième phase du processus de polymérisation de la résine et de formation de la structure du béton (cf. point 7). Le béton de monomère FA peut avoir une porosité comprise entre 3 et 12%, mais dans le cas de compositions judicieusement choisies et d'une technologie de travail convenable, la porosité ne dépasse pas 3 à 5% ; le béton est alors pratiquement imperméable, car les pores sont en général uniformément distribués dans sa masse sous forme de pores fins fermés. Ceci est confirmé par l'adsorption d'eau tout à fait insignifiante qu'ont les bétons de ce type, 0,16 à 0,36% au maximum après 360 jours d'immersion à la pression normale. Les principaux résultats des recherches, fournis par le tableau 2 entraînent les remarques suivantes : le degré d'imperméabilité est faible dans les compositions de bétons sans addition de filler, car le taux de résine de la composition n'est pas suffisant pour remplir intégralement le volume de vides des agrégats et nous obtenons ainsi une structure moins compacte (compositions 5, 8 et 12).

La résistance aux cycles gel-dégel répétés dépend des facteurs technologiques déjà indiqués pour la perméabilité et, en outre, de la résistance après conservation dans l'eau pendant une durée prolongée. Pour cette raison, et afin d'éviter des erreurs importantes — compte tenu des moyens à notre disposition — nous avons introduit trois classes de résistance (tableau 2), la dernière classe (faible) correspondant à la méthodologie indiquée par les normes pour déterminer la résistance au gel-dégel du béton de ciment. Les résultats des recherches (cf. tableau 2) présentent une très bonne concordance avec ceux relatifs à la perméabilité. On remarque aussi que toutes les compositions résistent au moins à

100 cycles de gel-dégel répétés. Le comportement très bon à 150 cycles correspond à des compositions de bétons préparées avec addition de filler (compositions optimales déduites des recherches effectuées pour déterminer d'autres propriétés) et qui ont un degré d'imperméabilité égal à P 12, les baisses de résistance y étant généralement inférieures à 5%. Ainsi, en admettant que la baisse de résistance qui apparaît à la conservation des éprouvettes dans l'eau dans l'intervalle 28 à 180 jours et celle due à l'action de 150 cycles sont annulées, il résulte que la baisse totale de résistance pour la classe très bonne est inférieure à 25% (ce que les normes pour le béton admettent) de la résistance des éprouvettes conservées uniquement à l'ambiance du laboratoire, ce que nous consi-

Tableau 2

Perméabilité et résistance au gel-dége

Numéro de la composition *	Dimensions des éprouvettes	Pression pour laquelle l'eau traverse l'éprouvette atm	Pression maximale d'essai avant que l'éprouvette ne soit pas traversée par l'eau	Résistance aux cycles gel-dégel répétés (x_{1-2})
5	20 × 20 × 5	4	—	× 1 — faible

* Voir tableau 1.

× 1 — éprouvettes cubiques de 10 cm de côte, ayant subi 100 cycles répétés gel-dégel (un cycle = 20 heures d'immersion dans l'eau à environ 20°, plus 4 heures dans des chambres frigorifiques à − 15 − 30°)

× 2 — idem × 1 après 150 cycles gel-dégel répétés.

L'appréciation a été effectuée de la manière suivante :

— très bonne — s'il s'agissait d'une perte de poids inférieure à 2% et d'une perte de résistance inférieure à 5% ;

— bonne — s'il s'agissait d'une perte de poids inférieure à 3% et d'une perte de résistance inférieure à 8%.

— faible — s'il s'agissait d'une perte de poids inférieure à 6% et d'une perte de résistance inférieure à 25%, en comparant aux éprouvettes témoin conservées dans l'eau pendant toute la durée des cycles gel-dégel.

Remarque

La pression maximale d'essai a été conditionnée par la puissance de l'installation disponible.

dérons comme suffisant en fonction du but poursuivi. Les mêmes observations sont valables pour la classe bonne après 100 cycles de gel-dégel répétés.[7,10,13-15]

6. DILATATION ET CONDUCTIVITÉ THERMIQUE

Les résultats des recherches et des calculs effectués à l'humidité relative de 50 % et à une température variable entre —20° et +60°, donnés dans la figure 6 entraînent les remarques suivantes :

Le coefficient de dilatation thermique des bétons de monomère FA augmente avec le dosage en résine et avec la réduction du fuseau granulométrique pour l'agrégat quartzeux utilisé. Ainsi, pour les bétons fins préparés au filler F2 et avec 24 % de résine (composition 30), le coefficient de dilatation thermique $K_t = 0{,}016$ à 0,022 mm/m°C, c'est-à-dire de 1,5 à 1,8 fois plus grand que celui de l'acier et de 1,7 à 2,2 fois plus grand que celui du béton. Pour les bétons fins à agrégats 0 à 3 mm et avec 16 % de résine (composition 7) le coefficient de dilatation thermique, $K_t = 0{,}010$ à 0,011 mm/m°C, a des valeurs assez rapprochées de celles obtenues pour OL 38 et pour le béton 1 : 4 préparé avec des agrégats quartzeux 0 à 15 mm et du ciment RIM 300 utilisés comme matériaux de comparaison. Pour les bétons à agrégats quartzeux 0 à 15 mm ou 0 à 1 et andésite basaltique, le coefficient de dilatation thermique $K_t = 0{,}005$ à 0,0058 est environ deux fois plus petit que celui de l'acier et du béton. L'influence particulière qu'exerce la résine utilisée comme liant sur la dilatation thermique du béton de la composition 25 (où 50 % de l'agrégat est représenté par les déchets d'acier utilisés) pour lequel $K_t = 0{,}062-0{,}075$ mm/m°C, donc 1,5 à 2 fois plus petit que K_t pour OL 38. La nature et la provenance de l'agrégat exercent une influence rela-

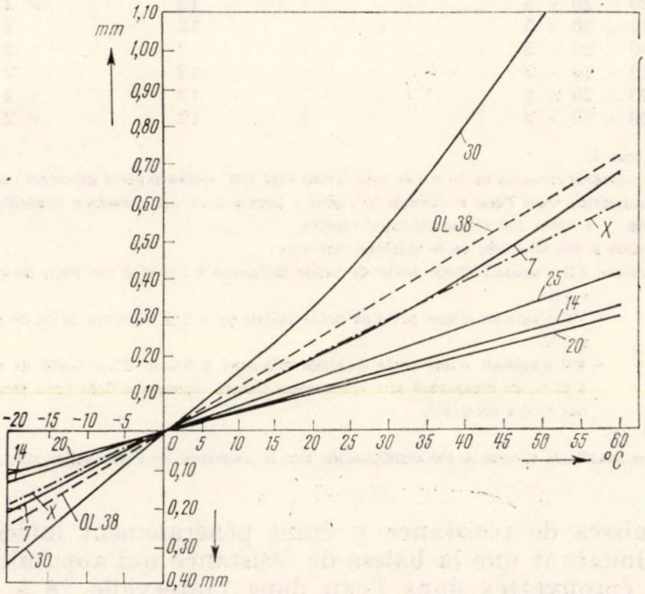

Fig. 6. — Dilatation thermique moyenne des bétons à monomère furfurol-acétone (compositions dans le tableau 1). x. bétons 1 : 4 de ciment RIM 400, agrégats quartzeux 0 à 15 mm.

tivement réduite, par rapport au dosage en résine, sur le coefficient de dilatation thermique. Les résultats obtenus démontrent la possibilité d'armer avec des aciers les bétons à agrégats 0 à 3 mm — 0 à 15 mm, contenant 13 à 16% de résine, et de les utiliser dans l'exécution des constructions mixtes ou de revêtements de protection pour les éléments de construction métalliques et en béton armé.

La conductivité thermique du béton de résine a été étudiée à l'aide de l'appareil du Dr Böke sur des plaques de 5 × 20 × 20 cm, avec différentes compositions d'agrégat quartzeux, d'andésite basaltique et d'agrégats avec addition de déchets d'acier ainsi qu'avec divers dosages en résine. Les résultats de ces recherches montrent que dans le cas des bétons aux résines synthétiques (comme dans le cas des bétons de ciment), le coefficient de conductivité thermique augmente fortement avec l'augmentation de la densité apparente du béton. Pour ce type de bétons, il semble que la nature de l'agrégat a une influence assez faible, de sorte que les bétons à andésite basaltique et ceux à agrégats quartzeux, dans des conditions identiques de préparation et à densité égale de béton, ont des coefficients de conductivité thermique pratiquement égaux (différence de ± 3 à 7%). A densités égales, les coefficients de conductivité thermique des bétons de monomère FA représentent environ 60% de la valeur des coefficients de conductivité thermique des bétons de ciment. Ceci s'explique probablement par le fait que la résine utilisée, le monomère FA, est, à des températures usuelles, un bon isolant thermique et contribue à réduire sensiblement le coefficient de conductivité thermique des bétons préparés avec des agrégats lourds.

7. RETRAITS ET GONFLEMENTS

On résume ici les principaux résultats de nos recherches et calculs, certains étant traduits graphiquement par la figure 7 *a*, et *b*. Ils montrent que le retrait des bétons de résine au monomère FA s'explique par la réduction du volume de résine utilisée comme liant pendant la période de polymérisation sous l'action de l'agent durcisseur, lorsque se produit le passage de la phase liquide à la phase solide, en même temps que la condensation des molécules et la formation d'une structure plus compacte, phénomène qui se manifeste par une légère augmentation du poids apparent du matériau durci. D'autre part, il faut tenir compte du fait que la résine utilisée contient, dans certaines proportions, des composants volatils, ou qu'on en a introduits sous forme de diluants pour le durcisseur (acétone, alcool éthylique, eau, etc.); leur perte provoque, après la coulée, un retrait du béton. Une autre cause qui contribue à accroître le retrait des bétons de résines synthétiques est le tassement et la réduction de volume consécutive du béton durant la période de durcissement du fait de la compression des pores formés par évaporation de l'eau ou des composants volatils de la masse du béton au cours de la polymérisation de la résine qui tend à prendre une structure compacte. Il en résulte que les bétons à fort dosage en résine sont ceux qui montrent les retraits les plus importants. Le retrait diminue donc avec la réduction du dosage en résine et avec l'élargissement du fuseau granulométrique de l'agrégat utilisé. Ainsi, avec des agrégats quartzeux, les bétons fins au filler et contenant 24% de résine montrent des retraits très importants (compositions 30 et 32, fig. 7 *a*), tandis que les bétons fins à agrégats 0 à 3 mm et contenant 16% de résine ont des retraits encore notables par rapport à ceux des bétons à agrégats 0 à 15 mm et contenant 13% de résine (compositions 7, 13, 14, 15 et 16, fig. 7 *a*). L'influence du type de résine, sur le retrait se manifeste différemment selon les propriétés de la résine, à savoir : sa propension à réduire de volume pendant le durcissement, sa teneur en substances volatiles, etc. Ainsi, avec le monomère FA et la résine phénol-formaldéhyde LS.1, dans différentes proportions, les retraits diminuent avec l'augmentation du taux de résine LS.1.[1] L'influence de la nature de l'agrégat utilisé se manifeste d'une manière différente, de sorte que les bétons à andésite basaltique 1 à 15 mm et contenant 13% de résine ont des retraits de 1,50 à 1,60 fois supérieurs à ceux des bétons à agrégats quartzeux 0 à 15 mm et contenant 13% de résine (compositions 13 et 20, fig. 7 *a*). Pour un même type d'agrégats et un même dosage en résine, dans les mêmes conditions de préparation, l'utilisation du filler spécial F4 (coke de haut fourneau broyé) entraîne un accroissement du retrait (compositions 13, 14, 16, 20, 23, fig. 7 *a*). Il est à remarquer que, même en remplaçant le filler F2 à un taux de 50% (quartz broyé) par du filler F4, on obtient un accroissement du retrait (compositions 13 et 15, fig. 7 *a*). De très grands retraits sont encore enregistrés pour les bétons au carbure de silicium corrigé (composition 27, fig. 7 *a*) ; par contre, les bétons aux déchets de fer (agrégats à gros module d'élasticité) montrent les retraits les plus faibles (compositions 24 et 25, fig. 7 *a*). Ceci prouve que dans le cas des bétons des résines synthétiques aussi, avec des agrégats à gros module d'élasticité on obtient de faibles retraits, exception faite pour des agrégats, tels que l'andésite basaltique et le carbure de silicium qui, bien qu'ils aient des modules d'élasticité élevés et qu'ils favorisent l'obtention de bétons de grande résistance et à hauts modules d'élasticité, les affectent de retraits importants ou même très importants (compositions 20, 22, 23, 27, fig. 7 *a*).

Pour un dosage optimal en durcisseur et avec les éprouvettes conservées à l'ambiance du laboratoire, la principale augmentation des valeurs du retrait des bétons de monomère FA a lieu dans les 24 premières heures suivant la coulée, environ de 50 à 65% de la valeur du retrait à 2 à 3 ans. Avec un taux de durcisseur réduit aux 2/3 ou à 1/3 du taux optimal, le retrait est plus faible dans la période initiale, mais continue à s'accroître rapidement, de sorte qu'il finit par atteindre pratiquement les valeurs maximales pour la composition correspondante (fig. 7 *a*, *b*). Si les éprouvettes sont conservées alternativement dans l'air et dans l'eau, on enregistre des gonflements à l'immersion (due à l'adsorption d'eau par les pores) et une tendance à revenir au retrait correspondant à la conservation dans l'air, lorsque les éprouvettes après le décoffrage sont conservées dans l'eau potable jusqu'à l'âge d'essai, le retrait est faible, probablement parce que l'eau qui a pénétré dans les pores empêche le développement normal du processus de polymérisation et, par conséquent, le retrait (compositions 7″, 10″, 13″, 20″, fig. 7 *a*).

D'après les faits exposés ci-dessus, on distingue 3 phases bien distinctes (fig. 7 *c*). Pendant la première phase, dont la durée dépend du taux de durcisseur utilisé et de la température du milieu environnant, et qui peut être de 2 à 3 heures pour le taux optimal de durcisseur et $t = 18$ à 22°, et de 12 à 30 heures pour de faibles taux de durcisseur et des températures de 12 à 18°, commence la polymérisation ; dans cette phase, le mélange ne perd pas encore complètement sa fluidité et le retrait est très faible, pratiquement négligeable. Pendant la deuxième phase, se termine probablement le processus de polymérisation, la chaleur est dégagée par exothermie, et le retrait, ainsi que les résistances mécaniques, augmentent rapidemment jusqu'à des valeurs atteignant 50 à 70% du retrait initial. Cette phase se développe approximativement pendant l'intervalle de 3 à 24 heures à la température normale et pour le taux optimal de durcisseur ; à des températures élevées, elle se développe en quelques heures, et pour de faibles taux de durcisseur elle peut même durer quelques jours (fig. 7 *a*, *b*, *c*). La troisième phase, où se développent 30 à 50% du retrait total, s'étend

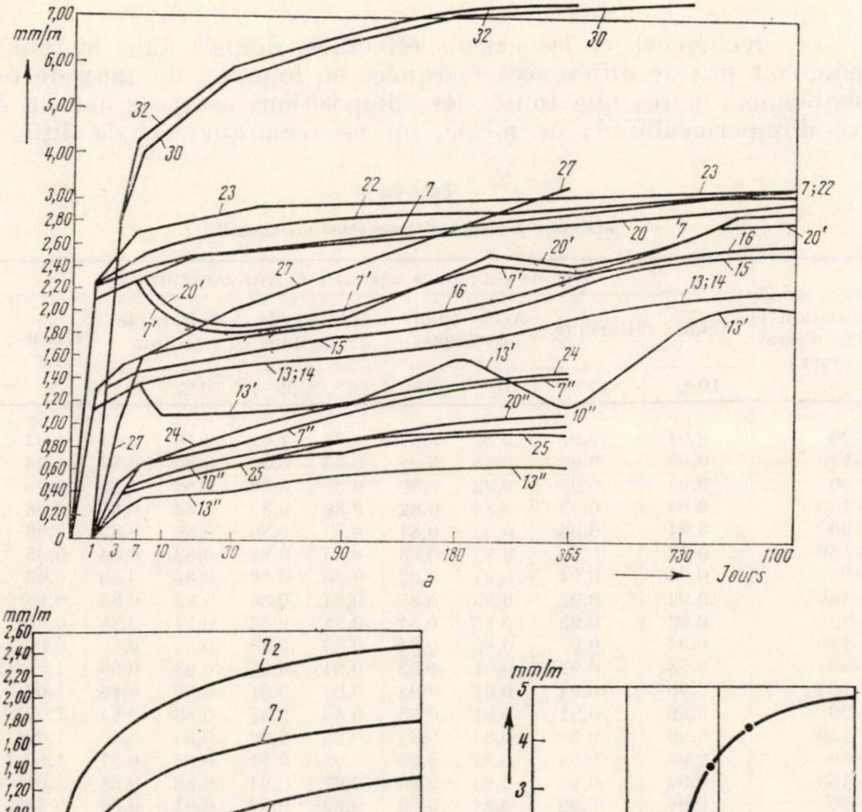

Fig. 7. — a) Retrait et gonflement de différentes compositions de bétons aux résines synthétiques (voir tableau 1) ; b) Retrait des bétons fins. Composition 7 du tableau 1 pour différents pourcentages de durcisseur (7=100%, 7'=67%, 7''=33%) et pour des éprouvettes conservées à l'atmosphère du laboratoire à $t = 20$ à 25°. c) Schéma du développement du retrait des bétons à monomère FA.

sur une période plus longue. Les retraits de la deuxième et de la troisième phase ayant des valeurs assez grandes peuvent entraîner la destruction de la structure des mortiers et des bétons aux résines synthétiques, l'apparition de fissures accentuées, des dégradations de la couche de support, etc., lorsque les déformations sont entravées. Pour cette raison, dans les travaux où l'on utilise ces matériaux, il est nécessaire de prévoir au stade du projet la neutralisation au minimum des effets négatifs qui pourraient être provoqués par la réduction des effets du retrait.[10,15]

8. RÉSISTANCE À L'ACTION DES AGENTS CHIMIQUEMENT AGRESSIFS

Les recherches et les calculs effectués, donnés dans le tableau 3 n'indiquent pas de différences marquées en fonction du taux de résine, probablement parce que toutes les compositions essayées ont un degré élevé d'imperméabilité ; de même, on ne remarque pas de différences sensibles d'après le type et la nature de l'agrégat, exception faite pour les compositions où l'on a utilisé comme filler le coke de haut fourneau broyé F4, qui ont des coefficients de résistance supérieurs pour tous les milieux agressifs où l'on a conservé les éprouvettes (compositions 16,

Remarque. On n'a pas remarqué de détériorations des éprouvettes après qu'elles aient été retirées de la solution d'agents chimiques agressifs.

*) Voir tableau 1.

22, 32, tableaux 1 et 3). Les bétons de monomère FA ont une très bonne résistance aux produits pétroliers (essence, pétrole lampant) ; ils ont également une bonne résistance à l'action des acides sulfurique et chlorhydrique, de l'hydroxyde et du sulfate de sodium, les coefficients de résistances obtenus aux essais étant généralement supérieurs à 0,8, ce qui prouve que les bétons essayés se sont comportés tout aussi bien sous l'action des acides que sous l'action des bases ; on peut donc envisager leur utilisation dans de très vastes domaines.

9. VARIATION DE LA VITESSE DE PROPAGATION DES ULTRASONS ET DU MODULE D'ÉLASTICITÉ DYNAMIQUE

Les résultats des recherches représentés graphiquement par les figures 8 et 9 montrent les faits principaux suivants : les courbes qui expriment la variation de la vitesse de propagation (fig. 8) et la variation du module d'élasticité dynamique dans le temps sont groupées par familles selon le dosage en résine et le fuseau granulométrique de l'agrégat. Pour un même type d'agrégats, la vitesse de propagation des ultrasons diminue avec l'augmentation du dosage en résine et avec la réduction du fuseau granulométrique pour l'agrégat utilisé.[13,15]

Les données représentées graphiquement par la figure 8 indiquent que les principales variations de la vitesse de propagation des ultrasons

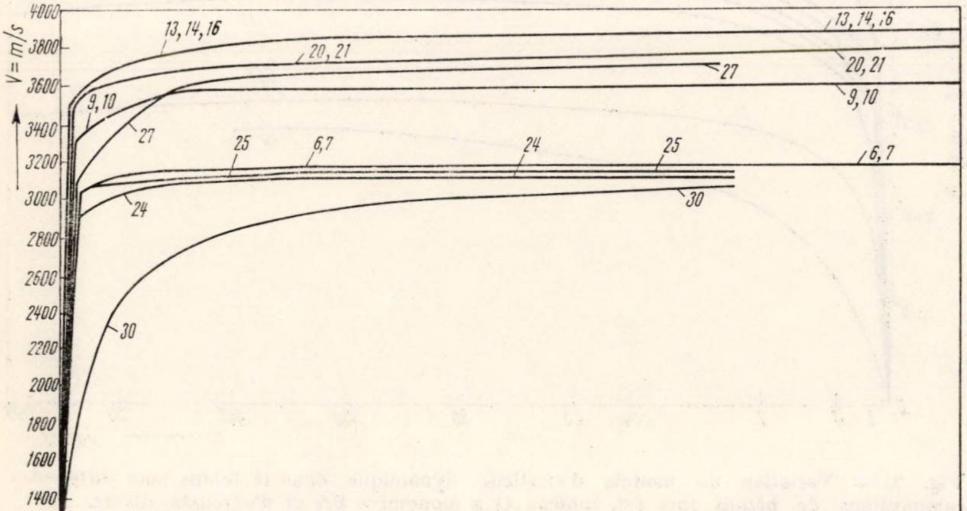

Fig. 8. — Variation de la vitesse de propagation des ultrasons dans le temps pour différentes compositions de bétons à monomère FA et d'agrégats divers (voir tableau 1)

à travers le béton de monomère FA sont enregistrées jusqu'à l'âge de 7 jours ; dans l'intervalle de 7 à 28 jours, la vitesse de propagation enregistre de faibles augmentations, et entre 28 et 1100 jours, la vitesse reste pratiquement autour des valeurs enregistrées à 28 jours.

Le module d'élasticité dynamique des bétons de résines synthétiques étudiés enregistre dans le temps des valeurs sensiblement différentes selon le dosage et le type de la résine utilisée, la nature, la composition granulométrique et la densité de l'agrégat, etc. (fig. 9). Ainsi, pour les bétons préparés avec des agrégats quartzeux, le module d'élasticité dynamique augmente de valeur avec la réduction du dosage en résine et avec l'élargissement du fuseau granulométrique pour l'agrégat utilisé. Les valeurs minimales pour le module d'élasticité ont été obtenues à tous les âges d'essai (jusqu'à un an) avec la composition n° 30 pour laquelle on a utilisé comme agrégat le filler F2 et 24 % de résine, et les valeurs maximales pour la composition 15 avec un agrégat 0 à 15 mm et 15 % de résine. La réduction du module d'élasticité avec l'augmentation du dosage en résine s'explique par la plus forte proportion d'un matériau à grande élasticité dans la masse du béton. Le module d'élasticité enregistre d'importantes augmentations dans l'intervalle de 1 à 7 jours pour toutes les compositions des bétons de monomère FA, et de très fortes augmentations avec des compositions à dosages élevés en monomère FA, phénomène explicable si nous tenons compte du fait que pendant cet intervalle la résine se polymérise en formant un réseau tridimensionnel

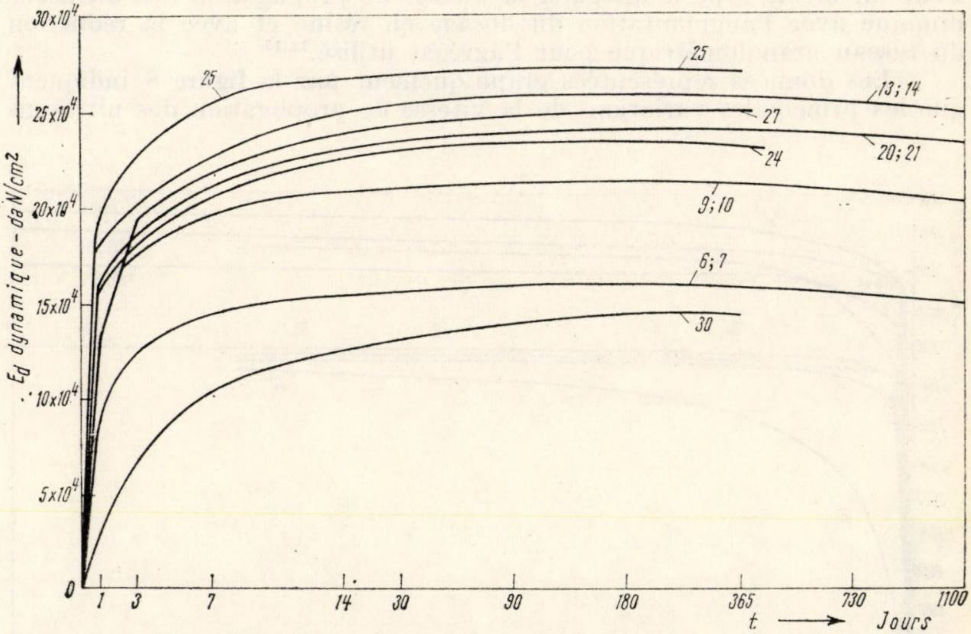

Fig. 9. — Variation du module d'élasticité dynamique dans le temps pour différentes compositions de bétons fins (cf. tableau 1) à monomère FA et d'agrégats divers.

qui devient compact et rigide à mesure que le processus de polymérisation avance. Dans l'intervalle de 7 à 28 jours, le module d'élasticité enregistre d'habitude des augmentations plus faibles. Après 28 jours, le module d'élasticité dynamique n'augmente pratiquement plus ; par contre, dans les compositions avec du monomère FA et de la résine LS.1, il augmente jusqu'à 90 jours, ce qui témoigne d'une polymérisation plus longue de la résine LS.1.

Les bétons à agrégats spéciaux Fc et Cs ont des modules d'élasticité différents selon le type et la nature de l'agrégat et selon le dosage en résine. Ainsi, les bétons au carbure de silicium (composition 27), même pour de forts dosages en résine (16 %), ont des modules d'élasticité élevés, tandis que les bétons aux déchets métalliques (Fc) ont des modules d'élasticité qui diffèrent suivant le dosage en résine et la densité de l'agrégat, le module maximal d'élasticité étant obtenu pour la composition 25 qui, pour un dosage en résine de 9 %, a atteint lors de la coulée, une densité de 3 780 kg/m^3. Mais il faut remarquer que la valeur maximale du module d'élasticité pour la composition 25 est de 270 000 kgf/cm^2, ou environ 1/8 du module d'élasticité de l'acier. Les recherches pour déterminer les relations entre le module d'élasticité statique E_{st} et le module d'élasticité dynamique E_d^* nous ont conduit à établir les relations statistiques moyennes suivantes (5) valables pour les bétons préparés avec des agrégats 0 à 3 mm et 0 à 15 mm, avec des dosages de 13 à 16 % de résine, sollicités sous des efforts $x = 0{,}16$, $0{,}33$, $0{,}50$ et $0{,}70\ \sigma_{\text{rupture}}$ et essayés à l'âge de 28 à 365 jours depuis la coulée :

$$E_{st} = E_d$$

$$E_{st} = 0{,}96\, E_d, \text{ pour } x = 0{,}16\ \sigma_{\text{rupture}} \tag{5'}$$

$$E_{st} = 0{,}84\, E_d, \text{ pour } x = 0{,}33\ \sigma_{\text{rupture}} \tag{5''}$$

$$E_{st} = 0{,}77\, E_d, \text{ pour } x = 0{,}50\ \sigma_{\text{rupture}} \tag{5'''}$$

$$E_{st} = 0{,}72\, E_d, \text{ pour } x = 0{,}70\ \sigma_{\text{rupture}} \tag{5^{iv}}$$

L'analyse des résultats des recherches pour déterminer les relations entre E_{statique} et $E_{\text{dynamique}}$ indique le module d'élasticité dynamique a des valeurs du même ordre de grandeur que le module d'élasticité statique déterminé à des stades d'essai au-dessous de $0{,}16\ \sigma_{\text{rupture}}$.

10. DÉFORMATIONS DES BÉTONS DE RÉSINES SYNTHÉTIQUES

Les résultats des recherches représentés graphiquement par la figure 10 *a* à *f* mettent en évidence les faits principaux suivants : le diagramme caractéristique (σ — ε) à la compression est semblable à celui du ciment. La valeur du coefficient de plasticité $\lambda = \varepsilon_p/\varepsilon_b$ varie selon la composition du matériau et, pour des matériaux de même composition, varie selon la température à laquelle sont conservées les éprouvettes avant l'essai et avec la vitesse d'application des charges. Le calcul statistique des résultats donne, pour les compositions avec des agrégats 0 à 3 mm jusqu'à 0 à 15 mm et 13 à 16% de résine, conservées et essayées à la température normale, $\lambda_{\text{moyen}} = 0{,}55$ avec des écarts allant jusqu'à 16% par rapport à la moyenne, et $\lambda_{\text{moyen}} = 0{,}38$ pour les bétons fins préparés avec du filler et ayant 20 à 24% de résine. Si les éprouvettes sont conservées plus longtemps à des températures élevées, de 50° à 75°, la valeur du coefficient de plasticité λ diminue beaucoup (fig. 10 *a*—*d*). Ainsi, seulement dans des conditions d'exploitation des travaux à température normale, et si l'on n'utilise que des compositions avec des agrégats 0 à 3 mm jusqu'à 0 à 15 mm, avec un dosage maximal de 16% de résine, on peut admettre pour les bétons de résine une courbe caractéristique conventionnelle du même type que celle de la figure 10 *b* et $\lambda = 0{,}50$. Les déformations du béton de résine sous l'action des charges de courte durée sont de 2 à 4 fois plus importantes que pour les bétons de ciment et augmentent avec la réduction du fuseau granulométrique de l'agrégat et avec l'augmentation du dosage en résine synthétique. Les déformations longitudinales limites à la compression peuvent atteindre 10 à 20 mm/m selon la composition du béton et le dosage en résine (fig. 10 *c* à *f*). Les différences entre les déformations pour diverses compositions de bétons (à consistance approximativement égale) augmentent avec le dosage en résine et avec le rapport $\sigma_c/\sigma_{\text{rupture}}$ ainsi, avec de dosages en résine de 13% (1/6,8), pour des efforts variant de 1/4 à 1/2 σ_{rupture}, les déformations augmentent de 0,90 % à 1,93%, tandis que pour les mêmes efforts, mais avec des dosages de 24% de résine (1/3,2) elles augmentent de 2,65% à 9% (fig. 10 *e*). A dosages égaux de résine, les bétons à andésite basaltique ont des déformations un peu plus grandes que les bétons à agrégats quartzeux. Ceci s'explique par les différences entre les caractéristiques physico-mécaniques des roches dont proviennent ces deux types d'agrégats. Il est à remarquer que les bétons à la limaille de fer, avec des taux réduits de résine, ont des déformations assez grandes par rapport aux bétons préparés avec des agrégats quartzeux.

Les déformations des bétons de monomère FA augmentent sensiblement avec la température, de sorte que, après conservation des éprouvettes pendant 72 heures dans une chambre climatisée à 50°, leurs défor-

mations sont de 1,6 à 2 fois plus grandes que celles des témoins conservés à température normale, bien qu'aux essais des éprouvettes de faibles dimensions on n'enregistre pas de différences sensibles des résistances à la compression et à la traction par flexion, ni après la conservation des éprouvettes à la température de 100 à 120° pendant un temps assez long. Le phénomène est en bonne partie réversible, après un lent refroidissement, les éprouvettes qui ont eu à des températures élevées de fortes déformations, une fois rechargées, ont des déformations de 1,00 à 1,20 par rapport aux éprouvettes témoins (conservées tout le temps à la température normale).

Pour l'étude des déformations sous charges prolongées, on a retenu les compositions 7, 14 et 30 (tableau 1). Dans les essais effectués, les principaux résultats obtenus sont représentés graphiquement par la figure 11 *a—d* et ils montrent principalement les faits suivants : les déformations des éprouvettes de bétons de monomère FA augmentent sous l'action des charges de longue durée avec la valeur des efforts unitaires et en fonction de leur composition, de sorte qu'à 0,54 à 0,63 σ_{rupture} les éprouvettes se rompent entre 3 et 72 heures. La limite supérieure des efforts unitaires sous l'action des charges de longue durée pour lesquelles il n'y a pas de rupture, pour les compositions essayées, est d'environ 0,50 σ_{rupture}. Les déformations initiales, ainsi que les déformations dues au retrait et au fluage, augmentent avec le taux de résine et avec la réduction de la granulométrie (fig. 11 *a—d*). L'influence de l'allongement de l'intervalle coulée — mise sous charge de longue durée à 350 kgf/cm^2 se manifeste par des diminutions différentes des déformations initiales (fig. 11 *a—d*). Ceci s'explique par l'augmentation des résistances dans le temps et par la diminution dans une certaine mesure du rapport σ_c/σ_r, qui contribue tant à la réduction des déformations initiales qu'à celle des déformations dues au fluage, le retrait croissant surtout dans les 28 premiers jours en outre, l'allongement de l'intervalle coulée-mise sous charge laisse à la structure de la résine le temps de se consolider par polymérisation, ce qui contribue également à reduire les déformations. Un autre facteur est l'accroissement de la résistance à la traction du béton et de l'adhérence dans le système liant organique-agrégat, ce qui favorise une meilleure redistribution des charges entre les composants du béton et une réduction des déformations. Les déformations sous l'action des charges de longue durée augmentent intensément dans les 30 premiers jours après le chargement ; ensuite l'accroissement est plus lent jusqu'à 90 jours, et 90 jours après, il devient presque insignifiant ; de sorte que dans l'intervalle 180 à 365 jours il y a une véritable tendance à l'amortissement (fig. 11 *a—d*). Après déchargement de certaines éprouvettes qui ont été conservées sous charge pendant un an, on a constaté un recouvrement partiel des déformations atteignant en 15 jours 0,65 à 1,60 $\varepsilon_{\text{stable}}$. Ceci prouve que, sous l'action des charges de longue durée, les bétons de monomère FA enregistrent des déformations élastiques, élasto-plastiques (ou intermédiaires), similaires à celles des bétons de ciment, ainsi que des déformations plastiques dont les valeurs dépendent des charges, du degré de polymérisation et de la structure du béton, du temps de maintien sous charge, etc.

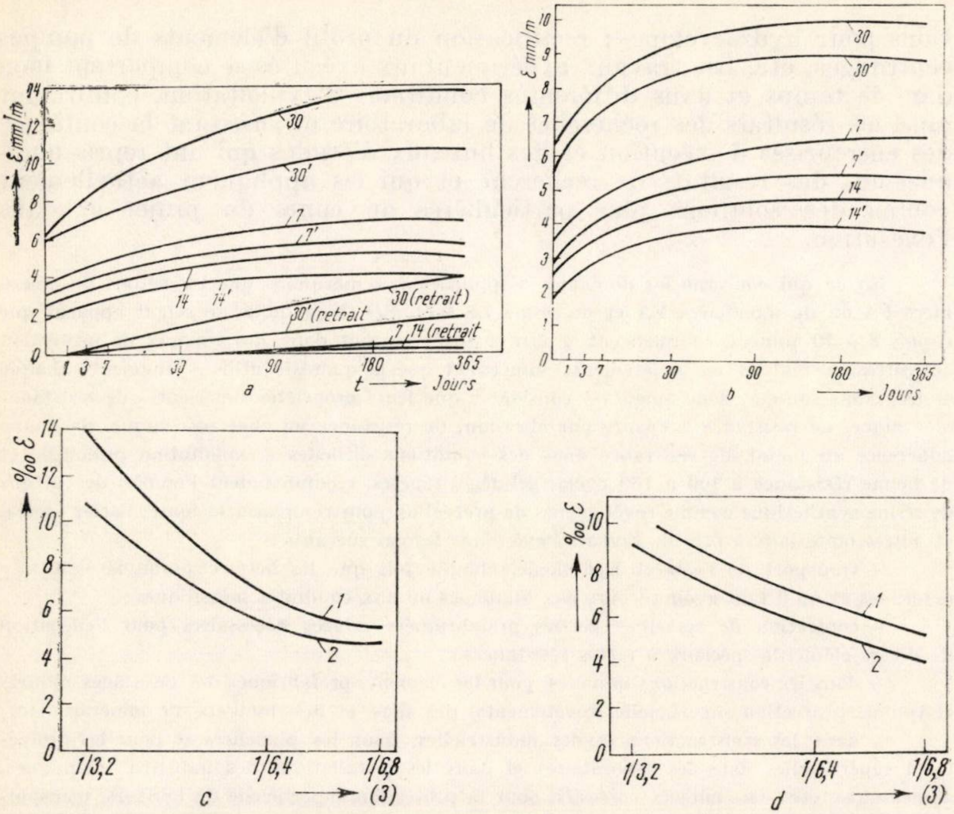

Fig. 11 — a) Déformations totales sous l'action des charges de longue durée et des retraits pour quelques bétons à monomère FA ; 7, 14, 30 — éprouvettes mises sous charge à 7 jours, 7', 14', 30' — éprouvettes mises sous charge à 28 jours depuis la coulée.

b) Déformations sous l'action des charges prolongées (sans retrait) pour quelques bétons à monomère FA. 7, 14, 30 — éprouvettes mises sous charge à 7 jours ; 7', 14', 30' éprouvettes mises sous charge à 28 jours depuis la coulée.

11. COMPORTEMENT DANS LE TEMPS DE CERTAINS TRAVAUX EXPÉRIMENTAUX EXÉCUTÉS ET CONSIDÉRATIONS SUR LES DOMAINES D'UTILISATION PRATIQUE

Pour vérifier les résultats des recherches de laboratoire dans les conditions d'exploitation, plusieurs applications expérimentales ont été effectuées : revêtement d'usure et de protection anticorrosive ; protections pour hydrocyclones; rectification du profil d'éléments de pompes centrifuges, etc. Les travaux expérimentaux exécutés se comportent bien dans le temps et dans différentes conditions d'exploitation, confirmant ainsi les résultats des recherches de laboratoire et suscitant la confiance des entreprises d'exécution et des bureaux d'études qui ont repris quelques-uns des résultats de recherche et qui les appliquent actuellement comme des solutions plus particulières au cours du projet et dans l'exécution.

En ce qui concerne les domaines d'application, remarquons que les bétons de monomère FA ou de monomère FA et de résine LS.1 étudiés, bien qu'ils ne soient apparus que depuis 8 à 10 années, commencent à être utilisés surtout dans des travaux de protection anticorrosive réalisés en revêtements minces et que la quantité utilisée augmente chaque année. Nous sommes donc amenés à considérer que leurs propriétés supérieures de résistance mécanique, de résistance à l'usure par abrasion, de résistance au choc mécanique, de bonne adhérence au métal, de résistance dans des conditions difficiles d'exploitation prolongée et de bonne résistance à 100 à 150 cycles gel-dégel répétés, recommandent l'emploi des bétons de résine synthétique comme revêtements de protection pour remplacer la fonte, l'acier spécial et autres matériaux à prix de revient élevé, dans les cas suivants :

— transport de l'eau et hydrologie, chaque fois que les bétons communs sont vite détériorés et qu'il faut avoir recours aux blindages ou aux conduites métalliques ;

— confection de certaines parties préfabriquées minces nécessaires pour l'exécution de divers éléments spéciaux à fortes résistances ;

— dans les constructions minières, pour les éléments préfabriqués des cuvelages miniers et comme protection superficielle (revêtements) des silos et des bunkers de minérais, etc. ;

— dans les constructions civiles industrielles, pour les planchers et pour les protections superficielles dans les laboratoires et dans les installations des industries chimiques, alimentaires, etc., en milieux corrosifs, pour la protection superficielle de bunkers, transporteurs et des réservoirs, et dans tous les cas où sont nécessaires des matériaux imperméables de haute résistance à l'abrasion mécanique et à la corrosion chimique ;

— protection de différents installations et outillages technologiques contre la corrosion chimique et contre l'abrasion mécanique dans différents domaines industriels, etc.

MÉTHODES DE DÉTERMINATION DE β, β′-DICHLORO-DIÉTHYL-AMINE

SPECTRE EN VISIBLE ET INFRAROUGE DU COMPOSÉ RÉSULTÉ ENTRE LE β,β′-DICHLORO-DIÉTHYL-AMINE ET LE REINECKATE D'AMMONIUM

GRIGORE TEODORESCU

Institut Polytechnique de Bucarest, Chaire de Chimie inorganique et analytique
Bucarest, 1, str. Polizu

Reçu le 29 mars 1973

On présente des méthodes de détermination de β, β′-dichloro-diéthyl-amine (abrégé DDA) — sous forme de chlorhydrate — réalisées par la combinaison avec le reineckate d'ammonium (abrégé $NH_4^+R_c^-$), la dissolution du composé obtenu dans l'acétone, suivie de la précipitation de l'anion reineckate d'argent et le titrage de l'excès d'azotate d'argent avec du thiocyanate d'ammonium. Vu que le composé formé est soluble dans l'acétone, résultant une solution colorée, le composé a été déterminé aussi colorimétriquement. La structure du complexe obtenu a été vérifiée par la détermination de la masse moléculaire, à l'aide des spectres en visible, pour le $NH_4^+R_c^-$ et le reineckate de DDA. La structure du reineckate de DDA a été caractérisée aussi par le spectre en IR de DDA et de son composé.

Pour la détermination des amines secondaires la littérature indique plusieurs méthodes comme : titrage avec l'HCl 1 N ou avec une solution méthanolique d'acide chlorhydrique, en présence des indicateurs,[1] titrage avec l'$HClO_4$ 0,1 N en acide acétique glacial,[2] titrage des acides dithiocarbamiques qui résultent de la réaction entre l'amine et le sulfure de carbone, avec une base,[3] titrage avec une solution alcaline de l'acide chlorhydrique qui résulte de la réaction entre le tétraphénylborate de l'amine avec l'$HgCl_2$[4].

Dans cette note on présente des méthodes de détermination volumétrique et colorimétrique de DDA, matière première utilisée dans la synthèse du Lisen, médicament usité dans la thérapie de la sclérose en plaques. La méthode consiste dans la combinaison de l'amine secondaire (passée en ion *onium*) avec l'$NH_4^+R_c^-$ réactif utilisé par l'auteur aussi à la détermination d'autres produits.[5–9]

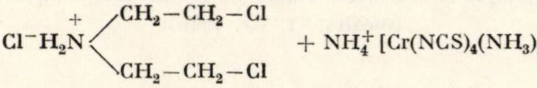
On présente également les caractéristiques spectrales en visible et en IR du composé obtenu entre le $NH_4^+R_c^-$ et le chlorhydrate de DDA.

PRINCIPE DE LA MÉTHODE

La combinaison du chlorhydrate de DDA a lieu dans une solution aqueuse d'acide sulfurique 1 % avec du $NH_4^+R_c^-$, selon le schéma suivant :



$$Cl^-\overset{+}{H_2N}\begin{matrix}\diagup CH_2-CH_2-Cl\\ \diagdown CH_2-CH_2-Cl\end{matrix} + NH_4^+[Cr(NCS)_4(NH_3)_2]^-$$

$$(ClC_2H_4)_2\overset{+}{N}H_2]\,[Cr(NCS)_4(NH_3)_2]^- + NH_4^+ + Cl^-$$

1. MÉTHODE VOLUMÉTRIQUE

On précipite la solution aqueuse de DDA par une solution de 2 % $NH_4^+R_c^-$,selon l'équation ci-dessus.

Le précipité cristallin rose obtenu est filtré, lavé et ensuite dissous en acétone.

La solution résultée est traitée par excès de solution d'azotate d'argent 0,1 N. Ainsi, le reineckate d'argent précipite conformément à la réaction :

$$[Cr(NCS)_4(NH_3)_2]^- + Ag^+ \rightarrow Ag[Cr(NCS)_4(NH_3)_2]$$

Après filtrage et lavage, l'excès d'azotate d'argent est titré avec le thiocyanate d'ammonium en présence de l'alun de fer (III) et de l'ammonium.

1.1. *Mode opératoire*

On prend 2,25 g de chlorhydrate de DDA (blanc, cristallisé) et on les entraînent quantitativement au ballon jaugé à 250 ml avec de l'acide sulfurique 1 % et on complète jusqu'à la jauge avec le même acide.

De cette solution on prend des épreuves entre 0,0360 et 0,1170 g, on ajoute 20 ml d'eau distillée et après, goutte à goutte, sous agitation continuelle, la solution fraîchement préparée de $NH_4^+R_c^-$ 3 %. Il précipite le composé cristallin nâcré rose-violet.

[6] GR. TEODORESCU, *Bul. Inst. Politech. București*, **32** (4), 79 (1970).

[7] GR. TEODORESCU, *Bul. Inst. Politech. București*, **33** (1), 67 (1971).

[8] GR. TEODORESCU, *Rev. Roumaine de Chimie*, **17**, 8, 1481 (1972).

[9] GR. TEODORESCU, *Rev. Roumaine de Chimie*, **17**, 9, 1621 (1972).

Le composé formé est filtré sur un creuset à filtre G_3, entraîné par une solution de $NH_4^+R_c^-$ 0,1 %, lavé avec de l'eau distillée (4°C) jusqu'au moment, où la solution passe incolore et ensuite lavé 2 fois avec 10 à 15 ml d'éther.

On dissout directement sur le creuset le composé avec 10 à 20 ml d'acétone, jusqu'à dissolution totale. On lave finalement le creuset à 20 ml d'eau distillée et on prend la solution et les eaux de lavage dans un verre de 250 ml.

On ajoute 100 ml d'eau distillée, 10 ml d'azotate d'argent 0,1 N et 3 à 4 gouttes d'acide azotique 2 N.

Le précipité de reineckate d'argent formé est filtré et lavé par décantage à l'eau distillée. Le filtrat et les eaux de lavage sont mis dans un flacon de 750 ml. On ajoute 3 à 4 ml de solution saturée d'alun de fer (III) et d'ammonium (environ 40 %), 3 à 4 gouttes d'acide azotique 2 N et on titre l'excès d'azotate d'argent par le thiocyanate de l'ammonium 0,1 N au facteur connu (F 0,1 N = 0,9090).

Un ml d'azotate d'argent 0,1 N correspond à 0,01785 g de chlorhydrate de DDA. Les résultats obtenus sont rapportés au tableau 1.

*) La méthode Korshun.

2. MÉTHODE COLORIMÉTRIQUE

2.1. *Principe de la méthode colorimétrique*

On précipite le DDA avec du $NH_4^+R_c^-$ selon le même procédé dans le rapport molaire 1 : 1. Vu que le composé formé est soluble en acétone, résultant une solution colorée en rouge, le DDA peut être déterminé aussi colorimétriquement.

2.2. *La pratique*

On applique la méthode des courbes étalon. A cette fin on a employé une solution de $NH_4^+R_c^-$ avec $T = 0{,}0560$ g/ml, dont on a pris des volumes correspondants, dans des ballons jaugés de 100 ml, dilués avec 50 ml d'acétone et complétés avec de l'eau distillée, afin d'obtenir des solutions avec des concentrations $T = 0{,}00028$; 0,000560 ; 0,00840 ; 0,001120 ; 0,001680 g.

Les déterminations ont été faites à l'aide du photocolorimètre de type B. Lange, en utilisant des filtres verts ($\lambda = 533$ nm) et on a tracé la courbe étalon.

De la solution de DDA avec $T = 0,00900$ g/ml on a prélevé des épreuves entre 0,0180–0,0450 g et l'on a précipité avec du $NH_4^+R_c^-$, selon la méthode volumétrique.

Après précipitation, filtrage et lavage, les épreuves ont été quantitativement dissoutes avec de l'acétone, en prenant la solution dans des ballons jaugés à 100 ml. Après l'homogénéisation, les épreuves ont été colorimétrées, les résultats obtenus étant indiqués au tableau 2.

3. ÉTUDE SPECTRALE

3.1. *Caractérisation du spectre en visible du reineckate de DDA*

La structure du composé obtenu peut être vérifiée par la détermination de sa masse moléculaire, à l'aide de l'absorbance (A) et de l'absorptivité (K).[10]

Les déterminations ont été faites avec le spectrophotomètre Zeiss de type VSU-1, avec une cuve de grosseur $l = 0,5$ cm et à une concentration $g_1 = 0,1\,\%$.

Les chiffres trouvés ont été pour le $NH_4^+R_c^-$:

nm	Absorbance
394	0,138
	⋮
420	0,102
	⋮
452	0,03
	⋮
482	0,093
	⋮
520	0,155
	⋮
560	0,105
	⋮

---

[10] KUM-TATT-LEE, *J. Pharm. and Pharmac.*, **12**, 666 (1960).

et pour le reineckate de DDA :

nm	Absorbance
400	0,1
420	0,07
450	0,034
480	0,062
520	0,112
553	0,083

Une caractéristique commune des spectres en visible du $NH_4^+R_c^-$ et du reineckate de DDA réside dans le fait que le maximum d'absorption (λ_{max}) est approximativement le même, $\lambda_{max} = 520$ pour le $NH_4^+R_c^-$ (dans l'éthanol 95% et $\lambda_{max} = 520$ pour le reineckate de DDA (aussi dans l'éthanol 95%).

L'absorptivité a été déterminée conformément à la relation :

$$K = A/c.l$$

sur le $NH_4^+R_c^-$, dans l'éthanol 95% à la concentration $c = 0{,}00297$ mole gramme $NH_4^+R_c^-$, à une grosseur de la cuve $l = 0{,}5$ cm et pour l'absorbance $A = 0{,}155$ correspondant à la valeur maximale $\lambda_{max} = 520$ à 525 nm.

La valeur K déterminée pour le $NH_4^+R_c^-$ est considérée, dans les limites des erreurs acceptables, comme étant valable aussi pour le reineckate de DDA, étant donné que λ_{max} pour le reineckate de DDA est égal (ou presque égal) à λ_{max} pour le reineckate.

La masse moléculaire (M_d) est déterminée selon la relation :

$$M_d = g_1/100.K/A.1.1000 \tag{1}$$

Pour le cas $g_1 = 0{,}1$ g de reineckate de DDA per 100 ml solution, la relation (1) devient :

$$M_d = (K/A).l \tag{2}$$

Pratiquement, la détermination de l'absorption en visible du reineckate est faite dans de l'éthanol 95%. L'absorbance pour $\lambda_{max} = 520$ nm à la concentration de 0,1% et à une cuve avec $l = 0{,}5$ cm (dans les mêmes conditions de travail) est de 0,112. En remplaçant dans la relation (2) on obtient :

$$M_d = (104/0{,}112) \cdot 0{,}5 = 464{,}27$$

La comparaison de cette valeur à celle de la masse moléculaire résultée du calcul $M_c = 461{,}40$ donne la possibilité de vérifier la structure du composé obtenu.

3.2. *Caractérisation en infrarouge du reineckate de DDA*

Le reineckate de DDA a été structuralement caractérisé aussi par spectre en infrarouge,[11–15] que l'on a interprété par comparaison avec le spectre du $NH_4^+R_c^-$ (tableau 3).

Tableau 3

Spectre en IR du reineckate d'ammonium

SPEKTROPHOTOMETRISCHE BESTIMMUNG DES THALLIUMS MIT META-NITRALGRÜN

CECILIA CONSTANTINESCU *) und [SIMON FIŞEL **)

*) Technische Hochschule für Erdöl, Gase und Geologie Bukarest, str. Av. Traian Vuia, nr. 6
**) Al. I. Cuza-Universität Jassy, Calea 23 August, nr. 11

Eingegangen am 21. Juni 1973

In der vorliegenden Arbeit wurden die optimalen Reaktionsbedingungen zwischen dem basischen Farbstoff *meta*-Nitralgrün und den Tl(III)-Ionen studiert. Der von den Verfassern gewonnene Farbstoff wurde zuerst zum Studium der Reaktion mit Thallium (III) benützt und es wurde festgestellt, daß er mit dem Komplexanion $TlBr_4^-$ eine in Wasser unlösliche Verbindung-Tetrabromthalat von *meta*-Nitralgrün-löslich aber in Benzol, in dem extrahiert wird, bildet. Die organischen Extrakte wurden dann spektrophotometrisch untersucht. Außerdem wurde die Verbindung ausgefällt und einer Elementaranalyse unterworfen. Die durch beide Methoden erzielten Ergebnisse stimmten überein. Die studierte Reaktion ist für die Analyse des Thalliums in einem pyritischen Konzentrat mit sehr guten Ergebnissen anwendbar, und kann als spektrophotometrische Methode für die Bestimmung des Thalliums empfohlen werden.

Die Reaktionen zwischen Tl(III)-komplexionen und basischen Farbstoffen der trimethanischen Klasse sind in lezter Zeit in Vordergrund der Interessen vieler Chemiker. Manche Arbeiten beschäftigten sich mit den theoretischen Aspekten [1–3] bzw. mit der Anwendung der schon studierten Reaktionen für die Bestimmung von Thalium in verschiedenen Rohstoffen, Mineralen und Gesteinen [4]. Der Mechanismus ähnlicher Reaktionen wurde von Onishi [5] studiert und besteht in der Bildung in wäßrigen Medien der komplexen hallogeno-metallischen Säuren HMX_4 ; H_2MX_5 ; H_3MX_6, die durch die Bindung des komplexen Anions am Farbstoffskation gefolgt wird. Die in organischen Lösungsmitteln extrahierbare Verbindung ist vom Typus der ionischen Assoziation.

In dieser Arbeit werden die Synthesen des basischen Farbstoffo *meta*-Nitralgrün, die Ergebnisse der Forschungen bezüglich der Bildungsreaktion einer ionischen Assoziation zwischen dem komplexen

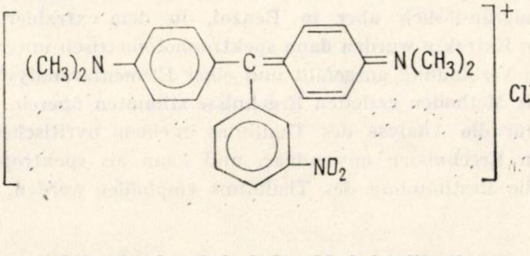
Anion $TlBr_4^-$ und des Kations der Farbstoffe, die Struktur der erhaltenen Verbindung sowie auch die Anwendung der Reaktion zur Bestimmung des Thalliums in pyritischem Konzentrat dargestellt. In einer anderen Arbeit wurden die Ergebnisse des Studiums ähnlicher Reaktionen mit *ortho-* und *para*-Nitralgrün veröffentlicht [6] und gezeigt, daß die Sensibilität der Reaktion 0,04 μg Tl/cm^3 beträgt.

VERSUCHSTEIL

SYNTHESE DES FARBSTOFFS

Meta-Nitralgrün wurde durch Anwendung der geeigneten Methode zur Erhaltung des triphenylmethanischen Farbstoffs Malachitgrün synthetisiert [7], d.h. durch die Kondensierung der *meta*-Nitrobenzolaldehyd mit Dimethylanilin. Die durch Erhitzung auf dem Wasserbad erhaltene dickflüssige Masse ist mit Wasserdampf angetrieben. Der gebliebene Rückstand ist in Äthylalkohol aufgelöst, woraus die Leukobasis wiederausgefüllt wird. Durch Oxydation der Leukobasis mit Bleidioxyd erhält man das entsprechende Carbinol, welches mit Chlorwasserstoff eine Verbindung mit folgender Struktur bildet:



Die Reinigung erfolgte durch wiederholte Umkristallisationen, wonach die Reinheit durch die Kaliumdichromatmethode [8] bestimmt und 85,7% festgestellt wurde.

REAGENZIEN UND LÖSUNGEN

Die wäßrige Lösung des Tl(III) war durch die Auflösung des Thallium I-Nitrats, Zufügung von konzentriertem Chlorwasserstoff und Oxydierung mit Bromwasser hergestellt. Nach der Entfernung des Chlorwasserstoffs durch Verdampfen wird eine Eichlösung vorbereitet, die 204 μg Tl(III) enthält. Der Titer der Thalliumlösung wurde durch Fällung in Form von Thalliumjodid bestimmt [9]. Die in dieser Arbeit benutzten Lösungen wurden durch angemessene Verdünnungen vorbereitet.

– Man verwendet 0,05 %ige Lösung bezogen auf die 100 %ige Reinheit von *meta*-Nitralgrün.

– Bromwasserstoff 64 % und 40 %.

– Benzol *p.a.*

– Lösungen verschiedener Kationen unter Form von Nitraten, Sulfaten und/oder Chloriden.

EXTRAKTION DES KOMPLEXES

Die 1.10^{-5} M Lösung von Tl(III) in Volumina von 0,5–10 cm^3 wird in einen Scheidetrichter von 50 cm^3 mit 40 %-igem Bromwasserstoff (2 cm^3) und mit Reagenzlösung (0,5–2 cm^3) geführt. Man füllt destilliertes Wasser bis zum Volumina von 10 ccm, fügt 10 cm^3 Benzol hinzu und schüttelt 2 Minuten lang. Ähnlich wird auch die Blindprobe vorbereitet. Man mißt die Extinktionen der gefärbten organischen Phase bei den entsprechenden Wellenlängen in 1 cm dicken Küvette.

DIE SYNTHESE DES KOMPLEXES

Um das Kombinationsverhältnis, im festen Zustand, des thallischen Anions mit dem uvtersuchten Reagenz festzulegen, wurden 0,270 g *meta*-Nitralgrün in 30 cm^3 Wasser gelöst und mit 0,25 g in 1 cm^3 Bromwasserstoff gelöster Tl(III) gemischt. Es erscheint ein dunkelblauer Niederschlag, der durch Filtrierung unter Vakuum getrennt und mit Wasser gewaschen wurde. Die Verbindung wurde bezüglich des Gehaltes an Thallium durch die Fällungsmethode (in Form von Thalliumjodid [9]) und an Brom durch die potentiometrische Bestimmungsmethode nach Schöniger analysiert. Die erhaltenen Ergebnisse sind in Tabelle 1 eingetragen woraus hervergeht, daß das Kombinationsverhältnis metall-Ligand 1 : 1 ist

Tabelle 1

Die Elementaranalyse der Komplexverbindung

Komplex	Thallium %		Brom %		Stickstoff		Kohlenstoff		Wasserstoff	
	gerehn.	gefnd.	gerehn.	gefnd.	gerehn.	gefnd.	gerehn.	gefnd.	gerehn,	gefnd
$m-R^+TlBr_4$	22,70	22,45	35,60	35,30	4,67	4,63	37,48	37,20	2,47	2,37

DIE ABSORPTIONSSPEKTREN IM SICHTBAREN BEREICH

Die elektronischen Absorptionsspektren der wäßrigen Lösung von *meta*-Nitralgrün (Kurve C_1) mit einem Maximalwert bei $\lambda_{max} = 635$ nm und von benzolschen Lösung der Komplexverbindung mit einem Maximalwert bei $\lambda_{max} = 650$ nm wurden in der Abbildung 1 wiedergegeben. Die Benzolextrakte der Blindprobe sind farblos. Die Verschiebung der

λ_{max} von Komplexverbindungen im Vergleich zur wäßrigen Lösung ist wohl einer Bildung von Komplexen mit Ladungsübertragung vom Typus $\sigma - \pi$ zuzuschreiben.

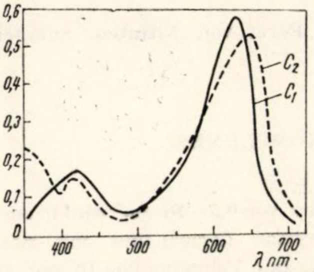

Abb. 1. — Absorptionsspektren : C_1 = Reagenz (meta-Nitralgrün), C_2 = Komplexverbindung ($TlBr_4$-meta-Nitralgrün).

DIE IR-ABSORPTIONSSPEKTREN

Diese Spektren werden in einem Bereich von 400—4000 cm^{-1} erforscht. Bei Vergleichung der IR-Spektren der freien Verbinder mit denen der entsprechenden Komplexverbindungen mit Thallium, wurde festgestellt, daß die Lagen und die Größen der Vibrationsbänder nach der Reaktion sich nicht verändert haben, ein Hinweis dafür, daß sich die Komplexe mit Ladungsübertragung bilden. Die charakteristischen Vibrationen der thallischen Verbindungen konnten nicht hervorgehoben werden, weil die betreffenden Vibrationen unter 400 cm^{-1} erscheinen und dieser Bereich nicht mit dem verwendeten Apparat erforscht wurde (Perkin-Elmer 337).

DIE AZIDITÄT DER LÖSUNG

Die Reaktion zwischen Tl (III) und der Reagenz *meta*-Nitralgrün läuft in Milieu von Bromwasserstoff ab. Bei 1,20 N HBr erhält man die maximale Absorbanz. Die Versuchsergebnisse werden in der Abbildung 2 vorgeführt. Im Medium von Chlorwasserstoff ist die Extraktionsfähigkeit klein.

DIE REAGENZKONZENTRATION

Bei Veränderung der Farbstoffsmenge von 0,2—0,3 cm^3 wurde eine Erhöhung der Absorption bis zun einer Konzentration von 1 cm^3 festgestellt, wonach sie konstant bleibt. Die optimale Konzentration liegt bei 1 cm^3 0,05%-iger wäßriger Lösung von *meta*-Nitralgrün.

DIE EICHKURVE

Das Studium der Absorptionsspektren in Abhängigkeit von der Konzentration von Tl(III) hat gezeigt, daß das Bouguer-Lambert-Beer'sche Gesetz zwischen den Grenzen 0,05—1,6 µg Metall/cm^3 Extrakt als wahr erwiesen ist, mit einem molaren Extinktionskoeffizient $\varepsilon = 69.800$ also eine kleinere Sensibilität der Reaktion im Vergleich zum *ortho*- bzw. *para*-Nitralgrün [6]. Die Beständigkeit der komplexen Kombination beträgt 48 Stunden.

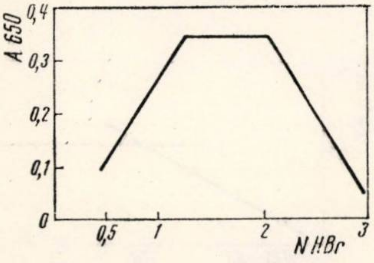

Abb. 2. — Einfluß der Lösungsazidität.

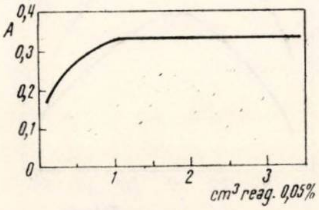

Abb. 3. — Einfluß der Farbstoffskonzentration.

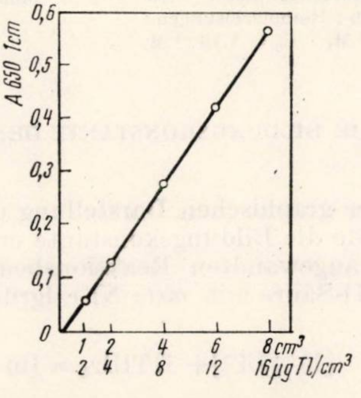

Abb. 4. — Die Eichkurve.

DAS STUDIUM DER ZUSAMMENSETZUNG GEBILDETER KOMPLEXVERBINDUNG

Für die Bestimmung des Kombinationsverhältnisses Metall/Farbstoff in der organischen Lösung kamen die Methode Job [10] und die Methode der Gefälle [11, 12] zur Anwendung. Die erhaltenen Ergebnisse bei der Durchführung der Methode Job sind in der Abbildung 5 wiedergegeben, bei der Benutzung zweier Paare von Isomolarlösungen : 1.10^{-4} M-Kurve C_1, 1.10^{-3} M-Kurve C_2. Bei der Methode des molaren Verhältnisses ist die Konzentration des Metalls konstant geblieben und die Konzentration des Farbstoffes verändert Abbildung 5. Bei der Methode des Gefälleverhältnisses verwendet man bei dem ersten Gefälle variable Mengen von Farbstoff und umgekehrt bei dem zweiten Gefälle. Die angewandten Methoden führten zum selben Ergebnis u.z. : das Kombinationsverhältnis Metall/Farbstoff für beide Verbindungen ist 1 : 1.

Abb. 5. – Die Bestimmung des Kombinationsverhältnisses. Die Methode Job : Isomolarlösungen : $C_1 = 1.10^{-3}$ M, $C_2 = 1.10^{-4}$ M.

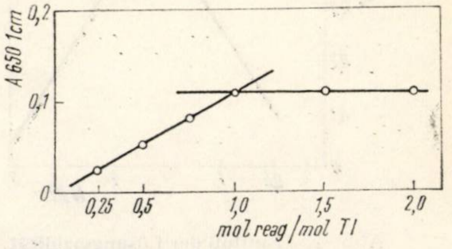

Abb. 6. – Die Bestimmung von Kombinationsverhältnis. Die Methode der Gefälle.

DIE BILDUNGSKONSTANTE DER KOMPLEXVERBINDUNG

Aus der graphischen Darstellung des molaren Verhältnisses (Abbildung 6) wurde die Bildungskonstante errechnet und $K_b = 1{,}6 . 10^5$ gefunden. Unter angewandten Reaktionsbedingungen bildet die tetrabromthallium (III)-Säure mit *meta*-Nitralgrün folgende ionische Assoziation :

$$[R^+][Cl^-] + HTlBr_4 = [m - R^+]TlBr_4^-] + HCl$$

DER EINFLUSS FREMDER IONEN

Es wurde die Interferenz jener Ionen geprüft, die gewöhnlich in verschiedenen Materialien Thallium begleiten. Die Reaktion ist vom Wachsen der Absorption in folgender Reihe gestört :

$$Au(III) > Fe(III) > In(III) > Ge(IV) > Sb(III) > Ga(III)$$

DIE BESTIMMUNG DER THALLIUMSPUREN IN ANGEREICHERTEM PYRITISCHEN KONZENTRAT

Die oben erwähnten besten Reaktionsbedingungen zwischen $HTlBr_4$ und *meta*-Nitralgrün wurden zu einer neuen Bestimmungsmethode von Thalliumspuren in einem angereicherten pyritischen Konzentrat von Baia Mare entwickelt. Die Arbeitsanweisung ist die gewöhnliche in diesen Fällen u.z. das Material wird in die Lösung gebracht, dann werden die

Einflüsse von fremden Ionen beseitigt, (SiO_2 und Fe-Ionen mit Po_4^{3-}) dann die anderen Elemente durch Zementierung mit metallischem Cadmium.

Es wurde dann der Gehalt an Thallium bestimmt. Als Vergleichsmethode kam die mit Methylviolett [4] zur Anwendung. Die Ergebnisse sind in der Tabelle wiedergegeben:

Tabelle 2

Die Ergebnisse der Analyse von angereichertem pyritischem Konzentrat

Einwaage g	Methode mit Methyl-Violett	Methode mit *meta*-Nitralgrün.
1,00	0,0131 % 131 ppm	0,0132 % 132 ppm

Revue Roumaine de Chimie, **19**, *2*, 329–335 (1974)

J. MIKA and **T. TÖRÖK**, "Analytical Emission Spectroscopy", Akadémiai Kiadó, Budapest, 1973, p. 529

Spectroscopic techniques are used nowadays for determining a large number of chemical elements in a wide range of both liquid and solid materials. By means of many improvements of the optical emission spectroscopy very low detection limits were obtained. This makes emission spectroscopy a very powerful technique as X-ray fluorescence spectroscopy. Recent developments, for instance the generation of emission by laser beams, have brought a new dimension which promises to find out new and interesting applications in metallurgical and geochemical sciences.

The subject of the present book is the optical emission spectroscopy analysis. The purpose of this volume is to provide an useful help for those who intend to deal with emission spectroscopy analysis in detail, and also to facilitate the work of those who devote their attention to the practical application of such techniques.

The basic theory of spectral analysis is presented in Chapter 1. Chapter 2 gives a detailed account on the various methods of excitation, including arc and spark sources, and their control. The analysis of the resulting radiations by both prism and grating devices is described in detail in Chapter 3, which also includes interference systems. The following chapter is devoted to the determination of wavelength. Measurement of the intensity of spectral lines is presented in Chapter 5. The subjects of the last two chapters are of major importance for emission spectroscopy, and, therefore, the detection of radiations and the methods of intensity measurement are largely discussed.

The limitations in the coverge have rendered it impossible to discuss all known procedures, or to provide an exhaustive literature list for them. By excluding obsolete methods from their scope the authors have aimed at a discussion of the essentials, advantages and drawbacks of the presently used methods. Also, the authors tried to cover such procedures that can only be used in special cases, or which have not found widespread applications. The list of references contains the papers that were used for writing the book; also, some monographs and general works on the topics are quoted. Numerous illustrations and tables make the book attractive and very useful for a reader.

The whole work is a very complete and competent study of various aspects of emission spectroscopy and should be of high interest for all scientists working in this domain.

NOTE POUR LES AUTEURS

La *Revue Roumaine de Chimie* publie des articles en anglais, français, russe, allemand ou espagnol. Les auteurs sont priés d'envoyer des articles, notes, communications et comptes rendus inédits.

Les manuscrits seront dactylographiés à deux intervalles. Les tableaux seront dactylographiés sur feuilles séparées, de même que la légende des figures. Les diagrammes seront tracés à l'encre de Chine sur papier calque. Les tableaux et les figures seront numérotés par des chiffres arabes, en nombre strictement nécessaire. Prière de ne pas inscrire les mêmes données dans les tableaux et les figures. Les formules chimiques seront incluses dans le texte ; en outre, elles seront transcrites sur des feuilles séparées. Les auteurs sont priés d'indiquer les caractères italiques (en soulignant les lettres au crayon), ainsi que tout autre caractère spécial. L'ordre des références bibliographiques sera celui de leur mention dans le texte ; le nom de l'auteur sera précédé de l'initiale du prénom ; les publications périodiques seront présentées suivant les prescriptions internationales. Les références seront ajoutées à la fin de l'article ; elles paraîtront comme des notes, au bas de la page. Le texte sera précédé d'un résumé comprenant 15 lignes au maximum.

L'entière responsabilité du contenu des articles appartient aux auteurs. On publie des articles dus aux collaborateurs roumains ou étrangers. Les auteurs recevront 50 tirés à part.

KINETIC STUDY OF OXIDO-REDUCTION REACTIONS, BY MEANS OF THE VIBRATED ELECTRODE TECHNIQUE

GHEORGHE FACSKO and MARIA PORAICU

Electrochemistry Laboratory,
Polytechnical Institute of Timişoara, Str. Bocşei, N° 6, Romania

Received May 29, 1973

In the following study the results of the researches, obtained at the determination of some kinetic parameters of the redox-systems Fe^{3+}/Fe^{2+} and Ce^{2+}/Ce^{4+}, are presented by means of the vibrated electrode technique. The vibration of electrode leads to a considerable increase of the limit-current density (about 10–13 times), consequently to an extension of the existence range of pure chargetransfer overvoltage and also to the possibility of determining some kinetic parameters. By means of this technique we determined the rate constants for the Fe^{3+}/Fe^{2+} system and we found : $k = 3.32 \times 10^{-3}$ cm/sec for the anodic process, and $k = 3.37 \times \times 10^{-3}$ cm/sec for the cathodic one ; the transfer coefficient was found to be $\alpha = 0.58$ and $(1 - \alpha) = 0.42$. Considering the system Ce^{4+}/Ce^{3+}, the rate constant and the transfer coefficient for the cathodic process were determined to be $k = 2.07 \times 10^{-4}$ cm/sec, respectively $(1 - \alpha) = 0.25$. The experimental results are in accordance with those described by other authors.

GENERAL CONSIDERATIONS

The redox-systems studied are represented by the following general electrode-reaction : [1,2,3]

$$\text{Red.} \rightleftarrows \text{Ox.} + e^- \tag{1}$$

There is no preceding or following chemical reaction with respect to the charge-transfer reaction, which could influence their kinetics.

The charge-transfer rate of the process could be given as current density by the following relation :

$$\begin{aligned} i = i_+ - /i_-/ &= nF\,(k_+\,C_r - k_-\,C_0) = \\ &= nF\left\{k'_+\,C_r\,\exp\left(\frac{\alpha nF}{RT}\,\varepsilon\right) - k'_-\,C_0\exp\left[-\frac{(1-\alpha)\,nF}{RT}\,\varepsilon\right]\right\} \end{aligned} \tag{2}$$

[2] R. D. Wales, *Electrochim. Acta*, **9**, 1675 (1964).

[3] Z. Gallus, and Ralph N. Adams, *J. Phys. Chem.*, **67**, 866 (1963).

where : i_+ and i_- are partial current densities, anodic and cathodic respectively, ε-the electrode potential referred to the standard hydrogen electrode, C_0 and C_r-the concentrations of the reactive kinds of ions, k'_+ and k'_--rate constants, independent of the electrode potential, the other quantities having the usual significance.

At the equilibrium, in the absence of an outer current, the two partial currents will be equal to each other, but opposite in sign and equal to the exchange-current i_0 :

$$i_0 = i_+ = /i_-/ = nF\,k'_+\,C_r\,\exp\left(\frac{\alpha nF}{RT}\,\varepsilon_{\text{ech.}}\right) = \\ = nFk'_-\,C_0\exp\left[\frac{(1-\alpha)\,nF}{RT}\,\varepsilon_{\text{ech.}}\right] \tag{3}$$

where $\varepsilon_{\text{ech.}}$ is the equilibrium potential of the electrode.

Combining relation (2) with (3) the following expression is obtained for the current density :

$$i = i_0\left\{\exp\left(\frac{\alpha nF}{RT}\,\eta\right) - \exp\left[-\frac{(1-\alpha)\,nF}{RT}\,\eta\right]\right\} \tag{4}$$

where $\eta = \varepsilon - \varepsilon_{\text{ech.}}$ is the value of charge-transfer overvoltage.

At small values of the charge-transfer overvoltage, when $/\eta/ \ll \frac{RT}{F}$, the development in series of the exponentials from equation (4) and the maintenance of each first term leads to the expression :

$$\eta = \frac{/i/}{i_0}\,\frac{RT}{F} \tag{5}$$

By graphical representation of overvoltage η dependence as a function of the current density $/i/$, we obtain a linear relation whose slope allows the calculation of the exchange current density i_0, but not of the value of the transfer-coeficient α.

For great positive overvoltages (anodic processes), the second term of equation (4) could be neglected and written as :

$$i = i_+ = i_0\exp\left(\frac{\alpha nF}{RT}\,\eta\right) \tag{6}$$

wherefrom it is obtained :

$$\eta = -\frac{RT}{\alpha nF}\ln i_0 + \frac{RT}{\alpha\,nF}\ln i \tag{7}$$

which is the well-known Tafel equation:

$$\eta = a + b \log i \tag{8}$$

For great negative overvoltages (cathodic processes) the first term of equation (4) could be neglected and written as:

$$i = |i_-| = i_0 \left\{ \exp\left[-\frac{(1-\alpha)nF}{RT}\eta \right] \right\} \tag{9}$$

from which results:

$$\eta = \frac{RT}{(1-\alpha)nF} \ln i_0 - \frac{RT}{(1-\alpha)nF} \ln |i_-| \tag{10}$$

or the Tafel equation for cathodic processes:

$$\eta = a' - b' \log |i_-| \tag{11}$$

Taking the slopes resulting from the Tafel equations (8) and (11), b respectively b', the values for αn, respectively $(1-\alpha)n$ could be calculated, where $b = 2.303\ RT/\alpha nF$ and $b' = 2.303\ RT/(1-\alpha)nF$. At 25° the calculated values are $b = 59.2/\alpha n$, respectively $b' = 59.2/(1-\alpha)\, n$ mV.

At the extrapolation of the straight line for $\eta = 0$ the logarithm of the exchange current i_0 is obtained.

If in equation (3) the value of the equilibrium potential is introduced:

$$\varepsilon_{\text{ech.}} = \varepsilon^0 + \frac{RT}{nF} \ln \frac{C_0}{C_r} \tag{12}$$

and if all the constants are included in the general constant k, it could be written as:

$$i_0 = nFkC_r^{(1-\alpha)}\, C_0^{\alpha} = i_0^0\, C_r^{(1-\alpha)}\, C_0^{\alpha} \tag{13}$$

where k is the standard rate constant, and i_0^0 — the standard exchange current, independent of concentration.

On the basis of relation (13) the value of k, or of i_0^0 could be calculated.

The considerations treated before are valid when the electrode process is controlled exclusively by charge transfer. But in reality on the charge transfer control superimposes to a greater or smaller extent the slow diffusion of ions to and from the electrode.

In this case relation (2) must be written as:

$$i = nF\left\{k'_{+}\ C_r^x \exp\left(\frac{\alpha nF}{RT}\ \varepsilon\right) - k'_{-}\ C_0^x \exp\left[-\frac{(1-\alpha)\,nF}{RT}\ \varepsilon\right]\right\} \tag{14}$$

where C_r^x and C_0^x are the concentrations of the reactive kind of ions from the immediate vicinity of the electrode, which are modified by the passing of electric current.

At equilibrium, relation (3) has its valability, the concentrations near the electrode being equal with those from the bulk of solution.

Combining relation (14) with (3) the following expression for the current density is obtained:

$$i = i_0\left\{\frac{C_r^x}{C_r} \exp\left(\frac{\alpha nF}{RT}\ \eta\right) - \frac{C_0^x}{C_0} \exp\left[-\frac{(1-\alpha)\,nF}{RT}\ \eta\right]\right. \tag{15}$$

Because the processes were studied in a great excess of indifferent electrolyte, compared with the concentrations of the reactive kind of ion, it could be written:

$$i = \frac{nFD_i}{\delta i}\,(C_i - C_i^x) \tag{16}$$

$$i_d = \frac{nFD}{\delta_i}\ C_i \tag{17}$$

where D_i is the diffusion coefficient of the kind of ion which reacts at the electrode, δ_i — the thickness of the diffusion layer, and C_i, respectively C_i^x are the concentrations of the kind of ion which reacts in the bulk of solution, respectively in the vicinity of the electrode.

Combining relations (16) and (17) it results:

$$\frac{i}{i_d} = \frac{C_i - C_i^x}{C_i} = 1 - \frac{C_i^x}{C_i} \tag{18}$$

from which:

$$\frac{C_i^x}{C_i} = 1 - \frac{i}{i_d} \tag{19}$$

If we set the values for C_i^x/C_i from relation (19) in relation (14), in the case of a combined control of charge-transfer-diffusion, we obtain the following expression for the current density:

$$i = i_0\left\{\left(1 - \frac{i}{i_{d,a}}\right) \exp\left(\frac{\alpha nF}{RT}\ \eta\right) - \left(1 - \frac{i}{i_{d,c}}\right) \exp\left[-\frac{(1-\alpha)\,nF}{RT}\ \eta\right]\right\} \tag{20}$$

Here $i_{d,a}$ and $i_{d,c}$ are anodic respectively cathodic diffusion currents. In this case relation (20) is not any more identical with relation (4), so that the dependence in the Tafel domain would not be a linear one. Thus, in the case of the superposition of the diffusion control, the method of determination of the exchange current i_0 and of the transfer coefficient α, presented before, cannot be applied any more. But it is to be seen that in the case of great diffusion currents, relation (20) approaches to and practically superposes itself with relation (4).

The diffusion-current density value increases in accordance with relation (17), with increase of concentration of the reactive kind of ion C_i, of the diffusion coefficient D_i and with decrease of the thickness of the diffusion layer δ_i.

The value of the diffusion coefficient could be increased by heating the solution. The increment of its increase with temperature has approximately the same value as that of the electrical conductibility : 2 % from its value/°.

The diffusion-layer thickness could be decreased by mixing the solution. Between all the mixing methods used to decrease the diffusion-layer thickness, the electrode-vibration is the most efficient, because it has a strong agitation effect, tearing off the adherent pelicular layer.

For this reason the electrode-vibration will bring about a considerable increase of the limit-current density, meaning an extension of the pure charge-transfer overvoltage as well as the possibility of application of the determination method of the kinetic parameters presented.

EXPERIMENTAL PART

A. THE STUDY OF THE SYSTEM Fe^{3+}/Fe^{2+}

The influence of electrode-vibration on the limit-current value was studied by drawing the polarization curves for the oxidation and also for the reduction processes of the $Fe_2(SO_4)_3/FeSO_4$ system, corresponding to the overall reaction :

$$Fe^{2+} \rightarrow Fe^{3+} + e^- \qquad (21)$$

The concentrations of the two kinds of ions (Fe^{3+} and Fe^{2+}) were equal to each other, in the limits of 2.5×10^{-2} and 10^{-2} the indifferent electrolyte being sulfuric acid of molar concentration.

The electolysis cell was constituted of a 400 ml capacity beaker-glass, separated in two compartments by a glass-cylinder, with a porous plate on its inferior part. The working electrode having a surface of 0.025 cm² was of platinum wire ; to it a Luggin tube was fixed, tied to the reference-electrode Hg/Hg_2SO_4, K_2SO_4 saturated solution. The working electrode was either stationary, or could be vibrated with a 50 Hz frequency and 3mm amplitude by means of an electromagnetic vibrator, whose construction is described in an anterior work. [4]

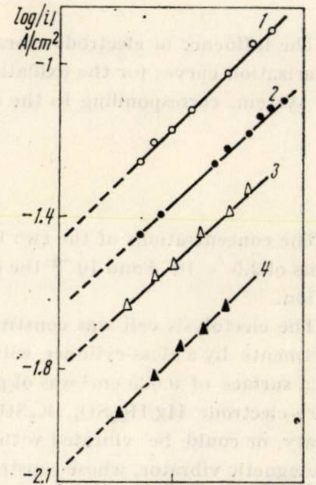

Fig. 2. — Representation of the linear portion of the logarithm of anodic current density as a function of overvoltage, for the system Fe^{3+}/Fe^{2+} in 1M H_2SO_4, on a vibrated electrode.
1, 1.0×10^{-1} M $Fe_2(SO_4)_3$ /1.0×10^{-1} M $FeSO_4$;
2, 7.5×10^{-2}M $Fe_2(SO_4)_3$/7.5×10^{-2}M $FeSO_4$;
3, 5.0×10^{-2} M $Fe_2(SO_4)_3$ /5.0×10^{-2}M $FeSO_4$;
4, 2.5×10^{-2} M $Fe_2(SO_4)_3$ /2.5×10^{-2} M $FeSO_4$;

The potential difference between the working electrode and the reference-electrode was determined using an electronic potentiometer (pH-Electrometer-ORION Type 2512).

The temperature was maintained constant at 25°, by means of a thermostat.

In figures 1 and 3, the curves of the logarithm of current densities as a function of over-voltage at the oxidation, respectively, at the reduction processes are presented, obtained on the vibrated electrode (curves *1*, *2*, *3*, and *4*) and on the stationary electrode, (curves *1'*; *2'*; *3'*; and *4'*).

There can be observed an appreciable increase of the limit-currents on the vibrated electrode, 10–13 times the corresponding values on a stationary electrode.

In figures 2 and 4 the linear portions of the curves $\log|i|$ are graphically represented as function of η for the vibrated electrode, corresponding to the equations :

$$\log i_{+} = \log i_0 + \frac{\alpha F}{2.303\,RT}\,\eta \tag{22}$$

for the oxidation process and :

$$\log |i_{-}| = \log i_0 - \frac{(1-\alpha)F}{2.303\,RT}\,\eta \tag{23}$$

for the reduction process.

From the values of ordinata at the origin $\log i_0$ and from the straight-line slopes $\alpha F/2.303\,RT$, respectively $-(1-\alpha)F/2.303\,RT$, the values for i_0, α, respectively $(1-\alpha)$ were calculated.

The calculation of the exchange-current density independent of concentration was effectuated by means of equation (13), considering that $C_r = C_0 = C$:

$$i_0^0 = \frac{i_0}{C} \tag{24}$$

whereas calculation of the rate constant, k, was done from the same expression (13) as follows :

$$k = \frac{i_0}{F}\,1\,000 \tag{25}$$

The results obtained are presented in tables 1 and 2.

B. THE STUDY OF THE SYSTEM Ce^{4+}/Ce^{3+}

The influence of electrode-vibration on the value of limit-current was studied only for the cathodic process :

$$Ce^{4+} + e^- \rightarrow Ce^{3+} \tag{26}$$

because at the anodic process, also at small values of the overvoltage, the oxygen-discharge curve superimposes itself.

The concentrations of the two kinds of ions (Ce^{4+} and Ce^{3+}) were equal and chosen in the range between 7.3×10^{-3} M and 3.32×10^{-2} M, the indifferent electrolyte being 1M H_2SO_4.

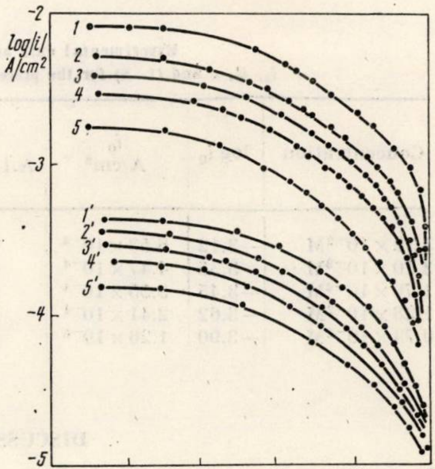

Fig. 5. — Graphic representation of the logarithm of cathodic current density as a function of overvoltage, for the system Ce^{4+}/Ce^{3+} in 1M H_2SO_4.

1,1' — vibrated electrode, respectively, stationary one, concentration : 3.32×10^{-2} M $Ce(SO_4)_2/3.32\times10^{-2}$ M $Ce_2(SO_4)_3$; *2,2'* — vibrated electrode respectively stationary one, concentration : 2.10×10^{-2}M $Ce(SO_4)_2$ 2.10×10^{-2} M $Ce_2(SO_4)_3$; *3,3'* — vibrated electrode, respectively stationary one, concentration : 1.70×10^{-2} M $Ce(SO_4)_2/1.70\times10^{-2}$ M $Ce_2(SO_4)_3$; *4,4'* — vibrated electrode, respectively stationary one, concentration : 1.28×10^{-2} M $Ce(SO_4)_2/1.28\times10^{-2}$ M $Ce_2(SO_4)_3$; *5,5'* — vibrated electrode respectively stationary one, concentration : 0.73×10^{-2} M $Ce_2(SO_4)_3/0.73\times10^{-2}$ $Ce_2(SO_4)_3$.

In figure 5 the logarithmic curves of the current density as a function of overvoltage are given, for the vibrated electrode (curves *1*, *2*, *3*, *4*, and *5*) and also for the stationary one (curves *1' 2'*, *3'*, *4'* and *5'*)

By analogy to the system Fe^{3+}/Fe^{2+}, an important increase of limit-current values by the influence of electrode-vibration was observed, namely 10 to 13 times the values obtained with the stationary electrode.

In figure 6 are represented the linear portions of the dependence of the logarithm of current densities as a function of overvoltage, obtained by electrode vibration.

The calculation were effectuated similarly to those from paragraph A, using equations (13), (23), (24) and (25), for the determination of the respective values for i_0, i_0^0, $(1 - \alpha)$ and k

The obtained results are given in table 3.

DISCUSSION OF THE RESULTS

Our experimental results show that the technique of electrode-vibration extends considerably the range of the pure charge-transfer overvoltage and thus permitted the correct calculation of the kinetic parameters in the case of systems Fe^{3+}/Fe^{2+} and Ce^{4+}/Ce^{3+}, by means of a relatively simple device. The results are comparable with those indicated in the literature, with respect to both : the values of exchange-current densities and the values of transfer coefficients.

In table 4 are given our results compared to the results given by other authors.

Table 4

Values of kinetic parameters for the systems Fe^{3+}/Fe^{2+} and Ce^{4+}/Ce^{3+} after various authors

* Calculated from i_0^0

The tentative to extend the method to systems having greater values of the density of exchange-current, like the system : $K_3Fe(CN)_6/K_4Fe(CN)_6$ did not give the expected results.

We consider that the method could be applied in the described conditions, for systems having the values of the standard exchange-current densities $i_0^0 \leqslant 0.4$ A·l·/mole·cm².

VISCOSIMETRIC STUDY OF POLYACRYLIC ACID IN WATER-ETHANOL MIXTURES

LUCIA ZADOR and IUDITA MUREŞAN

"Babeş-Bolyai" University, Faculty of Chemistry, Cluj, Str. Arany Janos, 11, Romania

Received June 21, 1973

Experimental results are reported which, compared with the previously obtained potentiometric data, prove the occurrence of a conformational transition of polyacrylic acid (PAA) in water -ethanol mixtures containing large amounts of ethanol. This transition takes place within a critical interval of the degree of neutralization α of the polyacid. The interval is shifted towards lower α as the content of ethanol is raised. An interpretation and a scheme are given for the transition in terms of change from swollen open coils to symmetrical compact globules.

INTRODUCTION

The previous potentiometric study on polyacrylic acid (PAA) behaviour in water-ethanol mixtures [1] have shown that the well-known monotonous increase of $pK = pH + \log \frac{1-\alpha}{\alpha} + \log c_{H_2O}$ with the degree of neutralization (α) is characteristic only of the high water percentage solutions. (Even here only for α not lower than 0.1 – 0.08). In EtOH mixtures containing large amounts of EtOH, pK values pass through a very pronounced minimum with increasing α. These results have suggested a conformational transition for PAA, different from those found for polymethacrylic acid and poly-L-glutamic acid in aqueous solutions.[2-7] Since conformational transitions must be reflected on viscosimetric behaviour, the purpose of the present paper is to investigate the existence and the peculiarities of the suggested transition process by means of the viscosimetry. The effect of solvent composition and degree of neutralization on the average size of PAA chains was studied.

So far viscosimetric measurements in water-ethanol mixtures were performed only for PAA with $\alpha = 0$ and $\alpha = 1$ in solvent mixtures containing less than 60 v% ethanol.[8]

EXPERIMENTAL

The *PAA* was prepared by polymerization in benzene solution at 70° using benzoyl peroxide as initiating agent. The unreacted monomer was removed by extraction with benzene. Then the polymer was washed with petrol ether and dried. The average molecular weight for the Na salt of the polyacid in 2N $NaNO_3$ was determined viscosimetrically using the Mark-Houwing coefficients given by Arnold and Overbeek.[9] It was found $M_v = 977700$.

Isomolar solutions of PAA and KOH were prepared in water and 96 w% ethanol, which were mixed in the desired ratio. In order to keep the polymer concentration in volume unity unmodified (1.11×10^{-2} base mol/l $= 7.92 \times 10^{-4}$ g/ml) a calculated amount of solvent mixture was added, to compensate for the volume contraction. The calculations were based on the densities of water-ethanol mixtures given by Troy.[10]

The measurements were carried out at $25 \pm 0.1°$ in an Ubbelohde suspended level viscosimeter at constant rate of shear (capillary constant 0.1).

Since the polymer concentration was unvariable, $\eta_r = \frac{\eta}{\eta_0} = \frac{t}{t_0}$ values could be used instead of $\frac{\eta_{sp}}{c}$ (t and t_0 are the times of the flow for solutions and of the correspondent solvent mixture, respectively. The values of $\frac{\eta_{sp}}{c}$ are related to η_r by

$$\frac{\eta_{sp}}{c} = \frac{\eta_r - 1}{7.92} x 10^4$$

in order to get more direct information about the shape of *PAA* chains in different solutions, it was determined η_r also for the completely uncharged PAA at the same polymer concentration in 0.2 N HCl aqueous solution as solvent.

Using Flory's[11] relations

$$[\eta] = \frac{\Phi(\bar{h}_0^2)^{3/2}\alpha^2}{M} \quad \text{respectively} \quad \frac{[\eta]}{[\eta]_\theta} = \alpha^3$$

and accepting the completely uncharged PAA as a reference state, the following conventional measure of the expansion coefficient was used

$$A = \frac{\left(\frac{\eta_{sp}}{c}\right)^{1/3}}{\left(\frac{\eta_{sp}}{c}\right)^{1/3}_{HCl}}$$

for the polymer concentration $c = 7.92 \times 10^{-4}$ g/ml.

[11] P. FLORY, *J. Amer. Chem. Soc.* **74**, 3364 (1952).

Although the value of A is not identical with Flory's expansion coefficient on account of finite concentrations used, this ratio seemed to reflect more correctly the extent of the expansion than $[\eta]^{1/3}/[\eta]^{1/3}_{\mathrm{HCl}}$ because of the uncertainties of the extrapolation for polyelectrolyte solutions without added salts (see e.g. fig. 5).

RESULTS

THE EFFECT OF α

Fig. 1 shows the influence of the degree of neutralization on the relative viscosity in various mixtures of solvents for a given polymer concentration. While in aqueous solutions η_r increases continuously with α, in H_2O — EtOH mixtures a twofold effect of α on the shape of PAA chains is evident. The increase of α first enhances the value of η_r, but after a critical value determined by the EtOH percentage it involves a pronounced decrease of the relative viscosity which, for the content of EtOH higher than 52.2w %, may continue below the values found in the case of the completely unneutralized polyacid. A further increase of α does not modify

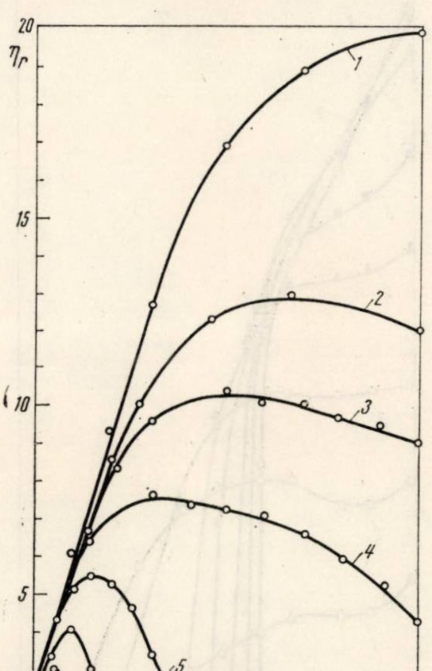

Fig. 1. — Plot of η_r against α for PAA in water-EtOH mixtures ($c = 1.11 \times 10^{-2}$ base mole/l).

1, 0 w% EtOH *2*, 19,9 w% EtOH *3*, 33.1 w% EtOH *4*, 41.3w% EtOH *5*, 52.2w% EtOH *6*. 62.2w% EtOH *7*, 72.7 w% EtOH *8*, 96. w% EtOH these low values of η_r. While the slope of the initial ascendent sections of the curves are not affected by the solvent composition (except the mixtures very rich in EtOH), as the EtOH percentage increases, the common slope is left at lower and lower α and concomitantly both coordinates of the maximum diminish. The degree of neutralization at which η_r reaches a constant minimal value also decreases with EtOH concentration.

In 96 w% EtOH only the decays and constant sections of the curves can be observed.

THE EFFECT OF EtOH CONTENT

In fig. 2 is shown the influence of solvent composition on the average size of PAA at various degrees of neutralization. The curve for $\alpha = 1$ is

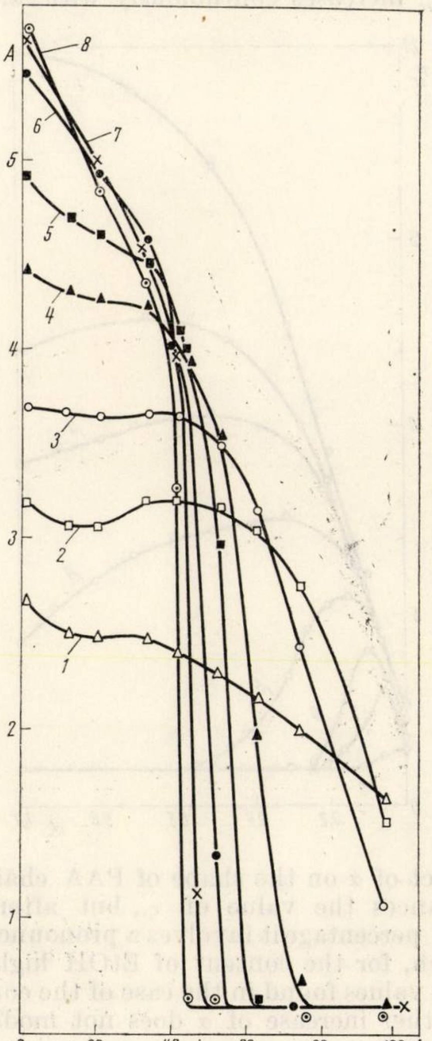

Fig. 2. — Plot of *A versus* EtOH concentration for PAA. *1*, $\alpha = 0$ *2*, $\alpha = 0.05$ *3*, $\alpha = 0.1$ *4*, $\alpha = 0.2$ *5*, $\alpha = 0.3$ *6*, $\alpha = 0.5$ *7*, $\alpha = 0.7$ *8*, $\alpha = 1$

in a good agreement with Eliassaf's [8] data for entirely neutralized PAA. Although the curves descend in each case of partially neutralized polyacid, their feature sharply depends on α.

The shape of polyions of any α does not vary significantly with the composition of solvent mixture up to about 33 w % EtOH. The further increase of EtOH percentage implies the contraction of the coils. The value of A decreases as steep as α becomes higher. For $\alpha \geqslant 0.2$ the decrease of A goes up to a value of 0.53, when the shape of the coils becomes more compact than for the completely uncharged PAA. The lowest EtOH percentage corresponding to this minimal value of A diminishes with increasing α and for $\alpha = 0.2-1$ it corresponds to 76 — 45 %.

COMPARISON WITH POTENTIOMETRIC DATA

In order to get a correct interpretation of the reported results a comparison between viscosimetric and potentiometric behaviour of the investigated solutions is given in figs.3 and 4.

The analysis of these figures permits the following facts to be pointed out :

1) For solvent mixtures containing large amounts of water the degree of neutralization at which the slope of A and pK curves suddenly diminish, has the same value. At the same time the descent of $A - \alpha$ curves corresponds to horizontal portions on the $pK - \alpha$ plots.

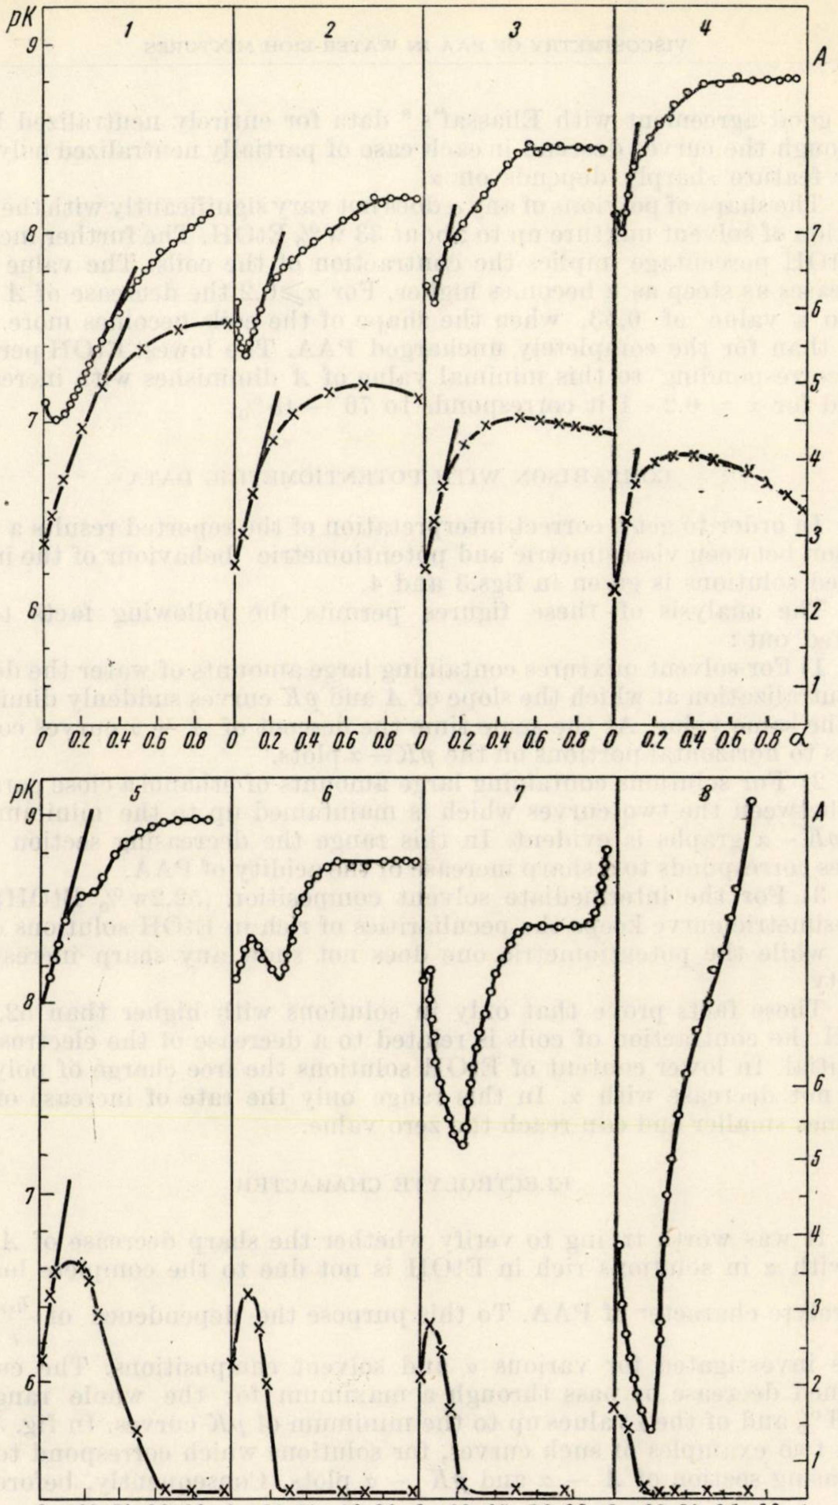
2) For solutions containing large amounts of ethanol a close parallelism between the two curves which is maintained up to the minimum on the $pK - \alpha$ graphs is evident. In this range the decreasing section of A curves corresponds to a sharp increase of the acidity of PAA.

3) For the intermediate solvent composition (52.2w % EtOH) the viscosimetric curve keeps the peculiarities of rich in EtOH solutions quite well, while the potentiometric one does not show any sharp increase of acidity.

These facts prove that only in solutions with higher than 52.2 % EtOH the contraction of coils is related to a decrease of the electrostatic potential. In lower content of EtOH solutions the free charge of polyions does not decrease with α. In this range only the rate of increase of pK becomes smaller and can reach the zero value.

ELECTROLYTE CHARACTER

It was worth trying to verify whether the sharp decrease of A and pK with α in solutions rich in EtOH is not due to the complete loss of electrolyte character of PAA. To this purpose the dependence of $\frac{\eta_{sp}}{c}$ on c was investigated for various α and solvent compositions. The curves obtained decrease or pass through a maximum for the whole range of EtOH % and of the α values up to the minimum of pK curves. In fig. 5 are given two examples of such curves, for solutions which correspond to the decreasing section of $A - \alpha$ and $pK - \alpha$ plots. Consequently, before the



Figs. 3,4 — Plot of A (×) and pK (○) as a function of α for different compositions of the solvent mixture.

1 0w%EtOH *2*, 19.9 w% EtOH *3*, 33.1 w%EtOH *4*, 41.3 w% EtOH *5*, 52.2 w% EtOH *6*, 62.2 w% EtOH *7*, 72.7 w% EtOH *8*, 96.0 w% EtOH minimum of pK curves the PAA keeps his electrolyte character. For higher α the low values of η_r do not allow a satisfactory accuracy for such measurements.

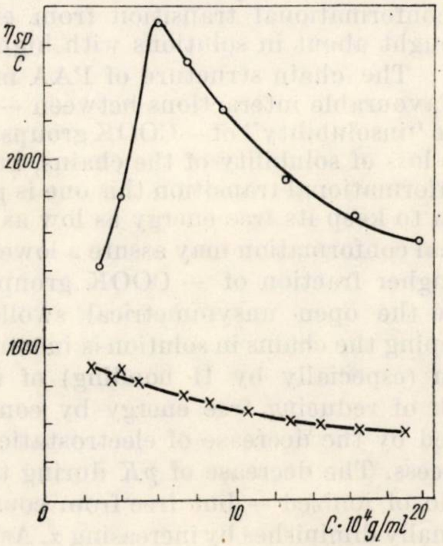


Fig. 5. — Plot of viscosity number versus c for PAA in solutions with 62.2 w% EtOH for degrees of neutralization: $\alpha = 0.15$ (.) $\alpha = 0.20$ (x).

DISCUSSION

In aqueous solution the decrease of the slope on $A - \alpha$ and $pK - \alpha$ curves above a given degree of neutralization may be attributed to the screening of the electrostatic potential in the wake of counterion binding.

The reported experimental results prove that the presence of EtOH in the solvent has besides the effect of enhancing the ion binding (by reducing the dielectric constant of the medium) another one very pronounced, to which has to be attributed the complex influence of α upon η_r, A and pK as well as the sudden decrease of A in a narrow EtOH percentage interval. This effect has to be related to the enthalpic interactions, which are responsible for the insolubility of potassium polyacrylate in absolute EtOH. The sudden decrease of η_r or A cannot be, however, the consequence of the loss of solubility of the polymer in the given solvent mixtures. Some attempts on solubility indicated that such solutions were thermodynamically stable. They were formed spontaneously if the components were put in contact in ratios corresponding to the range that follows the minimum on the $pK - \alpha$ curves. Therefore, the turbidity of such solutions has to be attributed to the more compact setting of the chain segments rather than to the loss of solubility. For the polymer concentration investigated the insolubility of the chains for a given EtOH concentration appears at α values much higher than it corresponds to the sudden contraction (for example in 72.7 % EtOH the contraction ends at $\alpha = 0.22$ while the insolubility begins at $\alpha > 0.75$).

Thus, the explanation of the observed phenomena requires to admit a conformational transition from expanded coils to compact globules, brought about in solutions with high EtOH percentage by increasing α.

The chain structure of PAA makes possible that the energetically unfavourable interactions between — COOK groups and EtOH molecules (the "insolubility" of —COOK groups in the solvent medium) do not lead to the loss of solubility of the chains, but to a change of their shape. As any conformational transition this one is predicted by the tendency of the solution to keep its free energy as low as possible. The new compact, symmetrical conformation may assure a lower interaction free energy by "hiding" a higher fraction of — COOK groups from the solvent medium than is able the open unsymmetrical swollen conformation. The function of keeping the chains in solution is incumbent in these conditions on the solvation (especially by H bonding) of unneutralized — COOH groups. The task of reducing free energy by contraction is presumably much facilitated by the decrease of electrostatic free energy, which accompanies the process. The decrease of *pK* during the transition indicates that here the ratio of ionized — but free from counterion binding — carboxylic groups actually diminishes by increasing α. As for the conformational chain entropy, it has to pass through a maximum during the transition from much more expanded conformations to those more compact than the statistical coil. Thus, the variation of the chain entropy free energy by contraction has to be negative, or if it is positive, its magnitude cannot be significant.

It can be assumed that the conformational transition is marked by the descendent sections of $pK - \alpha$ or $A - \alpha$ curves or by the sudden decrease of A — %EtOH curves. In table 1 are presented the correlated values of α and EtOH percentage where the transition is accomplished.

Table 1

The values of α marking the end of transition for different compositions of the solvent mixture

w % EtOH	α
45	1.0
50	0.7
55	0.5
61	0.3
65	0.25
70	0.21
76	0.20
96	0.19

By increasing the degree of neutralization up to higher values than are given in table 1, an aggregation process occurs, which does not imply any η_r modification (*Einstein's* rule for impermeable spheres seems to be valid) but involves the decrease of the acidity.

The independence of acidity of α, observable for 62.2 and 72.7 *w* % EtOH after the mounting sections of $pK - \alpha$ plots, between $\alpha = 0.53-0.96$ and 0.53 — 0.80 respectively, presumably corresponds to the formation of a stable secondary structure. It seems that only at higher α or EtOH percentage (f.e. $\alpha > 0.8$ for 72.7 % EtOH) the aggregation continues up to precipitation.

Fig. 6 suggests a schematic drawing of the investigated process.

It could be concluded that the observed phenomena may be attributed to a conformational transition opposed to that put in evidence for polymethacrylic acid in water solutions. [12]

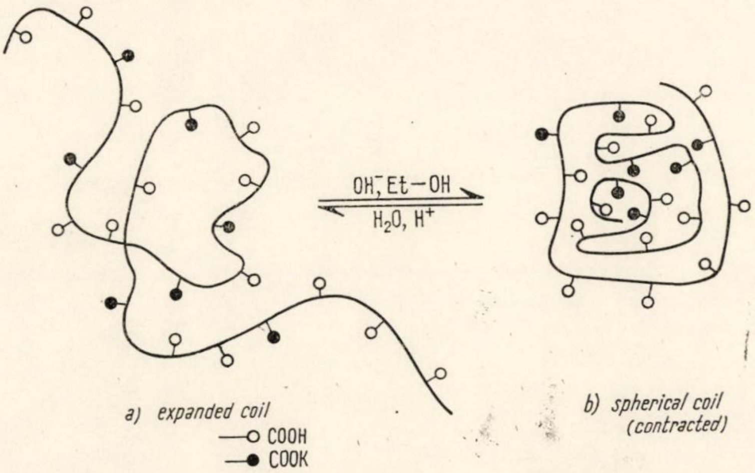

Fig. 6. — Schematic representation of PAA chains :

a) in solution containing large amounts of water or in solvent mixtures with raised EtOH content at low α b) in solution containing more than 52 w% EtOH at higher α than those given in table 1.

In the experimental measurement we acknowledge the assistance of the students I. Nistor and I. Bodea.

MAGNITUDES AND SIGNS OF ^{13}C COUPLING CONSTANTS IN SEVERAL ORGANIC MOLECULES BY DOUBLE RESONANCE

V. BĂRBOIU

The "P. Poni" Institute of Macromolecular Chemistry Aleea Gr. Ghica Vodă, nr. 41 A, Iași, Romania

Received April 14, 1973

The double resonance technique was used to determine the magnitudes and the absolute signs of the spin-spin coupling constants $^1J_{CH}$, $^2J_{CCH}$, $^1J_{CF}$, $^2J_{CCF}$, J_{HH} and J_{HF} in the following molecules: CH_3COOH, $CH_2ClCOOH$, $CHCl_2COOH$, CHF_2COOH, CH_2ClCHO, $H_3C-CH=CH-CHO$, CH_3CH_2OH and CF_3CH_2OH. The double resonance studies on $F_3^{13}C-CH_2OH$ and $H_3^{13}C-{}^{13}COOH$ are described in detail. It was found that the electronegativity and the number of substituents produce an increasing positive contribution to $^2J_{CCH}$ of halogenated acetic acids, opposite to that of halogenated acetaldehydes. Other dependences of the measured coupling constants are presented.

It is known that ^{13}C NMR studies are still difficult to be carried out Although the various PFT techniques allow to obtain ^{13}C NMR spectra of S/N ratio comparable to those of c.w. proton spectra, the following problems are not solved yet : The PFT techniques are widely used with total proton decoupling and therefore the spectra do not contain any information about J_{C-H} couplings. When the concentrations of samples are high enough these techniques can be used without the total proton decoupling, so that the ^{13}C spectra contain information about the magnitudes of hydrogen-carbon couplings but not about their signs, and the use of heteronuclear selective irradiations in PFT spectra to find the coupling signs is not yet instrumentally solved.

One way would be to use ^{13}C enriched samples but it is very expensive and even impassable for complex molecules.

However it is possible to completely study ^{13}C resonances of natural ^{13}C abundance compounds using the indirect observing methods[1-3] : the ^{13}C satellite spectra of nuclei of high sensivity, (^{1}H and ^{19}F) are observed and the parameters of their coupled carbon nuclei (chemical shifts, magnitudes and signs of coupling constants) are determined from the character-

[3] V. I. Kowalewski, *Progr. NMR Spectroscopy*, **5**, I (1969).

istic frequencies of double resonance spectra of types ^1H, $^{19}F - \{^{13}C\}$. The most used double resonance effects are the spin tickling and the selective decoupling. The precision of such methods is very high, (± 0.1 Hz), and it is not achieved even with PFT techniques. However, these double resonance experiments are quite difficult and require long determination times and some instrumental modifications.

All these inconveniences are the cause for the relative scarcity of data on heteronuclear couplings of ^{13}C nuclei, especially on those involving two or more bonds. This paper contains such data for a series of halogenated acetic acids, alcohols and aldehydes obtained by means of double resonance effects.

EXPERIMENTAL

We present below the double resonance experiments on the molecules $F_3^{13}C-CH_2OH$ (1,1, 1 trifluoroethanol) and $H_3^{13}C-{}^{13}COOH$ (acetic acid) to find the magnitudes and the signs of all coupling constants.

COUPLING CONSTANTS IN $F_3^{13}C-CH_2OH$

The signs of $^1J_{CF}$, $^2J_{CCH}$ and $^2J_{HF}$ and the magnitude of $^2J_{CCH}$, which is impossible to be directly observed, will be determined. Of the three spectra, (^{13}C, ^{19}F, ^1H), of this molecule, schematically shown in fig. 1 *a*, *b*, *c* assuming the same sign for all three couplings, only ^{19}F spectrum is directly observable (fig. 1 d). This single resonance spectrum allowed to determine : $|J_{HF}| = 9.1$ Hz and $|^1J_{CF}| = 277.5$ Hz. One characteristic of the double resonance experiments carried out on this molecule was that the observed spectrum (^{19}F) was obtained by field sweep mode and thus the optimum irradiating frequencies must be corrected before making a comparison between them.[1,2]

It was found that lines F_1 and F_2 are split (tickling affected) by the following two close irradiating frequencies in the ^{13}C spectrum : $\nu_2^e = 15087885.8$ Hz and $\nu_2^f = 15087892.0$ Hz, respectively (fig. 1 *e*, *f*). ν_2^e must be increased with $|J_{HF}| \cdot \gamma_{13C}/\gamma_{19F} = 2.4$ Hz (this is the difference in frequency units in ^{13}C spectrum corresponding to the field difference from F_1 to F_2) to be referred to the same magnetic field as ν_2^f. If all couplings have the same sign, the irradiating frequency which affects F_1 (of r. frequency higher than that of F_2) will be higher than that affecting F_2. As $\nu_2^{e\prime} = \nu_2^e + 2.4$ is lower than ν_2^f, it results that the couplings J_{HF} and $^2J_{CCH}$ have opposite signs and thus the ^1H spin states of ^{13}C spectrum or ^{19}F spectrum must be reversed.[1,2] The magnitude of $^2J_{CCH}$ is obviously equal to the difference $|\nu_2^{e\prime} - \nu_2^f| = 3.8$ Hz. Fig. 1 g,h shows how the two ^{19}F triplets collapse to single lines for two proton irradiating frequencies : $\nu_2^g = 59995726.0$ Hz for the high r.f. triplet (of α state for $I_z(^{13}C)$) and $\nu_2^h = 59996018.3$ Hz for the low r.f. triplet (of β state for $I_z(^{13}C)$). These selective decoupling effects happen only if the two irradiating frequencies coincide with the centres of the two proton quartets corresponding to α and β states for $I_z(^{13}C)$ and which are separated by $|^2J_{CCH}|$, ν_2^g must be increased with $|^1J_{CF}| \cdot \gamma_{1H}/\gamma_{19F} = 294.7$ Hz to be compared with ν_2^h. As $\nu_{r.f.}(F_2) > \nu_{r.f.}(F_5)$ and $\nu_2^g + 294.7 > \nu_2^h$, it results $^2J_{CCH}$ and $^1J_{CF}$ have the same sign. The difference $|\nu_2^g + 294.7 - \nu_2^h| = 2.4$ Hz does not coincide with $|^2J_{CCH}| = 3.8$ Hz, before determined, but the deviation is due to the lower precision of the decoupling experiments relative to the tickling experiments.

All three couplings and their relative signs are determined :

$$^1J_{CF} = \pm 277.5 \text{ Hz}; \; J_{HF} = \mp 9.1 \text{ Hz}; \; ^2J_{CCH} = \pm 3.8 \text{ Hz}.$$

Similar experiments, but of types $^1H - \{^{13}C, {}^{19}F\}$, on the molecule $F_3C-{}^{13}CH_2OH$ determined

$$^1J_{CH} = \pm 145.6 \text{ Hz}; \; J_{HF} = \pm 9.1 \text{ Hz}; \; ^2J_{CCF} = \pm 35.4 \text{ Hz}.$$

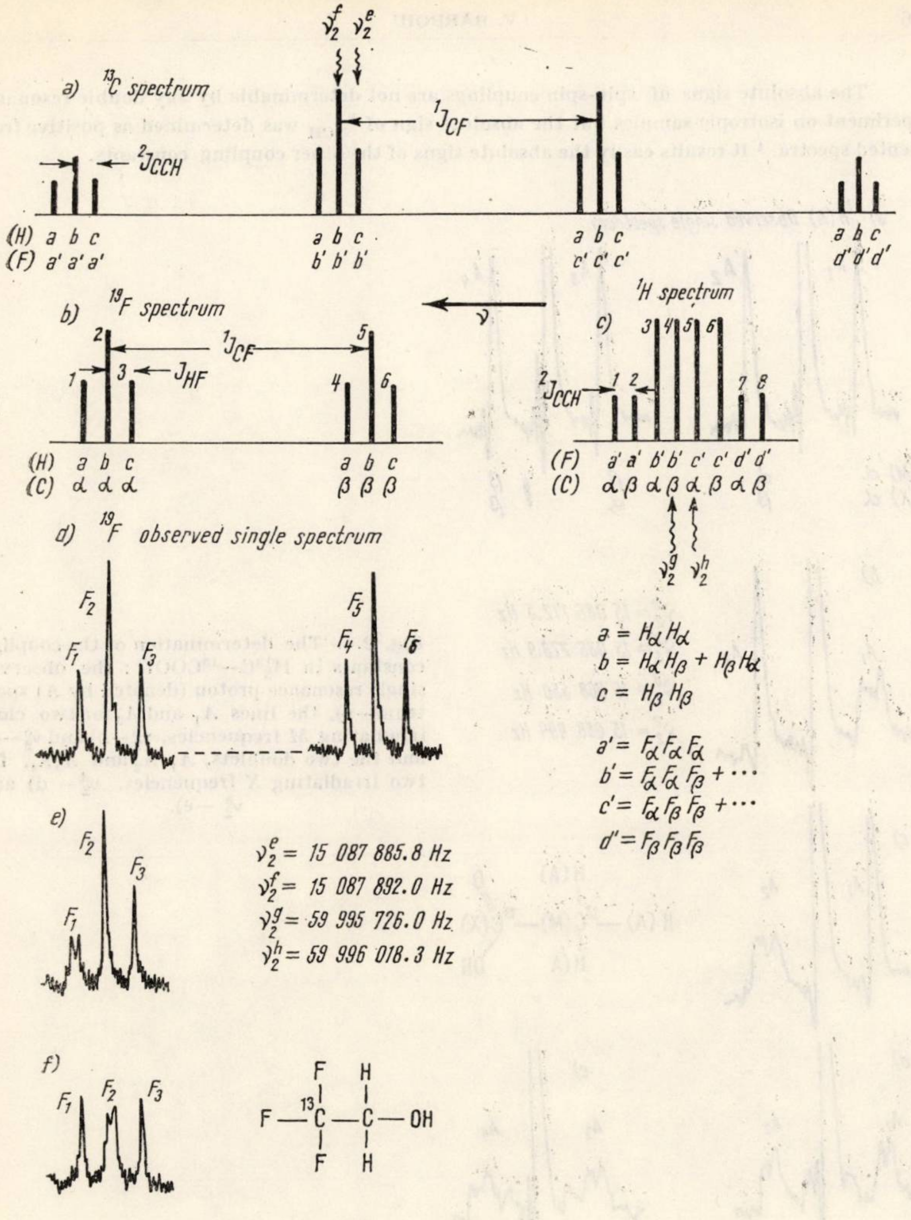

Fig. 1. — The determination of the coupling constants in $F_3^{13}C-CH_2OH$: the presumable spectra of this molecule, ^{13}C—a), ^{19}F—*b*) and ^1H—*c*), the observed single resonance ^{19}F spectrum — d), the lines F_{1-3} for two close irradiating ^{13}C frequencies, ν_2^e—e) and ν_2^f—*f*), and the collapse to single line of the two ^{19}F triplets for two irradiating ^1H frequencies, ν_2^g—*g*) and ν_2^h—*h*).

The assignment of spin states of presumable spectra is made assuming the same sign for all coupling constants.

The absolute signs of spin-spin couplings are not determinable by any double resonance experiment on isotropic samples but the absolute sign of ${}^1J_{CH}$ was determined as positive from oriented spectra. [4] It results easily the absolute signs of the other coupling constants.

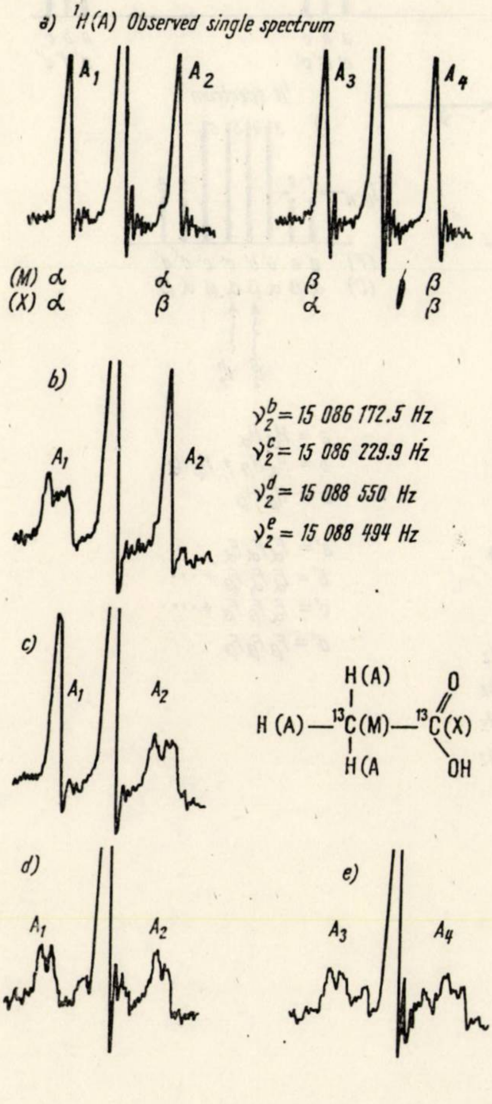

Fig. 2. — The determination of the coupling constants in $H_3^{13}C-{}^{13}COOH$: the observed single resonance proton (denoted by A) spectrum — a), the lines A_1 and A_2 for two close irradiating M frequencies, ν_2^b — b) and ν_2^c — c), and the two doublets, A_1 A_2 and A_3A_4, for two irradiating X frequencies, ν_2^d — d) and ν_2^e — e).

COUPLING CONSTANTS IN $H_3^{13}C-{}^{13}COOH$

The three coupling constants ${}^1J_{CH}$, ${}^2J_{CCH}$ and ${}^1J_{CC}$ denoted J_{AM}, J_{AX} and J_{MX} respectively (fig. 2), were obtained by $A-\{M\}$ and $A-\{X\}$ double resonance experiments. The proton spectrum A was the outer ${}^{13}C$ satellite proton spectrum of a 50 % ${}^{13}C$ enriched sample on the position — *COOH. It was recorded in frequency sweep mode, so that it is not necessary to correct the irradiating frequencies; they will correspond to the lines of ^{13}C spectra at least for the case of tickling effects. Fig. 2 *a* shows the experimental single resonance spectrum of *A* nuclei; the signals between A_1 and A_2 and A_3 and A_4 respectively arise from the molecules of type $H_3^{13}C-COOH$. This spectrum gave $|J_{AX}| = 6.5$ Hz and $|J_{AM}| = 129.5$ Hz.

---

[4] G. Englert and A. Saupe, *Mol. Cryst.*, **1**, 503 (1966).

The lines A_1 and A_2 are affected (split) by the following two close *M* irradiating frequencies : $\nu_2^b = 15086172.5$ Hz and $\nu_2^c = 15086229.9$ Hz (fig. 2 b, *c*). These frequencies must correspond to two close *M* lines of the same states for *X* spin as A_1 (α state) and A_2 (β state), and thus their difference is just $|J_{MX}|$. As $\nu_{r.f.}(A_1) > \nu_{r.f.}(A_2)$ but $\nu_2^b < \nu_2^c$ it follows J_{AX} and J_{MX} have opposite signs. The magnitude of $J_{MX} = {}^1J_{CC}$ is obviously equal to $|\nu_2^b - \nu_2^c| = 57.4$ Hz.

Two other experiments are necessary to compare the signs of J_{AM} and J_{MX}. The two doublets A_1A_2 (of α state for $I_z(M)$) and A_3A_4 (of β state for $I_z(M)$) are affected by $\nu_2^d = 15088550$ Hz and $\nu_2^e = 15088494$ Hz (fig. 2 *d,e*). The irradiating field level was kept very low to obtain a high precision. The two irradiating frequencies must correspond to the central frequencies of the two *X* quartets of the same states for $I_z(M)$ like the two A doublets. As $\nu_2^b > \nu_2^e$ it results J_{AM} and J_{MX} of the same sign. The difference $|\nu_2^d - \nu_2^e| = 56$ Hz is little different from $|J_{MX}| = 57.4$ Hz before determined by tickling effects. The absolute sign of $J_{AM} = {}^1J_{CH}$ is known as positive [4] and therefore

$$^1J_{CH} = +129.5 \text{ Hz}; \quad ^2J_{CCH} = -6.5 \text{ Hz and } ^1J_{CC} = +57.4 \text{ Hz}$$

Similar experiments were carried out to get the coupling constants of the other compounds listed in the table, except the mono and dichloroacetic acids for which $^2J_{CCH}$ was directly determined from accumulated ^{13}C spectra.

INSTRUMENTATION

All proton spectra were recorded on a JEOL JNM—C—60HL spectrometer operating in frequency sweep mode and the magnetic field was internally locked on the proton signal of a small quantity of TMS added into the samples, except the cases of acetic acids for which the lock signal was just their —OH signals. The fluorine spectra were observed in field sweep mode and the magnetic field was externally locked (the two samples method).

The irradiating fields in the experiments on compounds IV, XIV, XV were obtained using a FS—30 frequency syntesizer connected to a frequency doubler and an r. f. power amplifier, and an adjustable 15 MHz oscillator of type JNM—RH—C60A connected to a JNM—SD—HC hetero-spin-decoupler were used for the other compounds. The frequencies were measured by means of a RFT—3515 frequency counter with an error of ± 0.1 Hz.

All studied compounds were commercially available ones. The concentrations of samples were about 100 % and the work temperature was 25 ± 2 °C.

RESULTS AND DISCUSSIONS

The table below contains the coupling constants of the studied compounds. The accumulated (of 36 times) ^{13}C spectra of mono and dichloroacetic acids gave $^2J_{CCH}$ equal to 3.5 Hz and ~ 1Hz respectively. It is very plausible to consider that $^2J_{CCH}$ of monochloroacetic acid is negative because it is − 6.5 Hz in the acetic acid and + 2.2 Hz in the difluoroacetic acid. The sign cannot be deduced in the case of dichloroacetic acid. Anyway it is clear that the increasing of negativity and number of substituents at the sp^3 carbon of acetic acids has a positivation effect on the $^2J_{CCH}$ coupling constants.

Table 1

The table of the spin-spin coupling constants (magnitudes in Hz and absolute signs)

Compound	$^1J_{CH}$	$^2J_{CCH}$	$^1J_{CF}$	$^2J_{CCF}$	J_{HH}	J_{HF}	Others
I. $H_3C-COOH$	+129.5	−6.5					$^1J_{CC}=+57.4$
II. $H_2ClC-COOH$	+150	−3.5					
III. $HCl_2C-COOH$	+177	1					
IV. $HF_2C-COOH$	+193.5	+2.2	−247.9	−28.0		+52.5	
V. $F_3C-COOH$			−295.0	−44.5			
VI. $H_2ClC-{}^{13}CHO$	+182	−8.7			+1.7		
VII. $H_2Cl^{13}C-CHO$	+157	+31			+1.7		
VIII. $\overset{a}{H_3}{}^{13}C-\overset{b}{CH}=\overset{c}{CH}-\overset{d}{CHO}$	+125.2	+4.5			+6.3	(J_{ab})	$^3J_{CCH}=+6.5$
IX. $H_3C-{}^{13}CH=CH-CHO$	+153.5	−7.4	$(^2J_{CCH}{}^a)$	and	−1.9	$(^2J_{CCH}{}^c)$	
X. $H_3C-CH={}^{13}CH-CHO$	+160	+26.3	$(^2J_{CCH}{}^d)$		−1.5	(J_{ac})	
XI. $H_3C-CH=CH-{}^{13}CHO$	+172				+15.0	(J_{bc})	
XII. $^{13}CH_3-CH_2OH$	+125.4	−2.2			+7.3		
XIII. $CH_3-{}^{13}CH_2OH$	+140.4	−3.3			+7.3		
XIV. $^{13}CH_3-CH_2OH$		−3.8	−277.3			+9.1	
XV. $F_3C-{}^{13}CH_2OH$	+145.6			+35.4		+9.1	

$^1J_{CH}$ COUPLING CONSTANTS

Their magnitudes and signs agree perfectly with similar data of literature.[5] The positive signs and a proportionality dependence of the form $^1J_{CH} = A \cdot a_H^2$, where a_H^2 is the *s*-character of the C−H hybrid orbital, were well theoretically explained[6−8] and experimentally checked in detail.[9] This relationship allows to find the substituent electronegativity influence on the *s*-character of C−H bond. The values of + 177 Hz (III) and +193.5 Hz(IV) indicate an important increase of a_H^2 with the substituent electronegativity, and the values of +129.5Hz (I), +150Hz (II) and

+177Hz (III) are in agreement to the additivity rule of electronegative substituent effects on $^1J_{CH}$.[10,11] An empirical $a_H^2(E^x)$ dependence can be obtained using the experimental values of $^1J_{CH}$, the relation $^1J_{CH} = A \cdot a_H^2$ and the additivity rules.

$^2J_{CCH}$ COUPLING CONSTANTS

It can be observed that these coupling constants are very various, being negative and positive and having values from −10 up to +30 Hz. One distinguishes several types of such coupling constants.

— The $^2J(C_{sp3} - C_{sp3} - H)$ couplings are negative (compounds XII, XIII, XIV) being in agreement to the mechanism based on the contact interaction of Fermi and initially advanced by Ramsey[12] and then developed in the MO formalism.[7,13]

— The $^2J(C_{sp2} - C_{sp3} - H)$ couplings are also negative (compounds I, II, VI, IX) and the positive values found for the difluoroacetic acid (IV) is an exception. It may be concluded that the increase of the electronegativity and the number of substituents at the intervening carbon affects a positivation of these coupling constants for acetic acid (the table), which is opposite to the negativation evidenced for acetaldehydes (compound VI and others[5]).

— The $^2J(C_{sp3} - C_{sp2} - H)$ couplings are negative and positive.[5] Whilst the magnitudes of those negative are smaller than 3 Hz the positive couplings have uncommon large values (+ 46.3 for chloral[5]). It follows the sp^2 hybridization of intervening carbon has an important positive contribution J^π, which is larger than the negative contact contribution for most cases. Jameson and Damasco[13] calculated this π contribution by a MO method and they found a correct positive sign but too large values.

It is interesting to compare the value of this coupling in acetaldehyde (+26.6 Hz) with that in *trans*-crotonaldehyde-VIII (+4.5 Hz). The difference between them is that the intervening carbon is double bonded with an electronegative oxygen atom in the first case and with a carbon atom in the second. It seems that the positive J^π contribution increases with the polarization of π bonds; the C=0 bond is more polarized than the C = C. A semiclassical calculus[14] found that J^π is positive for values between 55° and 125° of the angle between the straight lines joining the two interacting nuclei with the most close π electron and has a maximum positive value at 90°. This angle is equal to 97° and 116° for the two cases and indicates that the positive J^π in acetaldehyde is larger than that in *trans*-crotonaldehyde-VIII.

$^1J_{CF}$ AND $^2J_{CCF}$ COUPLING CONSTANTS

The values found (compounds IV, V, XIV, XV) agree to similar data of literature.[15] The $^2J_{CF}$ couplings increase in absolute value with the number and the electronegativity of substituents at carbon atom as the $^1J_{CH}$ couplings do, but their negative sign is not well explained yet. It seems that the orbital mechanism of Gutowsky is much more important than the contact interactions because of the high polarity of C—F bonds.[16]

THE STUDY OF THE HARDENING PROCESSES IN TRICALCIUM SILICATE-WATER-ELECTROLYTE SYSTEM

I. TEOREANU and MARCELA MUNTEAN

Polytechnic Institute, Str. Polizu no. 1, Bucharest,
Romania

Received June 14, 1973

Using chemical, X-ray diffraction and thermodifferential analyses the influence of alkaline chlorides added in small quantities (0.5, 2, 5 % w) upon the processes in the tricalcium silicate-water system is studied in comparison with the action of calcium chloride.

1. The control of the hardening processes of binders, especially of the portland cement, and the influence in this way, on the evolution and the value of the physico-mechanical properties of the hardened system has a particular practical importance. A way to fulfil this scope, of great practical interest, is to use electrolytes added in small quantities, usually no more than 3 % in weight, to the water-binder mixture.

The study of the action of the electrolytes upon the hardening of complex binders is a very difficult task, due to the different influences that the addings may produce, as a function of the nature of mineralogical constituents of the binder, of the nature of the electrolytes themselves, of the added quantity and the hardening conditions. For this reason, the establishment of a correct picture of the mechanism by which the admixtures act upon the hardening of binders could be much facilitated by examining the influence of the additions upon the hardening of the individual mineralogical phases of the complex binders. Thus, for a thorough understanding of the mechanism and of the processes taking place during the hardening of the portland cement, in presence of electrolytes, of a great interest is to study their influence upon the hardening of silicate phases, especially of the tricalcium silicate.

There are relatively few studies in literature concerning the tricalcium silicate-water-electrolyte system; in addition, the data for this system are disparate, sometimes contradictory, and a systematic study is still lacking.

The most elaborate studies of processes taking place during hardening of the tricalcium silicate in presence of electrolytes refer to the action of calcium chloride and gypsum.

Generally, it is accepted the point of view, sustained by experimental data, that the action of calcium chloride upon the processes taking place during the hardening of tricalcium silicate is materialized by changes in structure, morphological aspects, specific surface of the hydrated products, and at the same time, due to modifications in the ionic equilibrium of the system, changes in hydration rate. [1-7] Some investigations in tricalcium silicate-water-calcium chloride system showed that, under normal conditions and for small amounts of calcium chloride (usually less than 3 %), complex products of tricalcium silicate with calcium chloride cannot be formed and identified. [1,2,4] Under special conditions (18–20 % of added calcium chloride, temperature under 0°), it seems that calcium chloride reacts with tricalcium silicate forming a complex compound of the type $3CaO \cdot SiO_2 \cdot CaCl_2 \cdot nH_2O$ ($n = 4 \ldots 15$). [8,9]

At temperatures greater than 0°, some workers evidenced the formation of some hydroxychlorides of the type $mCaO.CaCl_2.nH_2O$ as a product of the reaction of calcium chloride with calcium hydroxyde resulting from the hydration of tricalcium silicate. [1,10-12] In accordance with some studies [10-12] the formation of calcium hydroxychlorides could be considered as the principal accelerating action of calcium chloride upon the hardening of tricalcium silicate; but, as is known, the formation and the stability of the calcium hydrochlorides are possible only at higher calcium chloride contents, [1] which is not the case for the conditions considered optimum (around 2 % of calcium chloride).

As concerns the action of gypsum upon the hardening of tricalcium silicate, the literature data show positively that this action is "physical". [13-16] It consists principally in influencing the hydration kinetics of tricalcium silicate and the crystallization capacity of hydrated phases, having as final result a modification of the structure of these products.

2. In the present paper the influence of alkaline chlorides upon the processes in the system $3CaO \cdot SiO_2$-water is studied in comparison with that

of calcium chloride. Pure tricalcium silicate, synthesized at 1550° (constant temperature for a period of 4—5 h, for 6 cycles) was used.[17]

The electrolytes were added in 0.5 , 2 and 5 % proportions referred to dry tricalcium silicate. The water-solid ratio (w/s) was 0.5.

At one, seven and 28 days, the content of the water bound as hydrated formation (denoted in what follows as bound water-A_1) was ascertained and roentgenographic, thermodifferential and thermogravimetric analyses were made, with a view to obtaining information regarding the nature of the processes, the compounds which have been formed and the phase changes taking place in the system.

The bound water content was determined using Butt's method.[17] The results are shown in table 1.

Table 1

The bound water content for $3CaO.SiO_2$ hydrated in the presence of electrolytes

Electrolyte	% Electrolytes	Bound water %		
		1 day	7 days	28 days
Without	—	12.40	11.98	18.02
Lithium chloride (LiCl)	0.5	17.80	18.89	19.74
	2.0	19.60	20.40	21.02
	5.0	22.00	19.21	22.17
Sodium chloride (NaCl)	0.5	15.80	17.89	19.45
	2.0	16.05	20.80	21.10
	5.0	17.90	19.50	21.31
Potassium chloride (KCl)	0.5	17.89	19.10	20.02
	2.0	16.50	19.25	21.60
	5.0	16.70	20.12	20.16
Calcium chloride ($CaCl_2$)	0.5	16.30	17.55	19.25
	2.0	19.80	20.01	22.11
	5.0	20.30	21.98	21.35

As can be seen in all cases, the presence of alkaline chlorides determines an increase in the bound water content. This increase is, as a rule, more important for the 2 % added chlorides, in comparison with the 0.5 % ones. Higher proportions, up to 5 %, do not determine, for all cases, an increase in the bound water content ; even for higher values of A_1, the increase in bound water content was not so important as compared with the pastes with 2 % chlorides, especially for the longer hardening periods used in this experiment.

As the hydration process is advancing the existence of a diminution in the bound water content calls attention. This is clearly observed for the pastes without electrolyte, as well as for some pastes with 5 % electrolyte (LiCl or $CaCl_2$). This behaviour could be explained by the composition and structure transformations of calcium hydrosilicates appearing in the system.

---

[17] IU. M. BUTT, „Praktikum po tekhnologhii viajushchih veshchestv", Gosstroizdat, Moskva, 1953.

Kantro *et al.*,[18] after an elaborate study of the tricalcium silicate and β-dicalcium silicate hydration, gave the following description of the process : in the first step at the surface of the tricalcium silicate grains an intermediate hydrosilicate is formed, with a high CaO/SiO_2 ratio, similar with that of the unhydrated support ; in the second step this product decomposes, with the liberation of calcium hydroxide, in low-lime hydrosilicates ; in the third step, the formed calcium hydrosilicate is transformed into a stable one, richer in calcium oxide, as a result of its interaction with $Ca(OH)_2$ from the solution. Yong [19] presented a similar mechanism. Taking into consideration such a picture of the mechanism the fact should be underlined that the last two steps are essential for the process development. Andreeva and Segalova, [6] Malinin and Lopatnikova, [20] Kawada and Nemoto, [21] some of them starting even from different hydration mechanisms, have also evidenced the transformation process of low-lime hydrosilicates into hydrosilicates with higher lime content. The above-mentioned transformations have to be looked at in connection with pressure, temperature and hydration medium conditions. It results that the nature and the proportion of ions from the liquid phase have a great influence upon the processes analysed above.

The changes taking place in the structure and the composition of the calcium hydrosilicates determine also changes in the bound water content. The variation in time of the bound water content appears thus as a result of the interaction of the binder with water, as well as of the transformation processes of hydrosilicates. When the latter processes are predominant, diminutions in bound water content might appear ; this is the case, as mentioned above, of the hydration of tricalcium silicate without and with 5 % LiCl or $CaCl_2$. Such discontinuities in the H_2O/SiO_2 ratio trend, specific of hydrosilicates obtained at $3CaO . SiO_2$ hydration, were also observed by Yong. [19]

The information given by X-ray diffraction and thermodifferential analyses support also the explanations given for the results regarding the bound water content.

In figs. 1–9 the thermodifferential curves for the hardened pastes with and without electrolytes after 1, 7 and 28 days are shown. Three classes of thermal effects corresponding to the removal of water from silica and calcium hydrosilicates gels (temperature range 120–165°), the dehydration of the calcium hydroxide resulting from the tricalcium silicate hydrolysis (temperature range 505–540°) and the complete dehydration of calcium hydrosilicates and their lattice transformations (at higher temperatures) are evidenced in all cases. *

---

* The latter thermal effects reflect best the chemical and morphological modifications of the hydrosilicates formed in the first stage of the hydration process.

Electrolyte admixtures determine the increase of the hydrosilicates quantities appearing in the system, as a result of the increase of the tricalcium silicate hydration rate; calcium chloride has a more important influence.

The hydrosilicates appeared in the first stage of the hydration process have a gelic character; in time, as a result of the developing of the crystallization processes, they lose this character; the microcrystals of which they are formed grow, developing a resistance structure typical of the hardened binder. But, during the hardening period, due to hydration of new quantities of binder, new gelic hydrosilicates phases appear; thus one establishes ratios between the gelic phases and the crystalline ones

which change in time. The thermograms show that for not too long hardening periods this variation sometimes has a quasiperiodic character, for instance, this is the case of samples without electrolytes or with 2 % and 5 % natrium and calcium chloride. On the thermograms of samples with admixtures, one notices the existence of some, as a rule smaller, thermal effects corresponding to calcium hydroxide dehydration which, corroborated with what was said above about the interaction of $3CaO.SiO_2$ with water, leads to the conclusion that in the presence of electrolytes, the quantity and the formation rate of some higher-lime hydrosilicates are greater ; at the same time, one observes that the basicity of the formed hydrosilicates grows with the added amount of electrolyte (see the thermograms with calcium chloride). Taking into account the dependence on the CaO/SiO_2 ratio of the structure of the hydrosilicates, as well as the dependence of the hardened paste resistance on the structure of the formed hydrosilicates, it seems plausible to suppose, from the point of view of the mechanical properties of the hardened tricalcium silicate, the existence of an optimum amount of the electrolyte.

The thermograms show also important shifts of the thermal effects, the appearance of new ones (in case of LiCl, $CaCl_2$), changes of the ratios between the values of some thermal effects corresponding to the formed hydrosilicates transformations. This fact shows that the exothermal effects are determined by the transformations undergone by the calcium hydrosilicates formed during the hardening process. The shift of these effects to lower temperatures, their exothermic nature, under the conditions when one established the increase of the hydrosilicate basicity in the systems with electrolytes, underline the changes which the electrolytes bring about in the hydrosilicate phase morphology.

Ramachandran [22] found also on thermograms, for the $3CaO.SiO_2.CaCl_2$-water system the above-mentioned effects and considered that these effects may be attributed, in the induction period of hydration, to the formation of a complex adsorbed on the binder surface, as well as to a chemosorption of $CaCl_2$ on the hydrosilicate surface or between the layers of the hydrocompound lattice.

---

[22] V. S. Ramachandran, RILEM *Mat. Constr. Materials Struct.*, **4** (19), 3 (1971).

Without completely denying the picture presented by Ramachandran,[22] taking into account the structure peculiarities of the calcium hydrosilicates and the fact that $CaCl_2$ is a strong electrolyte it seems more probable to consider the adsorption or the inclusion of the Cl^- anion in the lattice in this latter case as a result of a partial substitution of the OH^- anion.

In the case when other chlorides are used, the nature of the cation with which Cl^- anion is bound seems to be important for the above phenomenon. From the point of view of the nature of the cation, it is to be expected that the lower the basicity of the cations, of the same group in the periodical system, the more intense the above phenomenon. The experimen-

tal data confirm this conclusion, for example in the Li—Na—K series the phenomenon is more intense for LiCl.*

The cations introduced into the system by the electrolytes may be adsorbed by the hydrosilicate complex. An exchange adsorption is possible, when Ca^{2+} ions may be replaced by more electropositive cations. In this way one should observe the relative electronegativity of the cations of the electrolytes

Cation :	Ca^{2+}	Li^+	Na^+	K^+
Electronegativity :	1.0	1.0	0.9	0.8

With a view to clarifying the nature and especially the evolution of the constituents appearing during the tricalcium silicate hydration, X-ray diffraction analyses were made.

All roentgenograms evidence the formation both of some CSH (I) type hydrosilicates (3.02Å, 2.80 Å, 1.82Å lines) and of CSH (II) type (3.07 Å, 2.80 Å, 1.83 Å, 2.00 Å, 2.97Å lines). Thus, by means of X-ray diffraction, too, the fact is put into evidence that the presence of electrolytes determines a more rapid evolution towards the formation of hydrosilicates with higher basicity — the greater the added amount, the greater the effect. In this respect an indicator is represented especially by the value of the intensity of the most characteristic line of the calcium hydroxide formed in the system and its variation in time and with the electrolyte proportion; this consideration was made also in correlation with the bound water data. All these information underline the influence of the electrolytes upon the chemical composition and therefore, upon the morphological structure of the formed hydrosilicates. The above-mentioned transformations seem to take place especially for relatively short hardening periods.

The formation of some compounds as a result of the interaction of the binder or of its hydration products with the electrolytes was observed only for longer hardening periods and especially for large amounts of electrolytes; for example, the oxychloride of the type $3CaO.CaCl_2.12H_2O$ for the sample with 5 % $CaCl_2$ after 28 days hydration period (the characteristic line of the oxychloride is 3.28 Å [23]) is well evidenced. It is known that the greatest effect on the mechanical properties of the paste hardened in presence of calcium chloride is obtained for an admixture of 2 %. Due to the fact that for this amount of chloride the formation of some chloride compounds is at least improbable, it results that the influence of this type of compounds upon the mechanical properties is of small importance and therefore it may be concluded from the above results that the main influence of the calcium chloride and of other electrolytes is of "physical" nature. This influence, due especially to the alteration of the ionic equilibrium of the system, determines changes of the hydration rate of the binder and modifications of the chemical and morphological structure of the hydrated formations.

The X-ray diffraction analysis has shown that the exothermal effects (620 — 650°) for samples with LiCl and $CaCl_2$ are due to the formation of

---

* Later works have led to the same conclusion for the Ca — Sr — Ba series, too.

[23] E. P. Andreeva and J. G. Malikova, "Fiziko-mehanika dispersnih structur", Izd. Nauka, Moskva, 1966.

$\beta - 2CaO \cdot SiO_2$. There is no evidence of any reaction between the electrolytes and the existing compounds in the system (during the thermal treatment at the above exothermal effect temperatures). Therefore, it is difficult to explain the nature of the LiCl and $CaCl_2$ influence which determines these exothermal effects. Probably this fact is, in the first place, a result of the chemical and morphological changes brought about by the electrolytes and which need further studies. A partial inclusion of the Cl^- ion in the calcium hydrosilicate network is also possible. [22]

3. From this paper we may conclude that :

— the electrolytes in amounts used in the present experiments accelerate the hydration processes ;

— the electrolytes determine the formation of some hydrosilicates with high basicity, their proportion in the hardened binder growing with the amount of the electrolyte added :

— products of interaction between the electrolytes and the system constituents appear only for large amounts of electrolytes and for longer hardening periods ($3CaO \cdot CaCl_2 \cdot 12H_2O$ for the sample with 5 % $CaCl_2$, after 28 days) ;

— the main influence of the electrolytes upon the hydration is of "physical" nature ; due to the changes in the ionic equilibrium of the system, modifications appear in the kinetics of the hydration and crystallization processes and in the chemical and morphological structure of hydrosilicates ; the existence of a certain optimum amount of the admixture results. The nature and the intensity of the effect of the admixtures upon the hardening of the calcium silicate depend on the chemical nature of the electrolytes.

ASPECTS OF THE VITREOUS PHASE SEPARATION PROCESS IN THE $Fe_2O_3-BaO-B_2O_3$ SYSTEM

ŞERBAN SOLACOLU and ECATERINA RUSU

Polytechnic Institute of Bucharest, Laboratory for Physical Chemistry of the Solid State,
Str. Polizu 1, Romania

Received June 11, 1973

The paper presents aspects of the development of the vitreous phase separation process in the $Fe_2O_3-BaO-B_2O_3$ system ; it investigates the influence of an isochronous treatment on the size of the separated particles and also on their concentration. The volume fraction of the phase with a Fe_2O_3 content is calculated for the glass having 20 % Fe_2O_3.

The separation of the vitreous phase caused by the immiscibility of two liquids occurs in most glass-forming systems. The resulting structure depends on the location of the particular composition within the limits of the immiscibility region as well as on the thermal history of the glass.

In the metastable area, decomposition takes place by nucleation and is characterized by the existence of particles from a random dispersed phase in the other phase which has the form of a continuous matrix. In the unstable area, the two phases are independently interconnected, having diffuse and irregular boundaries.

The mechanism and the kinetics of the phase separation phenomenon basically depends on a number of factors such as : the form of the gap, the cooling rate, the diffusion rate and others. The examination of these problems has both a theoretical and a practical importance in that they relate to the occurrence of some uniformly crystallized vitroceramic products.

In recent years, the advances made in various technologies involving ferromagnets and semiconductors arouse the interest in the crystallization of glasses rich in transitional metal oxides.

In this sense the masses in the $Fe_2O_3-BaO-B_2O_3$ system investigated by us have drawn attention due to their magnetic properties. [1,2] The investigations performed in the present paper deal with the liquid — liquid separations in the $Fe_2O_3 - BaO - B_2O_3$ system, a problem which has been only tangentially handled until now and only in the case of a single composition. [3]

[2] E. Rusu, *Ind. Uşoară*, **16**, 605 (1969).

[3] B. T. Shirk and W. R. Buessem, *J. Amer. Ceram. Soc.*, **53**, 192 (1970).

Although the specialty literature provides no data on thermal equilibria in this ternary system, a general consideration of the three component binary systems provides initial data concerning a clear tendency of meltings towards immiscibility. In addition, in agreement with the theory which considers the existing correlation between the immiscibility of meltings and the ionic potential (Z/r) of metal cations [4] in the case of systems containing cations $Z/r > 3$ (as in the case of iron with $Z/r = 4.5$), an intense immiscibility region is expected to exist, causing at least two distinct phases, one of which has the composition Me_xO_y.

EXPERIMENTAL METHODS

Two glass compositions were investigated : 30 % BaO ; 10 % Fe_2O_3 ; 60 % B_2O_3, and 30 %BaO ; 20% Fe_2O_3 ; 50 % B_2O_3 (% molar) termed as glass 1 and 2, respectively. The materials used and the operating procedure were described in a previous paper. [1] A preliminary assessment of the thermal treatment of phase separation was made by means of a high sensitivity differential thermal analysis.

The development of the phase separation process was observed under an electronic microscope at a 100 KV working voltage through the method of carbon and platinum replicas. Some reference samples were achieved by transparency using the chemical corrosion procedure. [5] An electronic diffraction was performed to make sure that the separated phases were vitreous and not crystalline.

The volume fraction of the separated phase was determined by direct measurement of the surfaces, considering larger areas than those presented in microphotographs.

In view of calculating the volume fraction it was assumed that the maximum thickness which may occur in the case of the replica (δ_{max}) is equal to the mean diameter (d_m) of the spheres in the dispersed phase. [6] In the case of the glasses studied preliminary experiments established that a reasonable magnification for the quantitative study is 25 000 times.

EXPERIMENTAL DATA AND DISCUSSION OF RESULTS

In accordance with the considerations postulated by Nayagawa and Izumitani [7] in the case of a third component addition to a binary system, the immiscibility region of the system increases when the difference between the immiscibility tendency between the third component (C) and the other two (A and B), in turn, is greater than the immiscibility tendency of the initial system A–B, that is, in the case in which.

$$\alpha_{AB} < |\alpha_{AC} - \alpha_{BC}|,$$

[6] J. MORIJA, D. H. WARRINGTON and R. W. DOUGLAS, *Phys. and Chem. Glasses*, **8**, 14 (1967).

[7] K. NAYAGAWA and Z. IZUMITANI, *Phys. and Chem. Glasses*, **13**, 85 (1972).

where α is a factor which primarily takes into account the ionic field strength.

By applying the rule cited in the case of the $Fe_2O_3-BaO-B_2O_3$ system and coding $A = B_2O_3$; $B = BaO$ and $C = Fe_2O_3$ it results :

$$\alpha_{B_2O_3-BaO} < |\alpha_{Fe_2O_3-B_2O_3} - \alpha_{Fe_2O_3-BaO}|$$

Consequently the immiscibility volume is expected to increase in the system studied.

Indeed, all the compositions comprised in the glass formation area show a pronounced tendency towards immiscibility.[8]

The thermograms performed for the two compositions studied in the present paper reflect the existence of an additional inflection besides the normal endothermic effect due to the transformation interval (fig. 1).

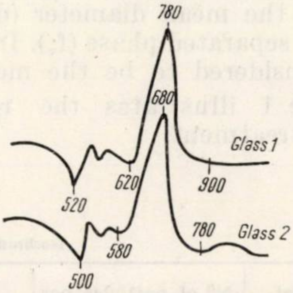

Fig. 1. – Thermograms of the studied glasses.

Since point Tg corresponds to the lower viscosity phase the inflection temperature refers to the conversion temperature of the other, the higher viscosity phase.[9] The great distance between the two conversion temperatures indicates the significant difference between the viscosities of the two phases. Figure 2 illustrates the general aspect of phase separations in glasses 1 and 2. The different morphology of the two compositions can be readily observed.

The glass containing 10 % Fe_2O_3 forms a specific interconnected structure which is maintained within the range of the studied temperatures, whereas the other composition, higher in Fe_2O_3, presents some more or less spherical distinct separations surrounded by the continuous matrix from the other phase. The dark spheres in fig. 3 present droplets from the separated phase which adhered to the replica during the detachment. This phase is more resistant to the HF action than the matrix, however it was easily attacked by HCl and this made us assume that even in this vitreous form, its composition is close to the subsequently separated magnetite which, in fact, confers to the material its magnetic properties.[10]

[9] L. Prod'homme, *Verres Réfract.*, **25**, 71 (1971).

[10] C. De Sebata, A. Poličec and E. Rusu, *Silic. Ind.*, **37**, 139 (1972).

Appropriate measurements were made on the samples subjected to a thermal treatment at temperatures ranging between Tg_1 and Tg_2.

Figure 4 shows the curve reflecting the increase in the sizes of the separated phase relative to temperature with various thermal treatment periods. The curve is not drawn through the origin since the original glasses themselves present phase separations reaching hundreds of Angstroms. [11]

The diagram of the three processes occurring in the glass during the thermal treatment is drawn in figure 5. The optimum area of thermal treatment for the nucleation process is observed.

The dependence of the liquid phase distribution on the temperature of the thermal treatment is better seen in the value of the volume fraction of the dispersed phase. By dividing the number of particles from a selected surface by the product between this surface and the mean diameter of the particles, one obtains the concentration of the separated phase expressed by the number of particles per volume unit (N). Knowing the N value and the mean diameter (d_m) one may calculate the volume fraction of the separated phase (f_v). In the case of elliptical particles, the small axis is considered to be the mean diameter.

Table 1 illustrates the results obtained in the case of an isochronous treatment.

Table 1

Isochronous treatment data

Thermal treatment (1 hour) T(°C)	N° of particles per surface unit Xn (N°/cm²)	Mean diameter $d_m(A)$	N° of particles per volume unit N (N°/cm³)	Volume fraction f_v
initial	218×10^8	400	54×10^{14}	1.80×10^{-1}
400	118×10^8	500	24×10^{14}	1.55×10^{-1}
450	50×10^8	800	6.26×10^{14}	1.47×10^{-1}
500	11×10^8	1600	0.7×10^{14}	1.41×10^{-1}
550	4.4×10^8	2400	0.18×10^{14}	1.35×10^{-1}

An initial high concentration of the separated phase is observed which decreases as the temperature of the thermal treatment increases (fig. 4, curve *2*) and the mean diameter of the separated particles increases (fig. 4, curve *1*).

This change causes the decrease of the volume fraction particularly at the beginning of the thermal treatment, after which its value becomes almost constant.

CONCLUSIONS

The two compositions studied present a pronounced difference in the separation morphology, which is explained by the position of the two glasses

within the immiscibility region, in accordance with a varied Fe_2O_3 content.

It has been observed a decrease in the concentration of the separated phase with the increase of the size of the separated phase particles depending on the temperature of the thermal treatment, so that the volume fraction remains practically constant within the measurement errors which may be estimated to maximum 10%.

By making a contribution to the study of phase separations the present paper provides the possibility of controlling the glass crystallization process in the BaO $-$ Fe_2O_3 $-$ B_2O_3 system.

NEW COORDINATE COMPOUNDS WITH MOLECULAR NITROGEN. I

SYNTHESIS AND CHARACTERISTIC PROPERTIES OF SOME DINITROGEN COMPOUNDS OF COBALT, NICKEL, IRON WITH TRIARYL-PHOSPHINES, TRIARYL-ARSINES AND TRIARYL-STIBINES

D. NEGOIU *, CONSTANŢA PÂRLOG ** and D. SĂNDULESCU ***

* University of Bucharest, Faculty of Chemistry, 89, Spl. Independenţei, Bucharest
** Center of Physical Chemistry, 31, Str. Galaţi, Bucharest
*** Institute of Petroleum, Gases and Geology, 2–6, Str. Traian Vuia, Bucharest

Received July 2, 1973

A number of 16 dinitrogen compounds of cobalt, nickel and iron with triaryl-phosphines, triaryl-arsines and triaryl-stibines were synthesized. UV, visible and IR spectrophotometric studies were performed and thermal stability determinations were made. The approximate calculations of the dissociation enthalpy provided values comprised between 8,000 and 12,000 (± 1000) cal/moles.

The early attempts at fixing the molecular nitrogen in coordinate compounds of ruthenium [1] were followed by the synthesis of a large number of compounds of this type with other metals. [2] Both synthesis in itself and the physico-chemical properties of the compounds in question constitute one the most important problems of modern inorganic chemistry, from a theoretical, chemical and biochemical aspect as well as from the standpoint of possible technological applications. These dinitrogen compounds correspond to the intermediates from the reactions of chemical and biochemical "fixation" of the atmospheric nitrogen. Indeed, nitrogen, as well as other elements such as H_2 and O_2 (X_2), may intervene in coordination reactions of the type:

$$ML_n + X_2 \rightleftharpoons ML_n(X_2)$$

in which the metal is found in a reduced oxidation state; the ML_n compound must correspond to an intense nucleophilic reactivity (supernucleophilic compounds) with an important localization of the negative charge on the metallic atom, the ligands must be "soft" (tertiary phosphines, CN, molecules with π electrons delocalized like Schiff bases). In general, the coordinate compound which fixes the nitrogen must be either neutral or under an anionic form so as to ensure an intensification of the nucleophilic character.

---

[1] A. D. Allen and C. V. Senoff, *Chem. Comm.*, **1965**, 621.

[2] C. Pârlog, D. Negoiu, A. Alistar and D. Săndulescu, *Studii şi Cercetări Chimie Acad.*, (under press).

The binding manner of nitrogen in this type of compound is particularly interesting; there is a strong probability that this metal nitrogen molecule bond corresponds to the $\sigma - \pi$ type. The analogy between the compounds of a metal-carbonyl type may be considered, for instance, $Cr(CO)_6$ and the hypothetical compound $Cr(N_2)_6$, since in the case of common compounds with molecular nitrogen, the ligands (L) have a complicated structure and the molecule has a reduced symmetry.

In this case, calculations show that the π bond in the metal-carbonyl compounds is weakened to a higher extent than in the case of the metal-nitrogen, whereas the metal-carbonyl bond is strengthened, since an important fraction of the electronic density is displaced from the 5σ orbitals which acquire thus a significant character of an antibonding orbital. As these effects must be influenced by the nature of the ligands L, different from nitrogen and from the spectral characteristics and the nitrogen-metal binding energy, we undertook to synthesize a series of compounds involving various metals with molecular nitrogen with a series of ligands gradually modifiying certain structural elements in order to establish whether the introduced effects for the differentiation of ligands, respectively of the coordinate compound generating metal may be revealed and may enable a correlation with the structure of the introduced ligands.

The ligands which we used in the coordinate compounds with molecular nitrogen correspond to tertiary phosphines, to arsines, stibines and tertiary bismuthines for the metals Co, Ni, Fe ; these compounds obviously correspond to the "soft" ligand condition and provide comparative data in the series of prepared nitrogen compounds.

The stability of nitrogen compounds must be determined in the first place by the π acceptor or the σ donor character of the ligand.

Therefore the following determinations were performed : thermal stability determinations, IR absorption spectra determinations, stability thermodynamic magnitudes determinations, as well as V and UV reflectance spectra and magnetic susceptibility determinations. [3]

The syntheses took place in a pure nitrogen atmosphere which ensures an inert atmosphere and intervenes in the coordination reaction simultaneously with the reduction of the metals valence to zero. Triethylaluminium, triisobutylaluminium, aluminium ethylate, sodium borohydride hydrogen, lithium aluminhydride, sodium dispersed in toluene * were tested as reducing agents ; the most widely used reducing agents in the above-mentioned syntheses were the organo-magnesium compounds, namely *n*-butylmagnesium bromide, which offered different advantages compared to the other indicated reducing agents.

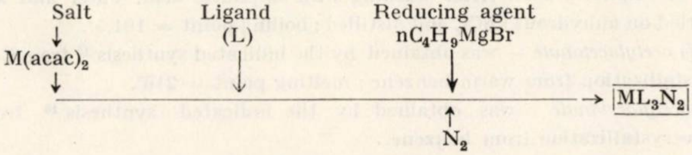
Thus, the scheme of the synthesis reaction corresponds to:



EXPERIMENTAL SECTION

The ligands were synthesized in the laboratory in agreement with indications from the literature, by means of adapted methods.[3]

Triphenlyphosphine $P\Phi_3$ — was synthesized by a known method[4] by means of the organomagnesium compound C_6H_5MgBr (prepared from $C_6H_5Br + Mg$) and of the phosphorus trichloride with yields higher than 70 %; melting point = 79.5° and the IR absorption spectrum according to data from the literature, after recrystallizing twice from absolute ethyl alcohol.

Triphenylarsine $As\Phi_3$ — was synthesized in an analogous reaction to that mentioned in the case of $P\Phi_3$ [5−7] with a 75—80 % yield, melting point = 60.5°, after recrystallization from absolute ethyl alcohol.

Triphenylbismuthine $Bi\Phi_3$ — was synthesized in an analogous reaction to the previous ones[8]; melting point = 76° and yield 35 %, after recrystallization from absolute ethyl alcohol.

*Tri-*p*-tolylphosphine* — was synthesized by an analogous method[9,10] starting from *p*-bromtoluene by means of organo-magnesium compounds; yield 60 % and melting point = 146° after recrystallization from absolute ethyl alcohol.

Tribenzylphosphine — was obtained by means of benzyl bromide which changes, with magnesium, iodine (initiator) in ethyl ether + tetrahydrofurane, in a hydrogen atmosphere, into benzylmagnesium bromide. The latter changes into raw phosphine, with phosphorus trichloride. After washing and removing the solvent, it is distilled (boiling point = 290 — 300°) and recrystallized from alcohol and ethyl ether[11]; melting point = 176°, yield = 55 %.

*Tri-*p*-xylyl phosphine* — follows the reaction scheme previously indicated, using *p*-bromxylene by means of the organo-magnesium compound, in absolute ethyl ether. Phosphine is obtained after it has been recrystallized twice from absolute ethyl alcohol, with a melting point = 155° and yield 65 %.[12]

α-Trinaphthylphosphine — is obtained by an analogous synthesis to bromnaphthaline. After recrystallization from absolute ethyl alcohol pure phosphine is obtained with the melting point = 196° and yield 45 %.[13]

α-Trinaphthylarsine — is obtained in an analogous manner from α-bromnaphthaline with magnesium and arsene chloride. After recrystallizing twice from absolute ethyl alcohol, melting point = 252°.[14]

n-*butyl bromide* — was obtained by the reaction between bromide and butyl alcohol in the presence of sulphuric acid. After washing with sulphuric acid, water and an alkaline solution, it is dried on anhydrous $CaCl_2$ and distilled ; boiling point = 101.5°.

Co(III) acetylacetonate — was obtained by the indicated synthesis [15] from $CoCO_3$ and purified by recrystallization from warm benzene ; melting point = 216°.

Co(II)acetylacetonate — was obtained by the indicated synthesis [16] from $CoCl_2$ *p.a.* (Merck) by recrystallization from benzene.

Ni(II)acetylacetonate — was synthesized from $Ni(NO_3)_2$ (0.12 mole) and acetylacetone (0.2 mole). After recrystallization from warm benzene, it is obtained in a pure state with a yield of 87%. [17]

The solvents — absolute ethyl ether, ethyl alcohol, tetrahydrofurane, benzene, toluene p.a. — were rendered anhydrous after the usual purifications and freshly distilled from sodium directly in the reaction vessel or in a burette directly linked to the reaction vessel through which pure nitrogen is passed.

THE INSTALLATION FOR NITROGEN PURIFICATION

Nitrogen purification was achieved by passing a nitrogen current through the solution of copper chloride I :

— absorption tube with a Deoxo BDS catalyst at 120—160° ;

— silicagel tube ;

— 4Å molecular sieves tube ;

— drying tube with P_4O_{10} ;

— diethylchloraluminium solution in benzene (5%).

Data pertaining to construction have been indicated. [3]

The obtained nitrogen contains under 0.5 ppm O_2 and 1—2 ppm H_2O. [18—20] The installation for the synthesis of compounds is well suited for handling the reactants and the initial solutions in an inert atmosphere, and for the filtering, washing and drying of the resulted precipitates.

Thermal decomposition. Samples from the synthesized nitrogen compounds were subjected to a thermal decomposition in a closed tube attached to a manometer. After degassing at 0.1 mm Hg during which the sample is frozen in liquid nitrogen, it is introduced into a thermostat and the temperature is gradually increased, reading the pressure when equilibrium has been reached (± 0.1° ; ± 0.2 mm Hg).

The resulting gas was analysed by gas chromatography on a C. Erba GV 207 device equipped with a 5 Å molecular sieve column long of 2 m, with a 4 mm inner diameter, at room temperature. The carrier gas : hydrogen, nitrogen, argon. The nitrogen determination was directly made in a V. Mayer apparatus and in a nitrometer. The presence of hydrogen was not identified.

IR absorption spectra were obtained in nujol or in tetrahydrofurane on a Zeiss UR 10 spectrophotometer.

THE NITROGEN TRIS-TRIPHENYLPHOSPHINE COBALT SYNTHESIS

$Co[P(C_6H_5)_3]_3N_2$ (I)

2.6 g (0.01 mole) Co(II) acetylacetonate and 7.8 g (0.03 mole) triphenylphosphine are dissolved in 200 ml absolute ethyl ether in an installation with purified nitrogen which is passed through the solution for roughly 30 minutes. 40 ml reducing reagent is added to the solution dropwise and by continuous stirring (0.04 mole *n*-butylmagnesium bromide in absolute ethyl ether) ; the solution becomes more and more red and reddish-orange crystals are being formed. The mixture is stirred for 2 hours under a nitrogen current and is kept in nitrogen at 0° for 1 hour until red crystals deposit. The solution is decanted and the crystals are allowed to dry in a nitrogen atmosphere and eventually in vacuo 5.8 g are obtained ; yield 60—70 %. Elementary analysis :

calc. Co 6.26 %, N 2.94 %, C 74.22 %, H 5.15 %
found : Co 6.21 %, N 3.1 %

THE NITROGEN TRIS(TRI-*p*-TOLYLPHOSPHINE) COBALT SYNTHESIS

$Co[P(pC_7H_7)_3]_3N_2$(II)

It is obtained starting from Co(II) acetylacetonate and tri-*p*-tolylphosphine in anhydrous ethyl ether at — 5° and reduction with a solution of *n*-butylmagnesium bromide under a pure nitrogen current. The end product is analogous to compound I. 5 g are being obtained.

The following compounds were found in an analogous manner :

— $Co[P(p\text{-}CH_3)_2(C_6H_3)_3]_3N_2$III — nitrogen tris(tri-*p*-xylylphosphine)cobalt ;
— $Co[P(C_{10}H_7)_3]_3N_2$ IV — nitrogen tris(tri-α-naphthylphosphine)cobalt ;
— $Co[P(C_6H_5 - CH_2)_3]_3N_2$ V — nitrogen tris(tribenzylphosphine) cobalt ;
— $Co[As(C_6H_5)_3]_3N_2$VI—nitrogen tris(triphenylarsine)cobalt ;
— $Co[As(C_{10}H_7)_3]_3N_2$ VII — nitrogen tris(tri-α-naphthylarsine)cobalt ;
— $Co[Sb(p\text{-}(CH_3)_2C_6H_3)_3]_2N_2$ VIII — nitrogen tris(triphenylstibine)cobalt ;
— $Ni[P(C_6H_5)_3]_2N_2$ IX — nitrogen bis(triphenylphosphine)nickel
— $Ni[P(p\text{-}CH_3 - C_6H_4)_3]_2N_2$ X — nitrogen bis(tri-*p*-tolylphosphine)nickel
— $Ni[P(p\text{-}(CH_3)_2 - C_6H_3)_3]_2N_2$ XI — nitrogen bis (tri-*p*-xylylphosphine)nickel ;
— $Ni[P(C_{10}H_7)_3]_2N_2$ XII — nitrogen bis(tri-α-naphthylphosphine)nickel ;
— $Ni[P(C_6H_5 - CH_2)_3]_2N_2$ XIII — nitrogen bis(tribenzylphosphine) nickel ;
— $Ni[As(C_6H_5)_3]_2N_2$ XIV — nitrogen bis(triphenylarsine)nickel ;
— $Ni[As(C_{10}H_7)_3]_2N_2$ XV — nitrogen bis(tri-α-naphthylarsine)nickel
— $Fe[P(C_6H_5)_3]_2N_2$ XVI — nitrogen bis(triphenylphosphine)iron.

The attempts at obtaining compounds with nitrogen and with triphenylbismuthine failed to give positive results under analogous conditions, due to the bismuth reduction to the metal.

Table 1 reveals the characteristic properties of the above-mentioned compounds : colour, approximate stability in nitrogen, solubility and position of the nitrogen molecule stretching band $\nu_{N=N}$ in the coordinate compound.

DISCUSSION OF RESULTS

The formulations suggested for the dinitrogen compounds prepared in this work are based on the elementary analysis, on the absence of some detectable amounts of hydrogen by gas chromatography of gaseous products resulted from the thermal decomposition of the synthesized compounds, on the paramagnetism determined in the case of cobalt compounds, [2] since the compound of $CoH(P\Phi_3)_3$ type is diamagnetic, [21] on the appearance of an intense IR absorption band corresponding to the stretching vibration of the nitrogen molecule as a ligand. In fact, the hydrides or the hydrogen compounds of $CoH(N_2)(P\Phi_3)_3$ and $Co(H_2)(PO_3)_2$ type, respectively, are unstable in the air compared to the dinitrogen compounds of the indicated formula, as was shown by Speier and Marko. [22]

Table 1

Characteristic properties of coordinate compounds with molecular nitrogen

Compound	Colour	Approx. nitrogen stability	Solubility	$\nu_{N=N}$ cm^{-1}
$Co[P(C_6H_5)_3]_3N_2$	orange	96	THF, ethyl ether, benzene, toluene	2100

$Fe[P(C_6H_5)_3]_2N_2$	orange	24	THF, ethyl ether	1990

The relatively high stability, particularly in pure solid state compared to other dinitrogen compounds enabled the study of the reflectance spectrum in the visible domain of the compound $Co(N_2)(PO_3)_3$ which presents a maximum in the diagram $F(R\infty)-\lambda$ at 600 nm, similar to the case of dinitrogen halides pentammine, osmium and ruthenium, recognized by their high stability [1] even in an aqueous solution, permitting to be handled in the air both for spectrophotometric and for diffractometric determinations. [2]

The stability in the air largely differs in the series of synthesized compounds, compared to the stability of osmium or ruthenium compounds and particularly in solution (ethyl ether, tetrahydrofurane). This stability is markedly reduced and for this reason it is impossible to perform the common spectroscopic study, particularly in the UV and visible domain, except for cobalt combinations.

[22] G. Speier and L. Marko, *Inorg. Chim. Acta*, **3**, 126 (1969).

The thermal stability determined by the manometric method enables a qualitative comparison, with the observation that the determinations were repeated as the impurities and even the solvents left in the purified substance significantly influence the decomposition. The determinations were made after repeated recrystallizations and after allowing a prolonged standing in nitrogen atmosphere.

Table 2

The temperatures of decomposition for coordination combinations with molecular nitrogen at 20 torr

Temperature °	Combination
70	$Co[P(C_6H_5)_3]_3N_2$
60	$Co[P(p\text{-}CH_3-C_6H_4)_3]_3N_2$
30	$Co[P(p\text{-}(CH_3)_2-C_6H_3)_3]_3N_2$
50	$Co[P(C_{10}H_7)_3]_3N_2$
24	$Co[P(C_6H_5-CH_2)_3]_3N_2$
40	$Co[As(C_6H_5)_3]_3N_2$
50	$Co[As(C_{10}H_7)_3]_3N_2$
32	$Co[Sb(p\text{-}(CH_3)_2C_6H_3)_3]_3N_2$
52	$Ni[P(C_6H_5)_3]_2N_2$
47	$Ni[P(p\text{-}CH_3-C_6H_4)_3]_2N_2$
35	$Ni[P(p\text{-}(CH_3)_2-C_6H_3)_3]_2N_2$
32	$Ni[P(C_{10}H_7)_3]_2N_2$
35	$Ni[P(C_6H_5-CH_2)_3]_2N_2$
32	$Ni[As(C_6H_5)_3]_2N_2$
25	$Ni[As(C_{10}H_7)_3]_2N_2$
50	$Fe[P(C_6H_5)_3]_2N_2$

Table 2 reflects the necessary temperatures for obtaining a decomposition pressure of 20 torr, a value which enables a direct comparison between the thermal stabilities of synthesized dinitrogen compounds. One clearly observes the decrease in the stability represented by this conventional temperature as a heavier aryl radical is introduced in the phosphine and arsine, respectively, found as ligands alongside with nitrogen in the molecule of the compound.

The approximate calculations of the dissociation enthalpy revealed values comprised between 8000 and 12,000 (± 1000) cal/mole, and this corresponds to the lower stability limit of the gas ligand-metal bond. [1]

As to IR spectrophotometric determinations, it has been noticed that the stretching vibration of nitrogen N_2 in the prepared dinitrogen compounds has frequencies lower by $200-400\ \mathrm{cm}^{-1}$ *vs* the frequency of the nitrogen molecule in Raman spectrum ($\nu = 2330\ \mathrm{cm}^{-1}$); this band is intensely active in IR. In general, measurements are found within a range of $20-40\ \mathrm{cm}^{-1}$ for the same compound. Since the link between nitrogen and the metallic atom is achieved by the weak acceptor orbital π and the weak donor orbital of nitrogen σ, the effect of the structure of ligands having a different acceptor nature has a large influence on the $\nu(N_2)$ band by the increase of the bonding contribution of electrons d of the metal. [23]

GALLIUM METATITANATE

EUGENIA PERŢE and M. STRĂJESCU
Institute of Chemistry, Cluj, str. Donath 65–103, Romania

Received April 21, 1973

The gallium peroxotitanate is studied by the thermogravimetric and thermodifferential method and by means of roentgenography. The results obtained show that the metatitanate is formed at a lower temperature than the hydroxide precipitates and that it has a metastable form, decomposing after a long heating at 1 000°.

Gallium and titanium hydroxides and complex oxalotitanates were studied thermally, roentgenographically and crystaloptically and the results were published by Soviet scientists.[1–3] The phase equilibrium diagrams are given in these papers and the existence of three phases, according to the different conditions, is found, namely : gallium metatitanate ($Ga_2O_3 . TiO_2$), gallium dititanate ($Ga_2O_3 . 2TiO_2$) and gallium titanate with a high titanium content.

The present paper contains the results referring to the formation of gallium metatitanate, starting exclusively from peroxotitanate.

To obtain peroxotitanates, using the method described in a former paper,[4] we have prepared several mixtures with different molar ratios of gallium and titanium, but only one product proved to be unitary. The others, according to the ratio between the components, contain, besides peroxotitanate, either a gallium, or a titanium excess.

Taking this into account, we shall further deal only with the compound resulting from the mixture with a gallium : titanium molar ratio of 2 : 1.

The obtained gallium peroxotitanate is in powder form, homogeneous, very fine-grained and of yellow colour. Submitted to chemical analysis it gives the following results (table 1).

The formula corresponding to these data is :

$$[Ga(OH)_2]_2 \cdot [O_2TiO\ (OH)_2] \cdot 3H_2O$$

Table 1

Results of the chemical analysis of gallium peroxotitanate

	Ti %	Ga %	O (peroxidic) %	H_2O %
Calculated	12.24	35.62	8.17	13.80
Found	12.22	35.78	8.08	13.64

The chemical analysis was based on :

— The reaction of Ti^{4+} with H_2O_2 in a sulphuric acid medium, with formation of the peroxi-sulphato-titanium $[TiO_2(SO_4)_2]^{2-}$ complex anion, orange-yellow coloured and colorimetrically determined.

— The determination of gallium as oxide, by the difference from the amount of oxides resulting through pyrolysis.

— The titration of peroxidic oxygen with potassium permanganate.

— The dosing of the crystallization water in vacuum (Abderhalden apparatus) at the water boiling point.

To study the thermal evolution of the formed compound we have carried through the thermogravimetric and thermodifferential analysis, by means of an Erdely-Paulik derivatograph, up to 1 000°, without maintaining it at maximal temperature under isothermal conditions.

The phasal analysis for different temperatures was achieved by the roentgenographic method, on powders (Debye-Scherrer), on a TU—R—60 (Dresden) apparatus. The experiments were carried out at 11 mA and 50 kV, making use of the CuK_α radiations ($\lambda = 1.5405$), filtered through Ni. The binding of the powdery material was achieved by means of collodium.

RESULTS AND DISCUSSIONS

Watching the thermal decomposition shown in figure 1, we notice that the loss of weight starts at 40° and takes place in two stages : till 220° the three molecules of crystallization water are lost, while between 220 — 500° the anhydrous peroxotitanate decomposes down to the oxides.

The chemical processes are recorded on the ATD curve (fig. 1. *2*), through an endothermal effect at 160°, marking the loss of the crystallization water, followed by two exothermal effects : the first one, at 295°, is due to the exothermal decomposition process of the peroxotitanate, and the second, at 560°, attests the interaction of the two oxides, with the formation of a metastable phase of gallium metatitanate, Ga_2TiO_5. At 920°, a small endothermal effect points out its polymorphous transformation.

The probable reactions taking place are :

$$[Ga(OH)_2]_2 \cdot [O_2TiO(OH)_2] \cdot 3H_2O \xrightarrow{40-220^\circ} [Ga(OH)_2]_2 \cdot [O_2TiO(OH)_2] + 3H_2O$$

$$[Ga(OH)_2]_2 \cdot [O_2TiO(OH)_2] \xrightarrow{220-300^\circ} 2Ga_2O_3 + TiO_2 + 3H_2O$$

$$2Ga_2O_3 + TiO_2 \xrightarrow{560^\circ} Ga_2TiO_5$$

The diffraction analysis of the X rays evidences the following :

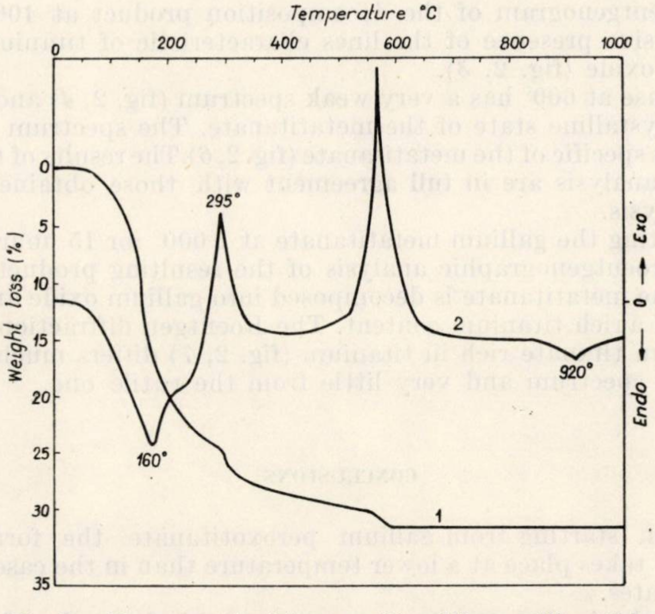

Fig. 1. — Thermogravimetric curve (*1*) and thermodifferential curve (*2*) of gallium peroxotitanate.

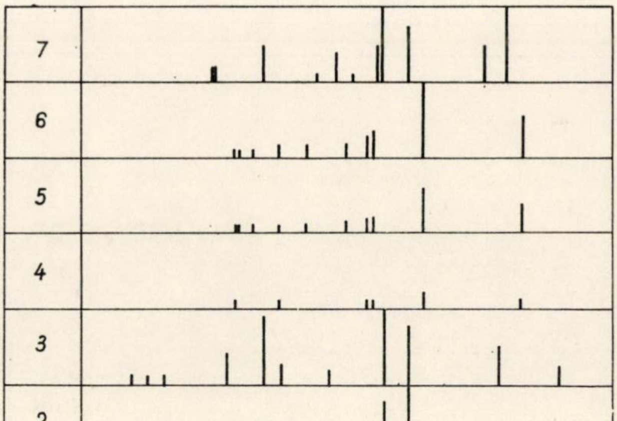

Fig. 2. — Roentgen diffraction spectra of :
1, TiO_2 ; *2*, Ga_2O_3 ; *3*, gallium peroxotitanate at 400° ; *4*, same at 600° ; *5*, at 800° ; *6* at 1 000° ; *7*, after 15 hours at 1 000°.

Revue Roumaine de Chimie, **19**, *3*, 395–398 (1974)

The roentgenogram of the decomposition product at 400° illustrates the exclusive presence of the lines characteristic of titanium bioxide and gallium oxide (fig. 2, *3*).

The phase at 600° has a very weak spectrum (fig. 2, *4*) and confirms the feebly crystalline state of the metatitanate. The spectrum at 800° of the product is specific of the metatitanate (fig. 2, *6*).The results of the reoentgenographic analysis are in full agreement with those obtained through thermal analysis.

By heating the gallium metatitanate at 1 000° for 15 hours and carrying out a roentgenographic analysis of the resulting product, we have found that the metatitanate is decomposed into gallium oxide and gallium titanate with a rich titanium content. The Roentgen diffraction spectrum of this gallium titanate rich in titanium (fig. 2, *7*) differs much from the metatitanate spectrum and very little from the rutile one.

CONCLUSIONS

— When starting from gallium peroxotitanate the formation of metatitanate takes place at a lower temperature than in the case of hydroxide precipitates.

— The obtained metatitanate is a metastable form, that decomposes into gallium oxide and gallium titanate with a rich titanium content after a fairly long heating at 1 000°.

LES RÉACTIONS DES LIGANDS COORDINÉS.[1-3] IV

L'ÉTUDE SPECTROSCOPIQUE ET THERMOGRAVIMÉTRIQUE DES COMBINAISONS ALUMINIUM-ORGANIQUES DE DIMÉTHYLGLYOXIME COORDINÉE

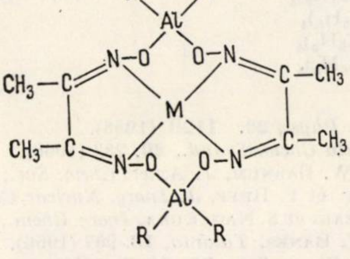
N. VOICULESCU, A. AIRINEI et I. POPESCU

Institut de Chimie Macromoléculaire « P. Poni », 41, Aleea Gr. Ghica Vodă, Jassy

Reçu le 22 novembre 1972

Les spectres en infrarouge et ultraviolet d'une suite de dérivés aluminium-organiques des bisdiméthylglyoximates de Ni(II), Pd(II) et Cu(II) ont été étudiés dans le but d'établir le mode de liaison et les modifications qui ont lieu dans les produits de départ par la substitution de l'hydrogène oximique par le groupe AlR_2, où $R = iC_4H_9$, C_6H_5. Ces études en corrélation avec les données thermogravimétriques ont permis à établir une suite des stabilités dépendant de la nature de l'ion métallique central du radical qui est lié à l'aluminium. Les spectres RMN des bisdiméthylglyoximates de Ni(II) et Pd(II) avec l'Al $(iC_4H_9)_2$ confirment la structure proposée par le rapport entre les intensités relatives des groupements méthyle du radical oximique et ceux du radical *iso*-butyle.

Dans les travaux antérieurs [1,2] on a présenté la synthèse de nouvelles combinaisons résultant de la réaction de $Al(iC_4H_9)_3$ et $Al(C_6H_5)_3$ avec les bisdiméthylglyoximates de quelques métaux transitionnels, qui correspondent à la formule I



où M = Ni(II), Pd(II), Cu(II) et $R = iC_4H_9$, C_6H_5.

Pour vérifier si cette formule est plausible et aussi pour déceler les modifications survenues dans la structure intime des chélates on a effectué

une étude spectrale (IR, UV, RMN) et thermogravimétrique de ces composés. Une attention à part a été accordée dans la littérature aux spectres en ultraviolet des bisdiméthylglyoximates de Ni(II), Pd(II) et Cu(II). [4–11] Au contraire, il n'y a qu'un petit nombre de données thermogravimétriques[12–14] et spectrales en infrarouge [7,15] (650 — 300 cm^{-1}) concernant ces composés. Le triphénylaluminium a été étudié [16] dans le domaine de 650 à 300 cm^{-1} et en ultraviolet [17].

PARTIE EXPÉRIMENTALE

Les composés étudiés ont été synthétisés d'après une méthode présentée dans [1,2].

Les spectres en U.V. ont été enregistrés dans une solution de *n*-heptane à l'aide d'un apparel Unicam SP — 800 B, en utilisant des cuves de 1 cm, à la température ambiante et ceux en infrarouge avec un appareil Zeiss UR—20 et Beckman IR—12 sur des pastilles à KBr.

Les spectres RMN ont été enregistrés en utilisant un spectromètre JEOL—JNM—C—6 OHL de 60 MHz à la température ordinaire.

Les thermogrammes ont éte enregistrés avec un dérivatographe MOM Budapest.

RÉSULTATS ET DISCUSSIONS

Les spectres en ultraviolet des dérivés aluminium-organiques des bisdiméthylglyoximates de Ni(II), Pd(II), Cu(II) sont discutés comparativement à ceux des composés de départ.

Les spectres des composés étudiés sont semblables à ceux des composés initiaux. Les maximums d'absorption des composés étudiés sont donnés dans le tableau 1.

Tableau 1

Faute de calculs mécaniquantiques il n'a pas été possible d'attribuer avec certitude les bandes d'absorption à certaines transitions électroniques. Les bandes d'absorption à 254 nm et à 277 nm des dérivés de Ni(II) et de Pd(II) avec le groupe $Al(iC_4H_9)_2$ peuvent être attribuées à la transition ligand-ligand [4,10] et sont observées dans le même domaine de fréquence que les bandes des produits de départ. La même transition peut être observée aux environs de 245 nm pour les composés avec le groupe $Al(C_6H_5)_2$.

Pour les deux suites de composés on constate un déplacement bathochromique de cette bande d'absorption dans l'ordre

$$Cu > Pd > Ni$$

ce qui suggère le même ordre de stabilité des composés. Les dérivés aux groupes $Al(C_6H_5)_2$ sont moins stables que ceux aux groupes $Al(iC_4H_9)_2$.

La bande intense située approximativement à 370 nm est attribuée à la structure plan quadratique avec des liaisons covalentes [18]. Cette bande est présente aussi dans les spectres de nos produits ce qui met en évidence le maintien de la structure covalente plan quadratique dsp^2 de ceux-ci.

Dans les spectres des dérivés avec de l'$Al(iC_4H_9)_2$ les bandes apparaissent à 466 nm, et 421 nm pour le composé avec du Ni(II) et à 406 nm pour le composé avec du Pd(II) qui ont été attribuées aux transitions [4] d–d. Ces transitions ont été aussi constatées par Schrauzer [19] dans les spectres en ultraviolet des composés résultés de la réaction du Ni(II) $(DMGH)_2$ avec du BR_3 ($R = F$, Cl, C_6H_5 et quelques radicaux aliphatiques). Dans les spectres des dérivées avec de l'$Al(C_6H_5)_2$ on ne constate pas l'apparition des bandes à environ 370 nm. La modification du champ des ligands des quatre atomes d'azote due à la substitution des atomes d'hydrogène oximiques par les groupes AlR_2 est réduite.

Dans le tableau 2 sont insérées les fréquences d'absorption IR observées dans le domaine de 650 à 300 cm^{-1}.

Tableau 2

Absorptions en IR caractéristiques

Produit												
$Ni(DMG)_2Al_2(C_4H_9)_4$	256					432			495	520	610	670
$Pd(DMG)_2Al_2(C_4H_9)_4$	255			373		441			490	513		
$Ni(DMG)_2Al_2(C_6H_5)_4$		325	350	360	400		437	480	492	532	615	
$Pd(DMG)_2Al_2(C_6H_5)_4$		325	345	382	395		455	480	492	527	613	671
$Cu(DMG)_2Al_2(C_6H_5)_4$		325	358		400		440		490	500	615	681

Les deux bandes intenses qui apparaissent dans ce domaine à 500 cm^{-1} et à 400 cm^{-1} sont dues probablement aux vibrations de valence M–N.

---

[18] J. B. WILLIS et D. P. MELOR, *J. Amer. Chem. Soc.*, **64**, 181 (1942) ; **69**, 1237 (1947).

[19] G. H. SCHRAUZER, *Chem. Ber.*, **95**, 1438 (1962).

L'absorption autour de 490 cm^{-1} peut être attribuée à la liaison Al—O. La liaison Al—O qui apparaît dans les dérivés aluminium-organiques des bisdiméthylglyoximates de Ni(II) et de Pd(II) est différente de la liaison Al—O des acétylacétonates [20,21].

Par comparaison avec les spectres des composés initiaux dans les spectres des dérivés aluminium-organiques-bisdiméthylglyoximates nous rencontrons un déplacement des vibrations de la liaison M—N vers des fréquences plus grandes, fait, probablement, dû à la polarisation de cette liaison.

La configuration moléculaire des composés Ni(II) $(DMG)_2Al_2(iC_4H_9)_4$ et Pd(II) $(DMG)_2Al_2(iC_4H_9)_4$ a été établie par la comparaison des spectres RMN de ces composés et de ceux des composés initiaux. Dans la figure 1 sont présentés les spectres RMN des :

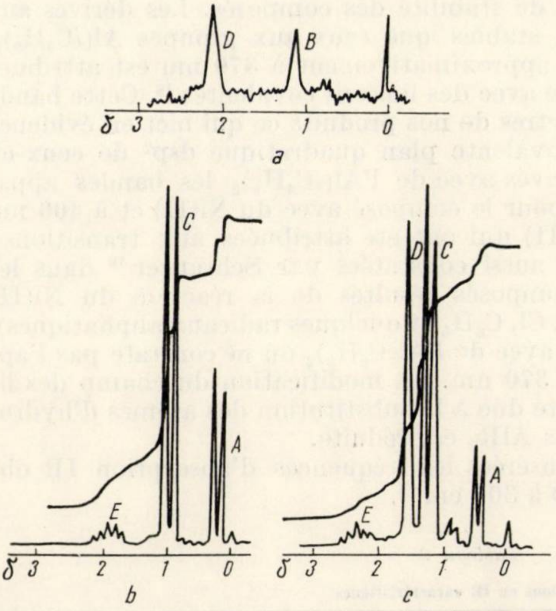

Fig. 1. — Les parts de haut champ des spectres RMN des : a) $Ni(DMGH)_2$; b) $Al(iC_4H_9)_3$; c) $Ni(DMG)_2Al_2(iC_4H_9)_4$

a) $Ni(II)(DMGH)_2$, b) $Al(iC_4H_9)_3$, c) Ni(II) $(DMG)_2Al_2(iC_4H_9)_4$

Les signaux notés avec A, C et E sont caractéristiques des protons des groupes $-CH_2$, $-CH_3$ et $-CH$ du radical iso-butyle. L'attribution est conforme aux rapports 2 : 6 : 1 des signaux intégrés, ainsi qu'à leur forme. Les signaux A et C sont des doublets dus aux couplages des protons méthyle et méthylène avec le proton méthyne, mais le signal méthyne (E) est un multiplet complexe.

---

[20] R. E. Lawson, *Spectrochim. Acta*, **17**, 248 (1961).
[21] C. Djordjevic, *Spectrochim. Acta*, **17**, 448 (1961).

Les signaux B et D sont caractéristiques des groupements méthyle du Ni(II) $(DMGH)_2$ dont les protons résonnent avec deux fréquences dû probablement à la stéricité. On remarque que le spectre (*c*) du composé Ni(II) $(DMG)_2Al_2(iC_4H_9)_4$ contient les mêmes signaux que les spectres (a) et (*b*) des composés initiaux, mais les positions de quelques-uns de signaux sont modifiées démontrant la formation du nouveau composé.

Les signaux intégrés C rapportés à la somme B + D donnent la valeur approximative 2 : 1, d'où il résulte que ce composé aurait la formule Ni(II) $(DMG)_2.2Al(iC_4H_9)_2$ qui est conforme à la structure I.

Cette structure est aussi confirmée par les déplacements observés pour quelques-unes des résonances. Ainsi les résonances B et D à 1,1 ppm et respectivement 2,1 ppm du Ni(II) $(DMGH)_2$ apparaissent à 1,60 ppm et respectivement à 0,90 ppm dans le composé avec de l'aluminium. Leur déplacement vers le haut champ (la croissance des écranages magnétiques) peut être expliqué par la formation des liaisons Al —O, c'est-à-dire par l'introduction de l'atome électropositif d'aluminium dans la molécule. La formation des liaisons Al—O expliquent aussi les désécranages (déplacements vers le bas champ) des signaux des protons du radical isobutyle. Ainsi les résonances A, C et E situées à 0,18 ppm ; 0,93 ppm et respectivement à 1,88 ppm dans l'$Al(iC_4H_9)$ apparaissent à 0.45 ppm ; 1,30 ppm et à 2,30 ppm dans Ni(II) $(DMG)_2$ $Al_2(iC_4H_9)_4$.

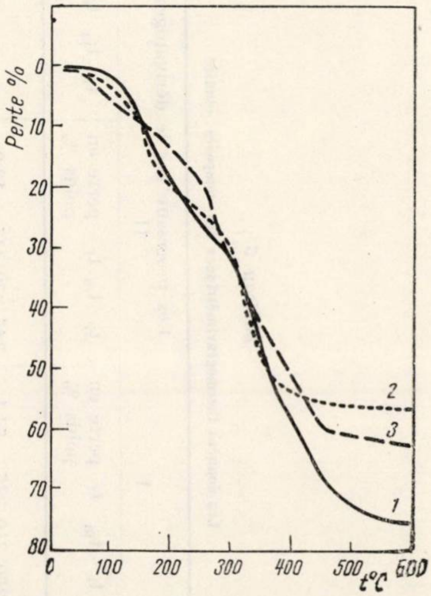

Fig. 2. — Thermogramme du composé $Ni(DMG)_2$ $Al_2(iC_4H_9)_4$; *2* — Thermogramme du composé $Pd(DMG)_2Al_2(iC_4H_9)_4$; *3*, — Thermogramme du composé $Ni(DMG)_2Al_2(C_6H_5)_4$.

La même interprétation appliquée au complexe avec du palladium conduit à une formule semblable Pd(II) $(DMG)_2Al_2(iC_4H_9)_4$.

Au point de vue spectral, la substitution de l'atome de nickel par le palladium n'affecte pas les résonances de l'isobutyle, mais seulement

Tableau 3

Les données thermogravimétriques des composés étudiés

Le composé	Nombre des processus de la décomposition	I				II				III				IV			
		t_i	t_m	t_f	perte en poids %	t_i	t_m	t_f	perte en poids %	t_i	t_m	t_f	perte en poids %	t_i	t_m	t_f	perte en poids %
$Ni(DMGH)_2$	2	260	310	345	54,1	345	370	415	13,9								
$Pd(DMGH)_2$	1	270	310	390	75,6												
$Cu(DMGH)_2$	2	150	205	240	69,4	310	340	380	6,5								
$Ni(DMG)_2Al_2(iC_4H_9)_4$	2	45	180	230	23,4	230	340	410	35,6	410	430	530	13,6				
$Pd(DMG)_2Al_2(iC_4H_9)_4$	2	40	160	230	22,2	230	325	400	32,3								
$Ni(DMG)_2Al_2(C_6H_5)_4$	4	25	70	125	8,1	125	190	210	7,3	210	270	400	32,5	400	415	480	13,8
$Pd(DMG)_2Al_2(C_6H_5)_4$	3	30	85	100	6,6	100	180	270	19,8	270	310	430	36,3				
$Cu(DMG)_2Al_2(C_6H_5)_4$	3	25	85	110	7,1	110	240	280	31,7	320	380	460	35,7				

celles de la diméthylglyoxime ; les signaux B sont situés à 0,95 ppm et respectivement à 1,80 ppm par rapport au TMS. On peut supposer aussi que les dérivés qui possèdent le groupe $Al(C_6H_5)_2$ ont le même configuration moléculaire par analogie avec les dérivés à l'$Al(iC_4H_9)_2$.

L'analyse des données thermogravimétriques (tableau 3) révèle que le mécanisme de la décomposition est d'autant plus compliqué que le volume du radical lié à l'aluminium s'accroît. Les produits du phénylaluminium sont moins stables que les produits à l'isobutylaluminium fait relevé aussi par les données spectrales en U.V. Les dérivés au palladium se décomposent plus rapidement que les dérivés aux nickel et cuivre dû probablement au volume de l'ion métallique qui a un rôle important.

Par rapport à la décomposition du M(II) ($DMGH_2$), celle des dérivés étudiés se produit à des températures de beaucoup inférieures, ceux-ci étant instables même à la température ambiante, tandis que les M(II) $(DMGH)_2$ sont stables jusqu'à des températures beaucoup plus élevées (voir tableau 3). La perte en poids totale est d'environ 70% (fig. 2).

La décomposition des dérivés M(II) $(DMG)_2 Al_2R_4$ a lieu en plusieurs étapes en comparaison des composés de type M(II) $(DMFH)_2$ qui se décomposent à une ou à deux étapes et à des températures finales plus élevées.

Les pertes en poids à différentes températures sont fonction de la nature du radical lié à l'aluminium, ainsi que de la nature du cation métallique. Le maximum de perte en poids se trouve entre les mêmes limites de température que les chélates initiaux. Nous considérons que la première décomposition peut être attribuée à la substitution des hydrogènes oximiques par le groupement AlR_2, qui conduit à l'instabilisation des molécules M(II) (DMG) $_2Al_2R_4$. Cette étape de décomposition est le résultat tant de la dégradation thermique que de l'hydrolyse des composés en présence de l'eau dans l'atmosphère.

KINETIK UND MECHANISMUS DER OXYDATION DES URANS (IV) MIT NATRIUM-PERSULFAT

F. MÁNOK, CS. VÁRHELYI und RODICA OPREAN

Lehrstuhl für Anorganische Chemie „Babeş-Bolyai“ Universität Cluj, Str. Arany János No. 11, Rumänien

Eingegangen am 25. April 1973

Es wurde die Kinetik der Oxydation der $U(SO_4)_2$-Lösungen in saurem Medium mit Natrium-persulfat untersucht. Die Änderung der U(IV)-Konzentration wurde bei 23°, 30° und 40° permanganometrisch verfolgt. Für die Aktivierungsenthalpie erhält man $\Delta H^{\ddagger} = 27{,}4$ kcal/Mol und für die Aktivierungsentropie $\Delta S^{\ddagger} = +23{,}1$ Cl. In Anwesenheit von sehr kleinen Eisen (II)-Mengen wird die Reaktion erheblich beschleunigt. Auf Grund der experimentellen Daten wurde ein wahrscheinlicher Mechanismus des Oxydationsprozesses diskutiert.

Das vierwertige Uran wird durch eine Reihe von Oxydationsmitteln in U(VI) oxydiert. Einige Oxydationsreaktionen des U(IV) verlaufen schnell, es sind aber auch Oxydationsvorgänge bekannt, welche bei Zimmertemperatur langsam stattfinden und vom kinetischem Standpunkt aus leicht zugänglich sind.

Die Kinetik des U(VI) – U(VI)-Oxydationsprozesses wurde mit Brom in Anwesenheit von Perchlorsäure von Gordon und Mitarbeiter [1,2], mit Kaliumchlorat in saurem Medium von Fedorova und Kanevski [3], mit salpetriger Säure von Koltunov [4], mit dreiwertigem Eisen von Minč und Mitarbeiter [5], mit molekularem Sauerstoff von Halpern und Smith [6], Sobkowski [7] und von Kraus und Nelson [8] untersucht. Es wurde der Mechanismus dieser Prozesse erörtert und der katalytische Einfluß von Schwermetallionen (V, Fe(II)) verfolgt.

Das Persulfation der Form $O-SO_2O - OSO_2-O$ ist ein sehr starkes Oxydationsmittel ($E_0 = \pm 2{,}0$ V), doch verlaufen im allgemeinen die

Oxydationsvorgänge mit Persulfat mit meßbarer Geschwindigkeit. Es wurde beobachtet, daß diese Vorgänge von Übergangsmetallionen (Cu^{2+}, Ag^{+}) katalysiert werden. Für die Erklärung des Mechanismus der Oxydationsprozesse mit Persulfat wurde die Bildung des freien SO_4^--Radikals, welche an monoelektronischen Übergängen teilnimmt, angenommen.

Es wurde die Kinetik der Oxydation des Eisens (II) [9], des Arsens (III) [10], des Oxalats [11], des Thiosulfats [12] und des Methanols [12] mit Persulfat untersucht.

In vorliegender Arbeit wurde die Kinetik der Oxydation des Urans (IV) mit dem obenerwähnten Oxydationsmittel in verdünnter Schwefelsäure untersucht.

Für die kinetischen Messungen wurde $U(SO_4)_2 . 3\,H_2O$ in 0,25 M Schwefelsäure verwendet. Die Untersuchungen wurden bei drei Temperaturen : 23°, 30° und 40° in Anwesenheit von verschiedenen $Na_2S_2O_8$ Mengen durchgeführt. Die Änderung der Konzentration des Urans (IV) wurde permanganometrisch verfolgt. Die Oxydationsreaktion wurde mit überschüssiger Kaliumpermanganat-Lösung rasch vollendet und der Permanganat-Überschuß mit Oxalsäure rücktitriert.

Die Meßergebnisse bei verschiedenen Temperaturen sind in den Tabellen 1—3 zusammengestellt.

Die graphische Darstellung von $\log \frac{[U_0]}{[U]}$ gegen die Zeit zeigt eine sehr gute Linearität, wie aus Abbildung 1 und 2 ersichtlich ist.

Aus diesen experimentellen Daten geht hervor, daß die globale Reaktion zweiter Ordnung ist, d.h. erster Ordnung gegen die U(IV)-Konzentration, und gegen die $S_2O_8^{2-}$-Konzentration.

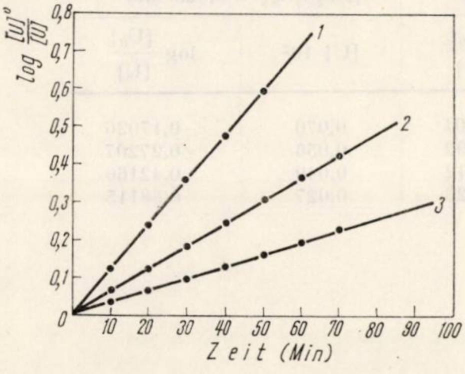

Abb. 1. — Kinetische Kurven für die Oxydation des Urans (IV) mit Persulfat bei 23°

40°: 1 – $[Na_2S_2O_8]$: 0,0125 M,
2 – $[Na_2S_2O_8]$: 0,005 M
30° : 3 – $[Na_2S_2O_8]$: 0,0125 M

Aus der Neigung der Geraden wurden die Geschwindigkeitskonstanten bei den obenerwähnten Temperaturen berechnet. Die graphische Darstellung zeigt, daß sich die Reaktionsordnung mit der Temperatur nicht ändert.

Die berechneten Geschwindigkeitskonstanten bei verschiedenen Temperaturen sind aus Tabelle 4 ersichtlich.

Es wurde auch der Einfluß des Eisens (II) auf die Oxydation des Urans (IV) in analogen Experimentierbedingungen untersucht. Die in der Tabelle 5 zusammengestellten experimentellen Daten zeigen, daß in

Tabelle 4

Abb. 3. — Kinetische Kurven für die Oxydation des Urans (IV) mit Persulfat bei 23° in Anwesenheit von Fe(II)-Katalysator $[H_2SO_4] = 0{,}25$ M, $[Na_2S_2O_8] = 0{,}025$ M ; 1— $[FeSO_4]$: $0{,}05 . 10^{-3}$M ; 2— $[FeSO_4]$: $0{,}025.10^{-3}$

Gegenwart von sehr kleinen Eisenmengen (U(IV) — Fe(II) Verhältnis : 20, bzw. 40) die Geschwindigkeit der Oxydation des Urans (IV) stark zunimmt.

Die graphische Darstellung von $\log \frac{[U_0]}{[U]}$ abhängig von der Zeit zeigt keine Linearität mehr und negative Abweichungen von den Geraden können beobachtet werden. (Abb. 3.)

Um den Oxydationsgrad des Urans (IV) in verschiedenen Experimentierbedingungen in An- und Abwesenheit von Fe(II) vergleichen zu können, bestimmten wir die für die Oxydation der Halbmenge des Urans (IV) nötigen Reaktionszeiten (Tabelle 6)

Tabelle 6

Die Halbzeiten der Uran (IV)-Oxydation bei verschiedenen Experimentierbedingungen

Temperatur	[Fe(II)]	$[Na_2S_2O_8]$ Mol	$t_{1/2}$ (Min)
23°	—	0,025	47
23°	$0{,}05 \cdot 10^{-3}$	0,025	6
23°	$0{,}025 \cdot 10^{-3}$	0,025	12

DISKUSSION

Aus den experimentellen Daten geht hervor, daß die Oxydation des Urans (IV) mit $Na_2S_2O_8$ in Abwesenheit des Fe(II)-Katalysators nach folgender Gleichung verläuft :

$$\frac{-\mathrm{d}[\mathrm{U(IV)}]}{\mathrm{d}t} = k[\mathrm{U(IV)}]\ [\mathrm{S_2O_8^{2-}}] \qquad (1)$$

Die globale Reaktion kann folgendermaßen ausgedückt werden

$$\mathrm{U(IV)} + \mathrm{S_2O_8^{2-}} = \mathrm{U(VI)} + 2\mathrm{SO_4^{2-}} \qquad (2)$$

Die graphische Darstellung von —log k gegen $1/\mathrm{T} \cdot 10^3$ gibt eine Gerade (siehe Abb. 4.) Aus der Neigung dieser Geraden wurde die Aktivierungsenthalpie ermittelt.

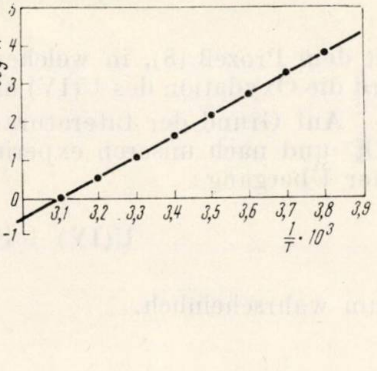

Abb. 4. — Bestimmung der Aktivierungsenthalpie der Oxydation des Urans (IV) mit Persulfat

Die Aktivierungsentropie wurde auf Grund der Gleichung:

$$\log k = \log \frac{kT}{h} + \frac{\Delta S^{\ddagger}}{2{,}3R} - \frac{\Delta H^{\ddagger}}{2{,}3\ RT} \tag{3}$$

berechnet. (k = die Boltzmann'sche Konstante, h = die Plank'sche Konstante). Die erhaltenen Aktivierungsparameter sind: $\Delta H^{\ddagger} = 27{,}4$ kcal/ /Mol; $\Delta S^{\ddagger} = +23{,}1$ Cl.

Der aktivierte Zustand ist folglich vom Standpunkt der Entropieänderung günstig, benötigt aber eine erhebliche Aktivierungsenthalpie.

Die obenerwähnte kinetische Gleichung steht mit mehreren monoelektronischen Übergangsmechanismen im Einklang.

Folgender, mit unseren Daten übereinstimmender Mechanismus, kann angenommen werden:

$$\mathrm{U(IV)} + \mathrm{S_2O_8^{2-}} = \mathrm{U(V)} + \mathrm{SO_4^{2-}} + \mathrm{SO_4^{-}}\ \text{(langsam)} \tag{4}$$

$$\mathrm{SO_4^{-}} + \mathrm{U(V)} = \mathrm{U(VI)} + \mathrm{SO_4^{2-}}\ \text{(schnell)} \tag{5}$$

Aus der Veränderung der Geschwindigkeit der Reaktion in Anwesenheit von Fe(II) geht hervor, daß wir in diesem Falle einen anderen Mechanismus des Oxydationsprozesses annehmen müssen.

Die Rolle des Katalysators und die Veränderung der Oxydationsgeschwindigkeit kann, durch folgendes Schema erklärt werden:

$$\mathrm{Fe(II)} + \mathrm{S_2O_8^{2-}} = \mathrm{Fe(III)} + \mathrm{SO_4^{2-}} + \mathrm{SO_4^{-}}\ \text{(langsam)} \tag{6}$$

$$\mathrm{U(IV)} + \mathrm{SO_4^{-}} = \mathrm{U(V)} + \mathrm{SO_4^{2-}}\ \text{(schnell)} \tag{7}$$

$$\mathrm{U(V)} + \mathrm{Fe(III)} = \mathrm{U(VI)} + \mathrm{Fe(II)}\ \text{(schnell)} \tag{8}$$

Bei Verminderung der U(V)-Konzentration konkurriert die Reaktion.

$$\mathrm{Fe(II)} + \mathrm{SO_4^{-}} = \mathrm{Fe(III)} + \mathrm{SO_4^{2-}} \tag{9}$$

mit dem Prozeß (8), in welchem das Fe(II) sich regeneriert. Demzufolge wird die Oxydation des U(IV) nachlassen.

Auf Grund der Literaturangaben über die Oxydationsprozesse mit $\mathrm{S_2O_8^{2-}}$ und nach unseren experimentellen Ergebnissen ist ein zweielektronischer Übergang:

$$\mathrm{U(IV)} + \mathrm{S_2O_8^{2-}} = \mathrm{U(VI)} + 2\mathrm{SO_4^{2-}} \tag{10}$$

kaum wahrscheinlich.

EXPERIMENTELLER TEIL

Darstellung von $U(SO_4)_2 \cdot 3H_2O$

25 g Uranylacetat werden auf einem Sandbad mit konzentrierter Schwefelsäure behandelt. Nach der Entfernung der Essigsäure wird die grüne Masse in 1 Lit. 40%igem Äthanol gelöst, mit 200 ml 50 %iger Schwefelsäure behandelt und in einem bedeckten Erlenmeyerkolben zwei Wochen lang, starkem Sonnenlicht ausgesetz. Es scheidet sich langsam eine grüne kristalline Masse aus. Nach Filtrierung wird die Substanz mit Alkohol und Äther gewaschen und an der Luft getrocknet.

Analyse : *gef.* U 49,21, SO_4 39,32, H_2O 11,10
Nach der Fomel $U(SO_4)_2\ 3H_2O$
ber. U 49,26, SO_4 39,54, H_2O 11,16

Das U(IV) wurde permanganometrisch, das SO_4^{2-} gravimetrisch, als $BaSO_4$ bestimmt.

Kinetische Messungen:

Das $U(SO_4)_2 \cdot 3\ H_2O$ wurde in vorerhitzter 1 Mol. Schwefelsäure gelöst, mit starkem Methanstrom der Sauerstoff aus der Lösung entfernt, mit luftfreier $Na_2S_2O_8$-Lösung vermischt und die Ionenstärke der Lösung mit verdünnter Schwefelsäure eingestellt. Die Konzentration des Urans (IV) war in allen Untersuchungen $0{,}105 . 10^{-2}$ Molar. Während den kinetischen Messungen wurden aliquote Teile der untersuchenden Lösung (10—20 ml) mit überschüssiger 0,1 n $KMnO_4$-Lösung versetzt und die unverbrauchte $KMnO_4$ mit 0,1 n Oxalsäure bei 60—70° volumetrisch bestimmt.

LA STRUCTURE CRISTALLINE ET L'INTERACTION AVEC LA MOLÉCULE DE L'HYDROCARBURE INCLUSE DANS LES CLATHRATES DU TYPE $M(SCN)_2$ $(4\text{-}MePy)_4 \cdot p$-xylène

I. SOLACOLU *, D. SĂNDULESCU ** et C. DRĂGULESCU ***

* Centre de Chimie Physique, Bucarest, 31, str. Galaţi

***Institut Polytechnique « Traian Vuia », Timişoara, 2, Bd. 30 Decembrie

Reçu le 1er août 1973

L'analyse diffractométrique des cristaux de $M(SCN)_2$ $(4\text{-}MePy)_4$, (M = Co, Ni ; 4-MePy = 4-méthylpyridine), avec et sans *p*-xylène, a mis en évidence l'existence des cellules élémentaires tétragonales à 8 molécules de combinaison coordinative, caractérisées par une symétrie Laue 4/m et le groupe spatial $I_4\,1/a$, défini par les paramètres $a = b = 16{,}81$ Å ; $c = 22{,}41$ Å, respectivement, $a = b = 17{,}96$ Å ; $c = 21{,}32$ Å. Dans le cas des combinaisons $M(SCN)_2$ $(4\text{-}MePy)_2$, on a mis en évidence un réseau orthorhombique à 18 molécules dans la cellule élémentaire et le groupe spatial I222, les paramètres caractéristiques étant $a = 20{,}20$ Å ; $b = 21{,}56$ Å ; $c = 17{,}93$ Å. Les déterminations sont en concordance avec une théorie proposée auparavant sur la stabilité des combinaisons avec des hydrocarbures aromatiques par des effets d'hyperpolarisabilité d'ordre supérieur et avec le modèle établi à partir des données thermodynamiques.

Les composés d'inclusion formés entre les hydrocarbures aromatiques et les combinaisons coordinatives des métaux, du type $M(SCN)_2$ $(4\text{-}MePy)_4$, ou M = Co, Ni et 4-MePy = 4-méthylpyridine, sont très importants du point de vue de la chimie théorique. Ces combinaisons se caractérisent par le fait qu'elles sont constituées par deux composants principaux : l'un des composés — le support — forme un réseau caractérisé par des lacunes dans lesquelles est inclus, dans certaines conditions, le deuxième composant. Ces composés sont différents par rapport aux combinaisons moléculaires (du type transfert de charge ou liaison d'hydrogène) beaucoup étudiées jusqu'à présent, tels que : hydrocarbures aromatiques — nitrodérivés aromatiques (du type picrates), quinones — phénols, hydrocarbures aromatiques — halogénures métalliques, hydrocarbures oléfiniques — halogénures métalliques, cétones — dérivés halogénés. Dans ce nouveau domaine de la chimie des combinaisons moléculaires du type clathrate, le problème de la liaison qui existe entre le composant inclus et le composant d'inclusion (ou support) présente un aspect spécial, étant déterminé par le facteur géométrique. Souvent, on peut se poser la question si le composé étudié correspond à la notion habituelle de combinaison chimique, pour laquelle on admet l'existence de certaines forces de liaison, suffisamment puissantes, qui permettent de considérer ce composé comme une espèce moléculaire indépendante. Généralement, les forces van der Waals sont exclues de cette définition mais, dans le cas des combinaisons d'inclusion, les forces van der Waals sont pourtant suffisamment puissantes pour que l'on puisse considérer l'interaction moléculaire comme base de la liaison chimique.

Dans quelques travaux antérieurs [1-4] on a présenté les problèmes actuels de ce nouveau domaine de la chimie :

— la clarification de l'interaction hydrocarbure — réseau support ;

— la détermination des conditions suffisantes et nécessaires pour la formation et la stabilité de ces combinaisons, par une étude thermodynamique des équilibres de formation et par une étude cinétique des réactions de formation, respectivement, de dissociation, études associées avec la détermination des caractéristiques du réseau et de la molécule incluse ;

— l'inclusion d'un grand nombre de combinaisons coordinatives dans le domaine de la chimie des clathrates;

— l'étude de quelques nouvelles classes de clathrates, dont les caractéristiques conduisent à leur application dans des nouveaux processus de séparation.

Nous allons essayer de développer brièvement les idées présentées ci-dessus.[4] L'état de la molécule incluse dans un milieu avec une symétrie parfaitement connue ou, en tout cas, déterminable, constitue l'objet de quelques recherches actuelles liées tant à la théorie proprement dite des interactions moléculaires, qu'à la théorie des solutions. Mais, d'autre part, il faut remarquer que beaucoup de catalyseurs doivent leur activité aux combinaisons de surface du type clathrate, d'où dérive leur haute spécificité. Comme on l'a indiqué ci-dessus, la liaison entre les deux composants de la combinaison moléculaire (la molécule incluse — le réseau support) est déterminée surtout par le facteur géométrique, mais ce facteur géométrique ne doit pas être limité seulement aux dimensions longitudinales et transversales ; il doit être étendu à la symétrie et à la forme.

Dans un travail antérieur [4] on a démontré qu'une caractéristique de la molécule incluse, qui constitue un critère d'appréciation de ces combinaisons correspond aux coefficients d'hyperpolarisabilité d'ordre supérieur. En effet, à l'intérieur du réseau cristallin, le champ électrique ($\mathcal{F}$) est de l'ordre de 10^8 V/cm et la bien connue équation du moment de dipôle induit (m)

$$m = \alpha \cdot \mathcal{F} \tag{1}$$

(dans laquelle α représente la polarisabilité) est valable seulement dans les conditions expérimentales habituelles ($\mathcal{F} < 10^7$ V/cm, valeur correspondant

à la rigidité diélectrique). Dans le cas des champs électriques intenses, il faut appliquer des équations du type

$$m = \alpha \cdot \mathcal{F} + \frac{1}{2}\,\beta \cdot \mathcal{F}^2 + \frac{1}{6}\gamma\mathcal{F}^3 + \cdots \qquad (2)$$

dans lesquelles β et γ représentent les coefficients d'hyperpolarisabilité du premier et du second ordre. Dans le cas des molécules polaires, β présente des valeurs négatives, tandis que, pour les molécules avec un centre de symétrie, $\beta = 0$.[5]

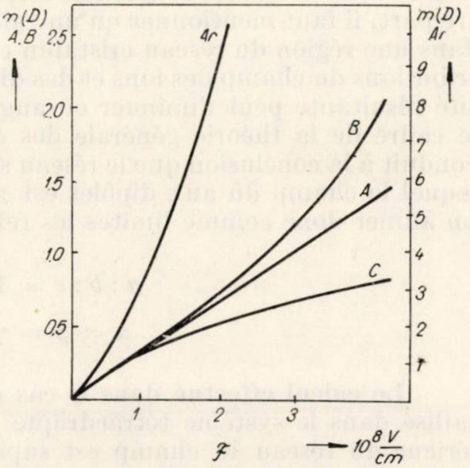

Fig. 1.— Variation du moment de dipôle induit en fonction de la valeur de champ électrique. A — champs électriques de faible intensité; *B* — champs électriques intenses, l'effet de l'hyperpolarisabilité du second ordre; *C* — champs électriques intenses, l'effet de l'hyperpolarisabilité du premier ordre; *Ar*-hydrocarbures aromatiques non disymétriques.

Dans la figure 1 on a représenté la variation du moment induit en fonction du champ électrique ; on peut observer une croissance importante du moment de dipôle induit (*m*), due au coefficient d'hyperpolarisabilité du second ordre (γ), en comparaison de la variation linéaire valable seulement pour les champs électriques de petite intensité[4] ; dans la même figure on peut aussi observer l'effet de l'hyperpolarisabilité du premier ordre (β) qui, étant négative, diminue la valeur du moment de dipôle induit (*m*). On peut aussi observer que, la croissance du moment de dipôle est très importante dans le cas de la courbe (Ar), correspondant aux hydrocarbures aromatiques non disymétriques (benzène, *p*-xylène, mésithylène). Certes, pour un calcul plus correct, il faut tenir compte de l'hyperpolarisabilité apparue dans un gradient de champ électrique (donc dans un champ électrique non uniforme), [6] qui correspond plus correctement à la situation de la cellule support. La valeur $\beta = 0$ correspond aux systèmes moléculaires non disymétriques (avec une symétrie d'inversion) [7], donc au benzène D_{6h}, au *p*-xylène

[6] A. Buckingham, *Quarl. Rev.*, **13**, 183 (1959).

[7] K. Mislow, « Introduction to Stereochemistry », W. Benjamin, New York, 1966, p. 33.

D_{2h}, et ne correspond pas aux autres xylènes isomères (C_3 ou C_{2v}), pour lesquels $\beta<0$. Cette interprétation a permis l'explication de l'ordre de préférence de la clathration et de l'ordre de stabilité pour la série tétra-4-méthylpyridine dithiocyanate de nickel (et de cobalt)

p-xylène > éthylbenzène > toluène > *o*- et *m*-xylène

On observe que l'ordre de stabilité ne correspond pas à l'ordre des valeurs des moments de dipôle, mais au contraire, à l'ordre inverse, parce que les moments de dipôle sont déterminés par la disparition de quelques éléments de symétrie. Il en résulte, évidemment, que la possibilité d'inclusion de la molécule d'hydrocarbure aromatique n'est pas conditionnée seulement par certaines dimensions géométriques : la molécule incluse doit remplir certaines conditions concernant la symétrie de la forme. D'autre part, il faut mentionner qu'un calcul de l'intensité du champ électrique dans une région du réseau cristallin correspond à la superposition des contributions du champ des ions et des dipôles du réseau et la valeur de l'intensité résultante peut diminuer ou augmenter. Le problème est résolu dans le cadre de la théorie générale des diélectriques et du magnétisme,[4] qui conduit à la conclusion que le réseau support ne peut pas être cubique (pour lequel le champ dû aux dipôles est nul à l'intérieur du réseau cristallin) ; on admet donc comme limites les relations cristallographiques suivantes :

$$a : b : c = 1 : 1 : y \text{ et}$$
$$\alpha = \beta = \gamma \ (= 90°) \tag{3}$$

Le calcul effectué dans le cas du clathrate $Ni(CN)_2NH_3.C_6H_6$ (cristallisé dans le système tétraédrique avec $c/a \cong 1,2$) démontre qu'à l'intérieur du réseau le champ est supérieur à la valeur calculée en tenant compte de l'effet des dipôles isolés. [4] Dans ce cas, même par un calcul approximatif, on a réussi à interpréter l'énergie de stabilisation du réseau de $Ni(CN)_2\,NH_3.C_6H_6$ ($U - U_0$), calculée à partir de la différence de l'énergie de dissociation et de l'énergie de sublimation du benzène

$$\Delta U_{\text{diss}} - \Delta U_{\text{sub}} \cong 13500 - 9200 \cong 4300 \text{ cal/mole} \tag{4}$$

qui, comparée à la valeur de l'énergie d'interaction avec le champ électrique ($E - E_0$), représentée dans la figure 2 :

$$E - E_0 = -\frac{1}{2}\alpha\mathfrak{F}^3 - \frac{1}{24}\gamma\,\mathfrak{F}^4 - \dots \tag{5}$$

démontre, dans l'hypothèse du champ uniforme, une concordance satisfaisante avec les paramètres cristallins correspondant à un champ $\mathfrak{F} \doteq 0{,}7 \ldots 0{,}8 \cdot 10^8$ V/cm.

Le diagramme présenté dans la figure 3 représente l'énergie potentielle du réseau du clathrate dans le cas de l'interaction normale de dispersion benzène — benzène (benzène pur solide) et dans le cas de la contribution de l'énergie électrique de stabilisation due à la polarisabilité .[4]

Dans le cas de l'étude de la dissociation des clathrates du type $M(SCN)_2(4\text{-}MePy)_4$. hydrocarbure aromatique [2] on a démontré que la monovariation de l'équilibre peut être interprétée par le modèle suivant : la combinaison coordinative $M(SCN)_2(4\text{-}MePy)_2$, en présence d'un excès de 4-MePy, ferme ces molécules dans des cellules du type clathrate (C_1) et, c'est le réseau de la combinaison résultante, $M(SCN)_2(4\text{-}MePy)_4$, qui contient les cellules nécessaires pour l'inclusion des molécules de l'hydrocarbure (C_2).

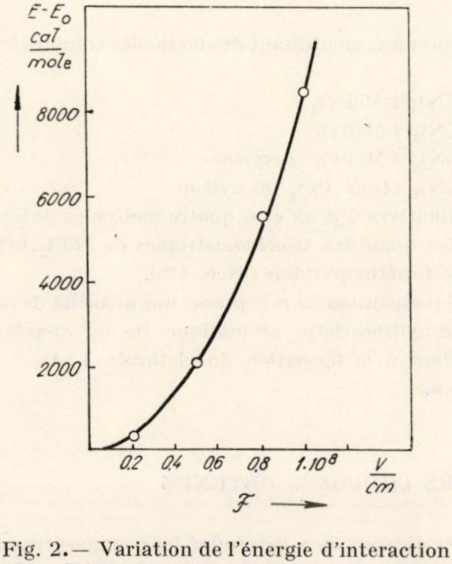

Fig. 2.— Variation de l'énergie d'interaction ($E - E_0$) en fonction du champ électrique dans le cas du composé clathrate $Ni(CN)_2 NH_3 . C_6H_6$.

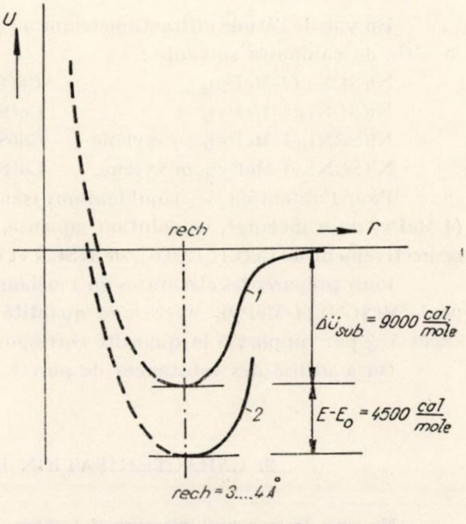

Fig. 3. — Energie potentielle du réseau du clathrate.

1, interaction normale de dispersion ; 2 – contribution de l'énergie électrique de stabilisation due à la polarisabilité.

Ce modèle qualitatif nous a permis l'interprétation de la différence qui existe entre les liaisons des quatre molécules du ligand (4-MePy) avec l'atome métallique, la dissociation de la combinaison ayant lieu en deux étapes, deux molécules de ligand par étape (déterminations manométriques, [3] gaz-chromatographiques [2] et l'analyse thermique ATD et ATG [8]). Les caractéristiques thermodynamiques de la première étape sont identiques, indépendamment de la présence de l'hydrocarbure et indépendamment du degré de remplissage, ce qui nous a conduit à la conclusion que le réseau du clathrate $M(SCN)_2(4\text{-}MePy)_4$.hydrocarbure aromatique est identique à celui du clathrate $M(SCN)_2(4\text{-}MePy)_4$: le premier a les cellules C_1 et C_2 remplies, tandis que le deuxième seulement les cellules C_1 et représente le réseau support.

Le but de ce travail est celui de vérifier ces hypothèses établies à partir des données d'équilibre de dissociation obtenues par des déterminations diffractométriques qui permettent l'appréciation des dimensions et du degré de remplissage de la cellule élémentaire des combinaisons coordinatives et des composés clathrates respectifs.

---

PARTIE EXPÉRIMENTALE

1. PRÉPARATION DES COMBINAISONS COORDINATIVES ET DES CLATHRATES

En vue de l'étude diffractométrique on a préparé, en utilisant des méthodes connues [2,9,10], la série de composés suivante :

$Ni(SCN)_2(4\text{-}MePy)_2$	$Co(SCN)_2(4\text{-}MePy)_2$
$Ni(SCN)_2(4\text{-}MePy)_4$	$Co(SCN)_2(4\text{-}MePy)_4$
$Ni(SCN)_2(4\text{-}MePy)_4$. *p*-xylène	$Co(SCN)_2(4\text{-}MePy)_4$. *p*-xylène
$Ni(SCN)_2(4\text{-}MePy)_4$. *m*-xylène	$Co(SCN)_2$ (4-Me $Py)_4$. *m*-xylène

Pour l'obtention des combinaisons coordinatives à deux et à quatre molécules de ligand (4-MePy) on a mélangé, en solution aqueuse, les quantités stœchiométriques de $NiCl_2 . 6H_2O$, respectivement de $Co(CH_3COO)_2$, de KSCN et de 4-méthylpyridine (excès 4 %).

Pour préparer les clathrates on a mélangé (suspension en *n*-héptane) une quantité de composé $M(SCN)_2(4\text{-}MePy)_4$ avec une quantité d'hydrocarbure aromatique (*p*- ou *m*-xylène), excès 5 % par rapport à la quantité correspondant à la formation du clathrate 1 : 1.

On a utilisé des substances de pureté *p.a.*

2. CARACTÉRISATION DES COMPOSÉS OBTENUS

En vue de la caractérisation des composés obtenus on a déterminé leur composition chimique : le contenu en soufre, en carbone, en hydrogène (par la microméthode de Pregl), le contenu en azote (par la microméthode de Pregl-Dumas [11]) et le contenu en métal — Ni, Co — (par voie gravimétrique [12]). La composition déterminée correspond aux formules proposées. [8]

3. DÉTERMINATIONS DIFFRACTOMÉTRIQUES

Pour les déterminations diffractométriques avec des rayons X on a utilisé des cristaux obtenus par la cristallisation lente d'une solution préparée à l'aide d'un solvant organique ; dans ce but les combinaisons coordinatives et les clathrates obtenus ont été dissous dans du chloroforme, les solutions obtenues étant évaporées lentement à la température ordinaire. (Le temps de l'évaporation de la solution a varié entre 25 et 30 jours.)

La dimension moyenne des cristaux obtenus, mesurée à l'aide d'un microscope du type I.O.R., a été de 0,5 à 1 micron.

---

[10] G. Gawalek et H. G. Könnecke, *Chem. Techn.*, **15**, 609 (1963).

[11] A. Friedrich, « La pratique de la microanalyse organique quantitative », Dunod, Paris, 1939, p. 112.

[12] G. Charlot et D. Bézier, « Méthodes modernes d'analyse quantitative minérale » Masson et Cie Ed. Paris, 1949, p. 402.

Pour obtenir les Debyegrammes on a utilisé un appareil de diffraction du type TUR—M60.

Les preuves ont été préparées en utilisant, en qualité de liant, le baume de Canada (coefficient d'absorption négligeable) ; les petits bâtons obtenus (de diamètre de 0,15 à 0,20mm) ont été exposés dans la chambre Debye — Scherer (au diamètre de 114,6 mm).

La température de travail a été de $22 \pm 3°$.

Pour l'irradiation des preuves on a utilisé les tubes suivants :

— pour les composés du nickel, la radiation CuK_α filtrée avec du nickel, la longueur d'onde λ étant de 1,54177 Å ;

— pour les composés du cobalt, la radiation CoK_α filtrée avec du fer, la longueur d'onde λ étant de 1,79021 Å.

Le temps d'exposition des preuves dans la chambre Debye — Scherer a été de 10 à 12 heures.

On a utilisé des films ORWO pour la structure fine RF 44, qui, en vue de la réalisation des Debyegrammes, ont été arrangés dans la chambre d'après la méthode Straumanis.

Pour chaque film on a fait les corrections de contraction, due au processus de développement ; la correction pour la longueur du film a conduit à une valeur d'approximativement

$$1 \text{ mm film} = 1{,}0020°$$

On n'a pas fait des corrections pour l'absorption, les coefficients d'absorption des combinaisons coordinatives et des clathrates, pour les radiations utilisées étant négligeables (les corrections se placent au-dessous de la limite des erreurs expérimentales).

Les distances entre les lignes ont été mesurées à l'aide d'un microscope Karl Zeiss Jena (l'erreur de la détermination a été de 0,05 mm).

4. DÉTERMINATIONS DE DENSITÉ

En vue de la détermination du degré de remplissage de la cellule élémentaire des combinaisons coordinatives et des clathrates, on a déterminé la densité de ces composés à l'aide d'un picnomètre (immersion en *n*-héptane).

RÉSULTATS ET DISCUSSIONS

L'analyse chimique des combinaisons coordinatives et des clathrates a démontré une bonne concordance entre la composition chimique des composés obtenus et la composition théorique correspondant à un degré de remplissage maximal. [8] On n'a pas observé la formation d'un clathrate avec le *m*-xylène, ce qui a confirmé la théorie concernant l'ordre de préférence dans les réactions de clathration.

Les données diffractométriques des combinaisons coordinatives et des clathrates sont présentées dans les tableaux 1 — 6.

A partir des données obtenues par l'étude diffractométrique, on a calculé les dimensions de la cellule élémentaire des combinaisons coordinatives et des clathrates et, à l'aide des valeurs des densités, mesurées par la méthode du picnomètre, on a calculé le degré de remplissage de la cellule élémentaire (le nombre des molécules du composé par cellule élémentaire). On a utilisé la formule :

$$n = \frac{\rho V}{M} \qquad (6)$$

Ainsi qu'on a démontré, le problème de l'activité catalytique de quelques matériaux (par exemple des zéolithes naturels et synthétiques) dans les réactions d'isomérisation et de craquage des hydrocarbures est très intéressant au point de vue théorique et présente des conséquences importantes pour la technologie. L'augmentation de l'activité catalytique, dans le cas des cations bivalents [13] par rapport à celle des cations monovalents, observée expérimentalement, n'a pas été interprétée de manière satisfaisante, en dépit du grand nombre de travaux publiés à ce propos ces dernières années. [14–19]

On a démontré que le système clathrate, caractérisé par un réseau support bien défini, avec une géométrie simple de la disposition des moléicules de l'hydrocarbure fermée, correspond parfaitement à un modèle déal pour l'étude de l'état de la molécule d'hydrocarbure fermée. [1,4,20].

Dans ces travaux on a démontré qu'il est possible que la valeur du champ électrique à l'intérieur de la cellule soit très importante; en même temps, la théorie générale de la structure cristalline a conduit à l'établissement des critères géométriques de fermeture, critères qui assurent des champs électriques intenses et des énergies d'interaction puissantes.

La vérification de l'existence de ces valeurs de l'intensité du champ électrique, tellement grandes, voisines au domaine d'ionisation de la molécule d'hydrocarbure, a été faite par Benson et Boudart, [21] par l'étude de l'absorption physique de l'hydrogène sur les zéolithes Ca—Y et Na—Y et, ce dernier temps, par l'étude de l'absorption physique du krypton sur les mêmes types de zéolithes. [19]

On peut appliquer, pour le calcul du champ électrique dans les supports cristallins, les modèles suivants :

— le modèle de Barrer et Gibbons, [22,23] appliqué aux zéolithes ;

— le modèle de Pickert, [13] appliqué aux zéolithes, ou

— le modèle appliqué au clathrate du type $Ni(CN)_2NH_3.C_6H_6$ [4].

Tous ces modèles conduisent à des résultats semblables, différents par le choix de l'unité de base de l'électroneutralité, par le système de la distribution des charges électriques et par le procédé de l'addition des contributions des composants de la cellule élémentaire dans le champ électrique total. Malheureusement, dans le cas des clathrates du type $M(SCN)_2(4\text{-}MePy)_4$.hydrocarbure aromatique, les données sur la disposition exacte des ions dans le réseau support sont à présent insuffisantes pour pouvoir évaluer correctement l'intensité du champ, ainsi que dans le cas du clathrate $Ni(CN)_2NH_3.C_6H_6$; tout de même les données existantes permettent l'interprétation du diagramme approximatif représenté dans la figure 4.

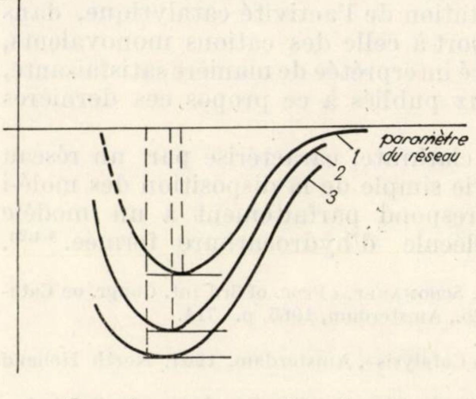

Fig. 4. — Valeur de l'énergie d'interaction avec le réseau support, pour différents xylènes isomères :

1, *m*-xylène; 2, éthylbenzène; 3, *p*-xylène.

On observe que les données diffractométriques ont vérifié l'hypothèse, démontrant une grande compacité dans le réseau du composé $M(SCN)_2(4\text{-}MePy)_2$, à 18 molécules dans la cellule élémentaire, en comparaison du réseau du composé $M(SCN)_2(4\text{-}MePy)_4$, qui comprend seulement 8 molécules.

[23] R. Barrer et R. Gibbons, *Trans. Faraday Soc.*, **61**, 948 (1965).

En conclusion, les déterminations diffractométriques effectuées sur les combinaisons du type $M(SCN)_2(4\text{-}MePy)_{n=2,4}$ démontrent que ces composés correspondent à des compacités différentes, ce qui explique les hypothèses antérieures sur les possibilités de clathration des combinaisons avec $n = 4$ et les hypothèses concernant la nature clathratique des nombreuses combinaisons coordinatives. De même, on peut observer la vérification des conclusions concernant le réseau support ($c/a \cong 1{,}33$), qui correspond à une intensification du champ électrique par rapport aux valeurs calculées pour les dipôles isolés.

COMPLEXES MOLÉCULAIRES DES THIOAMIDES. II[1]

COMPLEXES DE TRANSFERT DE CHARGE DU PHÉNYLTHIOACÉTAMIDE ET DE LA PHÉNYLTHIOACÉTOPIPÉRIDIDE AVEC L'IODE

FELICIA CORNEA*, CORNELIA FULEA* et ŞERBAN MOLDOVEANU **

* Laboratoire de Chimie organique, Faculté de Chimie, Université de Bucarest, 89, Spl. Independenţei

** Laboratoire de Chimie analytique, Faculté de Chimie, Université de Bucarest, 89, Spl. Independenţei

Reçu 31 mars 1973

En suivant les recherches antérieures on a étudié les complexes moléculaires des phénylthioacétamide et phénylthioacétopipéridide avec l'iode, en utilisant les méthodes spectroscopiques (des spectres UV, en visible et IR). A l'aide des valeurs obtenues par le calcul des paramètres thermodynamiques caractéristiques de ces complexes on a tiré la conclusion que le phénylthioacétamide et la phénylthioacétopipéridide sont des donneurs d'électrons plus faibles que le thiobenzamide et la thiobenzpipéridide. La différence entre les stabilités de ces complexes est due à la densité électronique différente à l'atome de soufre, comme une conséquence de l'effet de la nature du radical sur la densité électronique du groupement thioamidique.

Vu que les thioamides peuvent fonctionner comme donneurs d'électrons dans l'interaction avec l'iode [1], nous avons étendu l'étude concernant la formation des complexes moléculaires de type thioamide-iode soit pour obtenir de nouveaux complexes soit pour déterminer l'influence exercée par la nature du radical sur la structure électronique du groupe thioamidique afin d'expliquer la réactivité différente de quelques thioamides.

Ainsi, ont été employés comme donneurs d'électrons le phénylthioacétamide (FTA) et la phénylthioacétopipéridide (FTAP) qui forment avec l'iode comme nous avons démontré, des complexes moléculaires.

Nous avons choisi, comme donneurs, les thioamides mentionnées, pour mettre en évidence l'influence exercée par la présence du groupe méthylène intercalé entre le radical phényl et le groupement fonctionnel thioamidique.

Les complexes moléculaires formés en solution ont été étudiés par des méthodes spectrales et puis comparés avec les complexes moléculaires du thiobenzamide et de la thiobenzpipéridide.

ÉTUDE SPECTROPHOTOMÉTRIQUE EN VISIBLE ET EN UV DES COMPLEXES FTA – I_2 ET FTAP – I_2

L'étude des solutions de FTA et FTAP dans le tétrachlorure de carbone en comparaison de celles obtenues en mélangeant quelques solutions de FTA ou FTAP et l'iode en tétrachlorure de carbone met en évidence la formation des complexes moléculaires entre les thioamides mentionnés et l'iode.

Les spectres d'absorption en visible et UV représentés dans les figures 1 et 2 indiquent des différences distinctes dans l'allure des courbes.

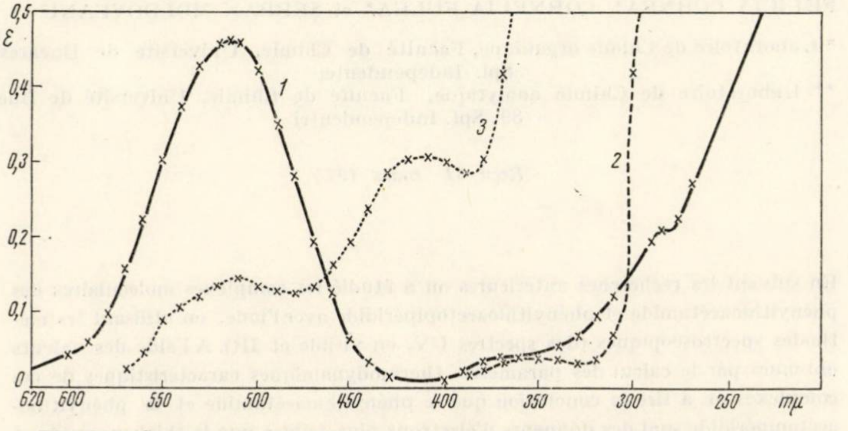

Fig. 1. — Spectres d'absorption en visible et UV des solutions de I_2, FTA et FTA – I_2 (*1*, I_2, *2*, FTA, *3*, FTA – I_2).

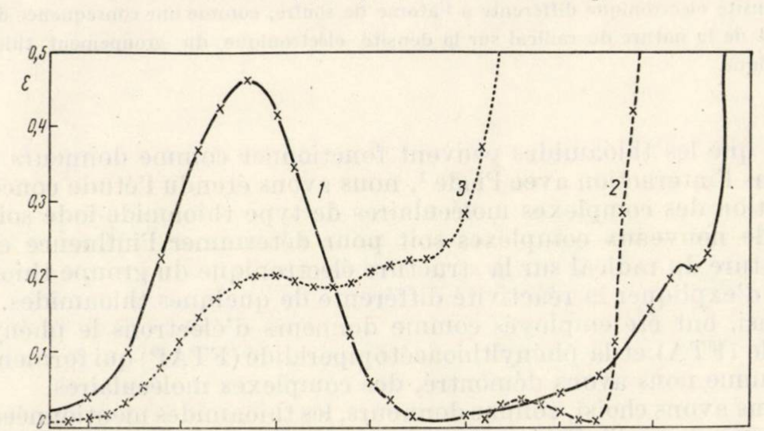

Fig. 2. — Spectres d'absorption en visible et UV des solutions de I_2, FTAP et FTAP – I_2 (*1*, I_2, *2*, FTAP, *3*, FTAP – I_2).

Le changement de couleur après le mélange des solutions du thioamide et l'iode en tétrachlorure de carbone, qui conduisent à l'apparition d'un maximum d'absorption situé à $\lambda = 410$ nm (fig. 1, courbe 3) et $\lambda = 420$ nm (fig. 2, courbe 3) sont des arguments pour la formation des complexes moléculaires thioamide-iode en solution de tétrachlorure de carbone.

Les maximums situés à 410 nm et respectivement à 420 nm peuvent être associés aux bandes de transfert de charge des complexes formés ; on remarque que la formation du complexe de transfert de charge conduit au déplacement de l'absorption avec 50 nm vers une longueur d'onde plus grande et aussi on constate une augmentation de l'intensité de l'absorption de l'ordre 10^2, en comparaison du donneur.

Le complexe FTA$-I_2$ n'a pu être séparé à l'état cristallin comme dans le cas du thiobenzamide; l'étude a été effectuée directement en solution.

Le rapport de combinaison entre les thioamides mentionnés et l'iode trouvé est 1 : 1, tel qu'il a été déterminé dans nos recherches antérieures pour le thiobenzamide et la thiobenzpipéridide.

La détermination de la variation de l'extinction des solutions dans lesquelles se forment les complexes FTA$-I_2$ et FTAP$-I_2$ à $\lambda = 410$ nm et respectivement $\lambda = 420$ nm en différentes conditions a permis la détermination des constantes de stabilité des complexes et des paramètres thermodynamiques de ceux-ci.

Ainsi on a déterminé la variation de l'extinction pour divers mélanges de solutions isomolaires d'iode et de FTA ou FTAP en tétrachlorure de carbone pris en deux concentrations, ainsi qu'à diverses températures.

Dans les tableaux 1 et 2 sont données les valeurs de l'extinction des mélanges des solutions isomolaires de FTA et I_2 et respectivement FTAP et I_2 en tétrachlorure de carbone de concentration $0{,}5 \cdot 10^{-3}$ M et $0{,}8 \cdot 10^{-3}$ M pour différentes températures.

Les constantes de stabilité des complexes étudiés ont été déterminées par une variante de la méthode Sakellaridis [2] pour les solutions isomolaires en rapport de combinaison 1 : 1.

La méthode Schwartzenbach[3] pour la détermination des constantes d'instabilité est moins précise que la variante Sakellaridis et bien que les résultats obtenus par les deux méthodes ne présentent pas de différences sensibles, nous avons considéré corrects ceux obtenus par la méthode Sakellaridis.

Dans le tableau 3 sont données les valeurs moyennes des constantes d'instabilité et de stabilité des complexes FTA$-I_2$ et FTAP$-I_2$.

LES PARAMÈTRES THERMODYNAMIQUES

Le calcul des paramètres thermodynamiques caractéristiques des complexes formés a été effectué d'une manière analogue à celle indiquée dans l'étude précédente [1].

Dans le tableau 4 on donne les valeurs obtenues pour l'énergie libre, l'enthalpie et l'entropie des complexes.

1 :9	0,070	0,055	0,045	0,140	0,105	0,080
9 :1	0,070	0,055	0,045	0,140	0,105	0,080

La précision des déterminations est conditionnée par la méthode graphique utilisée pour trouver les constantes de stabilité. Les déviations des valeurs obtenues donnent une erreur générale d'environ 10% obtenue graphiquement pour ΔS et ΔH.

Les données indiquées dans le tableau 4 montrent le fait que le FTAP est un donneur un peu plus fort que le FTA.

Les paramètres obtenus en comparaison des paramètres thermodynamiques caractéristiques des complexes $TB-I_2$ et $TBP-I_2$ sont de beaucoup inférieurs, ce qui indique le fait que le FTA et le FTAP sont des donneurs plus faibles que les TB et TBP.

Tableau 3

Valeurs moyennes de constantes d'instabilité et stabilité du complexe $FTA-I_2$ et $FTAP-I_2$

Tableau 4

Paramètres thermodynamiques des complexes $FTA-I_2$ et $FTAP-I_2$

	$FTA-I_2$			$FTAP-I_2$		
t°C	$-\Delta F$ cal/mole	$-\Delta H$ cal/mole	$-\Delta S$ cal/mole	$-\Delta F$ cal/mole	$-\Delta H$ cal/mole	$-\Delta S$ cal/mole
20°C	+5194	+8300	+10,6	+5100	+8500	+11,6
30°C	+5088			+4985		
40°C	+4982			+4870		

Le groupement méthylénique dans la molécule du FTA placé entre le groupement thioamidique et le radical phényle détermine la diminution de l'interaction entre ces deux parties de la molécule en comparaison du thiobenzamide.

L'augmentation de la densité électronique à l'atome de soufre est déterminée presque exclusivement par la conjugaison $p-\pi$ existant dans le groupement thioamidique.

Dans le cas de FTAP la densité électronique à l'atome de soufre sera plus grande qu'au cas de FTA comme une conséquence de l'effet + I du groupement méthylénique du noyau pipéridine.

En vue des raisons données plus haut la différence entre la capacité de donneur du FTA et celle du TB semble explicable.

LES SPECTRES EN IR

En général, les spectres en IR appartenant aux complexes de transfert de charge de type *n*, donneur-σ, accepteur[4] présentent de petites différences en comparaison des spectres de leurs composants.

Les spectres en IR des complexes $FTA-I_2$ et $FTAP-I_2$ diffèrent par rapport aux spectres de thioamide par la diminution de l'intensité des bandes caractéristiques et par un léger déplacement vers les plus petites fréquences.

Le fait que les maximums caractéristiques du groupement NH_2 ne sont pas déplacés indique que l'atome d'azote ne fonctionne pas comme donneur.

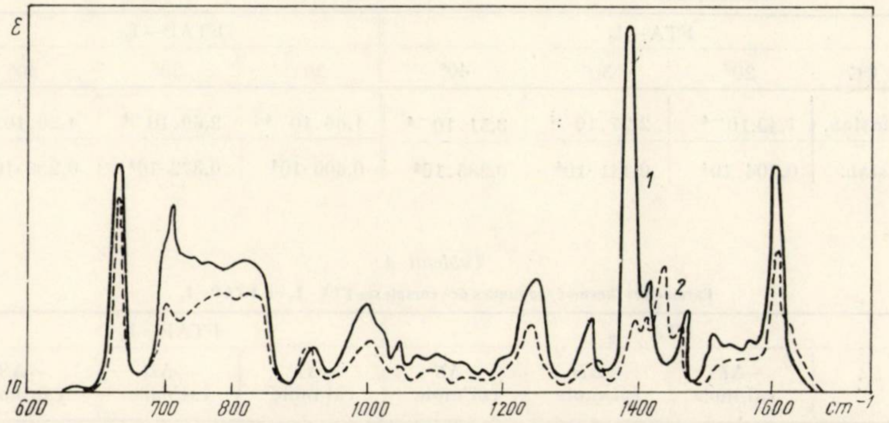

Fig. 3. — Spectres d'absorption en IR de FTA et $FTA-I_2$ (*1*, FTA 10^{-2} M en CCl_4, *2*, $FTA-I_2$, 10^{-2} M en CCl_4).

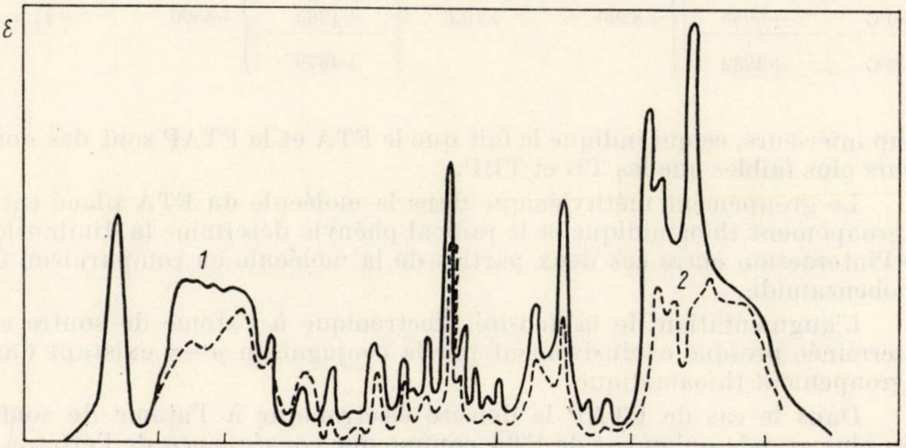

Fig. 4. — Spectres d'absorption en IR de FTAP et $FTAP-I_2$. (*1*, FTAP 10^{-2} M en CCl_4, *2*, $FTAP-I_2$ 10^{-2} M en CCl_4).

---

[4] R. FORSTER, «Organic Charge-Transfer Complexes», vol. 15, chap. 4, Academic Press, London — New York 1969.

Significatif c'est le fait que nous retrouverons les mêmes différences entre les spectres IR des complexes et des donneurs comme dans le cas des TB et TBP, ce qui indique la même manière de formation, respectivement que le donneur le plus probable c'est l'atome de soufre.

PARTIE EXPÉRIMENTALE

Le FTA a été préparé de phénylacétonitrile et de thioacétamide en milieu de chlorhydrate de diméthylformamide [5] et recristallisé de ligroïne jusqu'au P. f. = 97 – 98°.

Le FTAP a été préparé par une réaction Willgerodt-Kindler [6] et recristallisé d'éthanol jusqu'au P. f. = 79°.

Le tétrachlorure de carbone a été séché sur du $CaCl_2$ et distillé sur une colonne Vigreux de 60 cm. L'iode a été purifié par des sublimations répétées.

Les complexes moléculaires ont été obtenus en mélangeant des volumes égaux de solutions isomolaires de thioamide et d'iode.

Les complexes $FTA-I_2$ et $FTAP-I_2$ n'ont pas pu être séparés en état cristallin, étant étudiés directement en solution.

Les spectres en UV et visible ont été effectués à l'aide d'un spectrophotomètre Beckmann, de type DB muni d'un ultrathermostat U 10.

Les spectres ont été réalisés avec un appareil UR 20 dans du tétrachlorure de carbone, en utilisant des cuves de 1mm.

PHTHALAZINIUM YLIDS. VI*

ACTION OF DIMETHYLACETYLENEDICARBOXYLATE ON DISUBSTITUTED AT THE EXOCYCLIC CARBON PHTHALAZINIUM-YLIDS

MAGDA PETROVANU, ARIADNA SAUCIUC and I. ZUGRĂVESCU

Organic Chemistry Department,

Str. 23 August no. 11, Jassy, Romania

Received May 22, 1973

Phthalazinium-cyanocarbethoxymethylid (XI) reaction with dimethylacetylenedicarboxylate (DMAD) leads to an indolizine derivative (XII) through a mechanism which involves the appearance of the intermediate ylid XIV. By the intramolecular nucleophilic attack on the 1-position of the phthalazinic ring, the 5-membered ring is closed simultaneously with HCN elimination. Phthalazinium-dibenzoylmethylid (XV) reaction with DMAD leads to XIV by a probably analogous mechanism.

The occurrence and reactivity of some phthalazinium-ylids was studied in previous papers. [1,2] The present investigation studied the influence of electronegative groups as substituents of the exocyclic carbon on the behaviour of these ylids.

Phthalazinium-dibenzoylmethylid (I) in nonanhydrous solvents is inactivated [2] leading to dimer (IV). Since benzoic acid has been isolated and taking into account the fact that dimer (IV) is also obtained directly from phthalazinium-phenacylid (II), obtained by other means, [2] we have suggested a reaction mechanism through a carbene intermediate (III).

It has been proved experimentally that the dimerization reaction does not take place in perfectly anhydrous aprotic solvents. In this case the occurrence of the carbenic intermediate by a proton transfer seems to depend on the possibility of eliminating the benzoyl group.

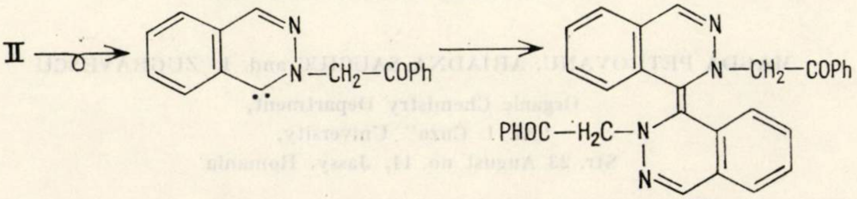
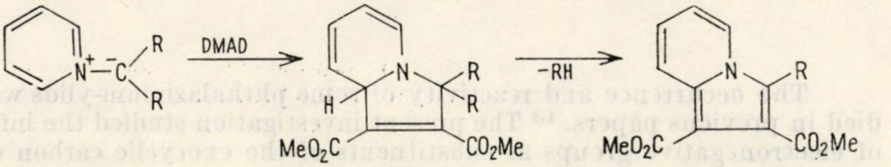
I II



III IV

Linn and co-workers [3] have found that an indolizine derivative (VIIa) is obtained in the reaction between pyridinium-dicyanomethylid (Va) and dimethylacetylenedicarboxylate (noted DMAD) by elimination of a CN group. Henrick and co-workers [4] also show that ylid (Vb) and (Vc) lead to (VIIb) and (VIIc), by elimination of the components of ethyl formiate or benzaldehyde, respectively. A mechanism was suggested for these cases admitting the formation of the intermediate (VI) from which, by 1,4-elimination, the indolizinic derivatives (VII) are obtained.



VI

Va R = CN
Vb R = CO_2Et
Vc R = COPh

VIIa R = CN
VIIb R = CO_2Et
VIIc R = COPh

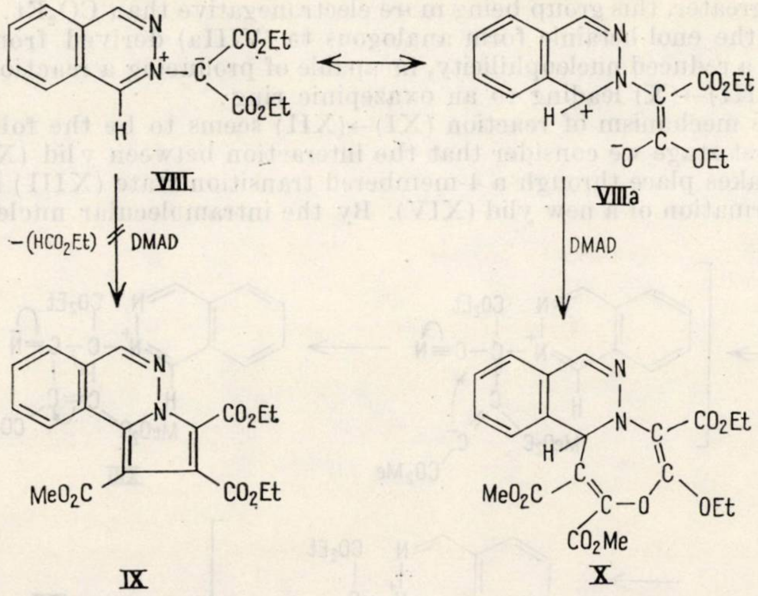
As the dihydroindolizinic derivatives of structure (VI) could not be isolated, and also for steric reasons, this mechanism seems less probable for these cases. It is more convenient to admit a cyclic transition state between DMAD and the ylid, from which the formation of new covalent bonds and the RH elimination constitute a synchronous process.

We have shown [1] that the reaction between phthalazinium-dicarbethoxymethylid (VIII) and DMAD leads to an oxazepine derivative (X).

---

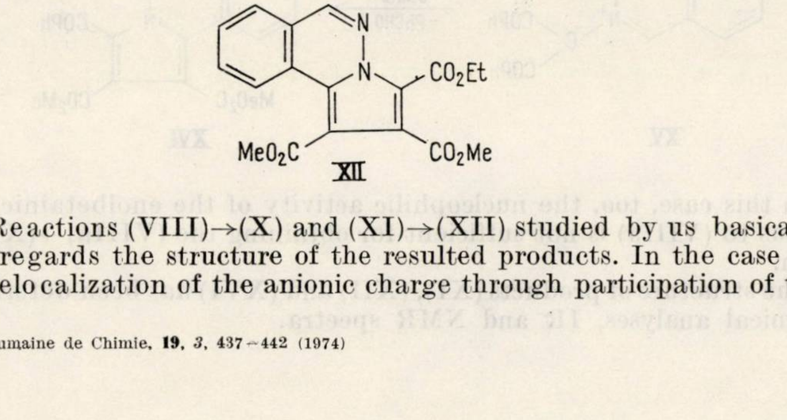
[3] W. J. Linn, O. W. Webster and R. E. Benson, *J. Amer. Chem. Soc.*, **87**, 3651 (1865).

[4] C. A. Henrick, E. Ritchie and W. C. Taylor, *Austral. J. Chem.*, **20**, 2467 (1967).



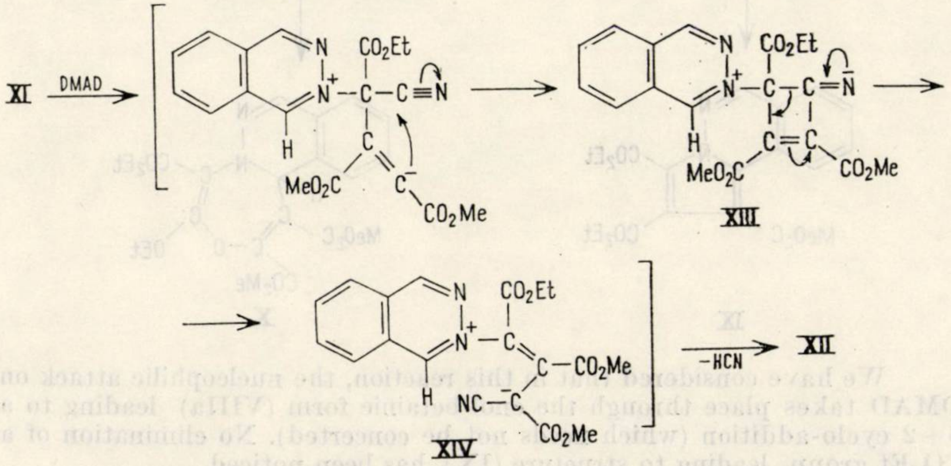
We have considered that in this reaction, the nucleophilic attack on DMAD takes place through the enol-betainic form (VIIIa) leading to a 5+2 cyclo-addition (which needs not be concerted). No elimination of a CO_2Et group, leading to structure (IX), has been noticed.

This unexpected result prompted us to study the reaction between phthalazinium-cyanocarbethoxymethylid (XI) and DMAD. In this case, by eliminating the CN group, a product (XII) analogous to indolizine (VII) is obtained.



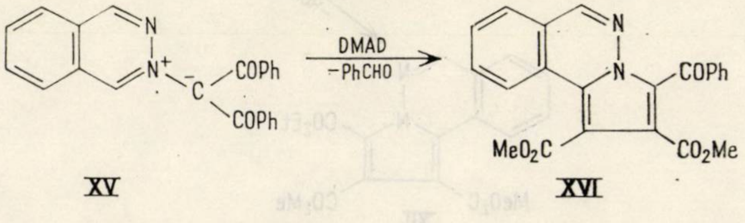
Reactions (VIII)→(X) and (XI)→(XII) studied by us basically differ as regards the structure of the resulted products. In the case of ylid (XI) delocalization of the anionic charge through participation of the CN group is greater, this group being more electronegative than CO_2Et. Consequently, the enol-betainic form analogous to (VIIIa) derived from (XI) will have a reduced nucleophilicity, incapable of producing a reaction similar to (VIII)→(X) leading to an oxazepinic ring.

The mechanism of reaction (XI)→(XII) seems to be the following. In the first stage we consider that the interaction between ylid (XI) and DMAD takes place through a 4-membered transition state (XIII) leading to the formation of a new ylid (XIV). By the intramolecular nucleophilic attack on the 1-position of the phthalazinic ring the closure of the 5-membered ring is obtained. We suppose that the HCN elimination takes place simultaneously with this process.



The mechanism that has been suggested is valid in the case of the phthalazinic cation whose 1-position in the ring is very sensitive to the nucleophilic attack.

We have also studied the reaction between phthalazinium-dibenzoylmethylid (XV) and DMAD which by a probably analogous mechanism leads to (XVI).



In this case, too, the nucleophilic activity of the enolbetainic form analogous to (VIIIa) is not sufficient for obtaining the (VIIIa)→(X) type reaction.

The structure of products (XI), (XII) and (XVI) has been determined by chemical analyses, IR and NMR spectra.

EXPERIMENTAL

CYANOCARBETHOXYMETHYL-PHTHALAZINIUM BROMIDE

Phthalazine, 1.3 g (0.01 mole), is dissolved in 50 ml anhydrous benzene. Ethylbromocyanoacetate, 2 ml (0.01 mole), is added. The mixture is kept at room temperature until next day. A yellow product separates, m.p. = 161–162°. Yield 75 %.

Analyses for $C_{13}H_{12}N_3O_2Br$: *Calcd.* C, 48.44 ; H, 3.72 ; N, 13,04. *Found* : C, 48.11 ; 48.07 ; H,3.90 ; 3.92 ; N, 12.55 ; 12.65 %.

PHTHALAZINIUM-CYANOCARBETHOXYMETHYLID (XI)

Cyanocarbethoxymethyl-phthalazinium bromide, 3.2 g (0.01 mole), is suspended in 100 ml water. It is cooled and a solution of 3 g (0.03 mole) K_2CO_3 in about 50 ml water is added under stirring. The ylid is extracted with chloroform, the solution is dried on Na_2SO_4 and petroleum ether is added. A yellow product separates, m.p. 204–205°. Yield 45 %.

Analyses for $C_{13}H_{11}O_2N_3$: *Calcd.* C, 64.73 ; H, 4.56 ; N, 17.42. *Found* : C, 64.78 ; 64.60 ; H, 4.95 ; 5.01 ; N, 17.63 ; 17.32 %.

IR spectra : $\nu = 3020\ cm^{-1}$ (CH aromatic) ; $2235\ cm^{-1}$ (CN) ; $1740\ cm^{-1}$ (–COOR) ; $1645\ cm^{-1}$ (C = N) ; $1620\ cm^{-1}$ (C = C) ; $1277\ cm^{-1}$ and $1220\ cm^{-1}$ (C–O–C).

1, 2-DICARBOMETHOXY-3-CARBETHOXY-PYROLO–[2.1–a]-PHTHALAZINE (XII)

Cyanocarbethoxymethyl-phthalazinium bromide, 3.22 g (0.01 mole), is suspended in 100 ml acetonitrile. DMAD, 1.42 ml (0.01 mole), and triethylamine, 2 ml (0.02 mole), is added. The mixture is kept at room temperature till next day. Meanwhile a crystalline white product is formed which is filtered ; the product recrystallizes from methanol. Light white crystals, m.p. = 125°. Yield 30 %.

Analyses for $C_{18}H_{16}O_6N_2$: *Calcd* : C, 60.67 ; H, 4.49 ; N, 7.86. *Found* : C, 60.08 ; 60, 07 ; H, 4.73 ; 4.59 ; N, 7.09 ; 8.01 %.

IR spectra : $\nu = 3025\ cm^{-1}$ (CH aromatic) ; $1637\ cm^{-1}$ and $1710\ cm^{-1}$ (3 esteric CO groups) ; $1620\ cm^{-1}$ (C = C) ; $1240\ cm^{-1}$ and $1218\ cm^{-1}$ (C–O–C) ; the characteristic band $2250\ cm^{-1}$ for CN group is missing.

NMR spectra : triplet ($3H_a$) $\delta = 1.4$ ppm, J = 7 cps ; singlet ($3H_{b\ or\ c}$)$\delta = 3.95$ ppm ; singlet ($3H_{b\ or\ c}$) $\delta = 3.98$ ppm ; quadruplet ($2H_d$) $\delta = 4.46$ ppm, J=7 cps ; centred multiplet ($3H_{1,2,3}$) $\delta = 7.8$ ppm ; singlet ($1H_4$) $\delta = 8.78$ ppm ; centred multiplet ($1H_5$) $\delta = 9.4$ ppm.

A similar spectrum is obtained through deuteration.

1.2-DICARBOMETHOXY-3-BENZOYL-PYROLO-[2.1-a]-PHTHALAZINE (XVI)

Phthalazinium-dibenzoylmethylid, 3.52 g (0.01 mole), is suspended in 50 ml anhydrous benzene. DMAD, 1.5 ml (0.01 mole), is added and the mixture is boiled for *ca* 1 hour. Meanwhile the solution is decoloured from red to orange. The hot solution is filtered to separate the white product which is formed. The orange solution evaporates and the brown resin which is separated is dissolved in benzene. Petroleum ether is added until a yellow product separates. Compound is washed with methanol, the white product is recrystallized from *o* xylene. A white crystalline product is obtained, m.p. 174–175°. Yield 30%.

Analyses for $C_{22}H_{16}O_5N_2$: *Calcd.* C, 68.04 ; H, 4.12 ; N, 7.21. *Found* : C, 67.79 ;67.93 ; H, 4.59 ; 4.32 ; N, 7.78 %.

IR spectra: $\nu = 1736\ cm^{-1}$ (esteric CO) and $1730\ cm^{-1}$ (esteric CO) ; $1656\ cm^{-1}$ (cetonic CO) ; $1265\ cm^{-1}$ (C–O–C) ; 1580 and $1606\ cm^{-1}$ (C = C).

NMR spectra : singlet $\delta = 3.57$ ppm (esteric–OCH_3) ; singlet $\delta = 3.98$ ppm (esteric –OCH_3) ; multiplet $\delta = 7.6$ ppm (aromatic 8H) ; singlet $\delta = 8.43$ ppm ($1H_4$ position of phthalazinic ring) ; supplementary coupling doublet $\delta = 8.76$ ppm apart $J = 7.5$ cps ($1H_8$ position of phthalazinic nucleus).

Received June 26,1973

The pyrolytic elimination of tricyclo[7.3.1.$0^{2,7}$]trideca-2-en-13-acetate (I) at 470° has been studied and one established that it followed the ion — pair mechanism. Due to the impossibility to introduct a double bond at the bridgeheads of the bridged bicyclic system, the reaction occurs by heterolytic breakage of the C—O bond with the formation of homoallylic carbonium ion A, which isomerizes giving as main reaction products : tetrahydronaphthalene (III), β-methyl-tetrahydronaphthalene (IV), β-propyl-tetrahydronaphthalene (VI), 2,3-tetrahydrobenzindane (VII), and 3,4-tetrahydrobenzindane (VIII). The structure of pyrolytic elimination products has been studied by IR, NMR and mass spectroscopy.

INTRODUCTION

The products formed in pyrolytic eliminations often differ appreciably in composition from those formed in other types of elimination. The pyrolytic eliminations of bicyclic [n.m.1.] acetates with the acetate group in the one-membered bridge were not studied.

The pyrolytic elimination of tricyclo [7.3.1.0 ^{2,7}] trideca-2-en-13-acetate (I) has been studied in the present work to establish the structure of the elimination products as well as the reaction mechanism, due to the theoretical importance of the elimination reactions of such class of compounds.

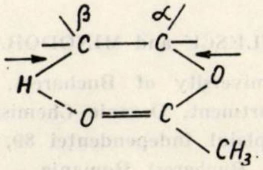
Acetic esters undergo elimination on heating at elevated temperatures (300 — 550°), with no other reagent present. The mechanisms of such reactions are obviously different from those of the elimination reactions in solution, which occur at low temperatures and always require a base (the solvent may be the base in some cases).

---

[1] Part III : N. Bărbulescu and M. Leca, *Rev. Roumaine Chim.*, in press.

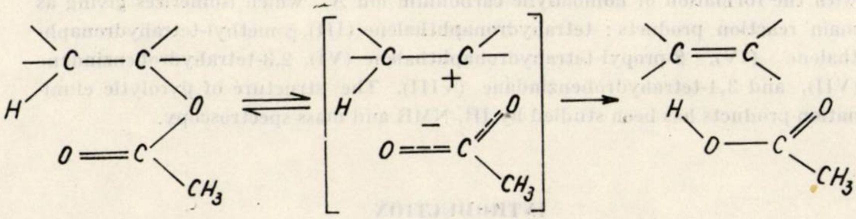
The following mechanisms have been suggested for the pyrolytic elimination of acetates [2,3]:

a) *The six-membered ring concerted mechanism Ei.* This mechanism, suggested by Hurd and Blunck,[4] postulates a six-membered ring transition state in which a basic α atom, or one belonging to an α group, removes intramolecularly a β hydrogen; the two groups leave at the same time:



The mechanism explains the *cis* eliminations observed in most of the cases,[5] why the reactions are homogeneous and unimolecular and why the activation entropy is usually found to be negative. The model does not allow for the *trans* eliminations found in some molecules, fails to explain why the composition of the final alkene mixtures does not depend on the nature of the acid and the positive activation entropy found for tertiary acetates.[6]

b) *The ion-pair mechanism.* Maccoll[7], to eliminate some of the difficulties with the six-membered ring mechanism, postulated an intimate ion-pair as transition state:



The ion-pair mechanism is very much like the E1 mechanism, except that, under the pyrolytic elimination conditions, where there is nothing available to solvate the negative ion, it remains near the carbonium ion. The ion-pair and the Ei mechanisms differ only in the timing of the steps involved.

The heterolytic dissociation of the C—O bond requires a much higher energy compared to homolytic dissociation. Part of this energy may be compensated for by the Coulombic attraction of the two ions.

[7] A. Maccoll, *J. Chem. Soc.*, **1958**, 3398.

Some workers consider the transition state very polar, but not quite an ion-pair.[8]

The finding of the rearranged products is a strong evidence for the ion-pair mechanism.

The pyrolytic elimination of 1-arylethyl and 1,2-diarylethyl acetates follow this mechanism,[9-11] due to the carbonium-ion character of the C_1 carbon atom.

c) *The free radical mechanism* considers that by going into higher vibrational states, the molecule must reach a state where its weakest bond dissociates. The activated complex consists in the critical state where the vibrational degree of freedom of the R—OAc stretching oscillator changes into a translational degree of freedom. The formation of such a transition state being the rate determining step, the two radicals react very quickly, by a nonchain or a chain process, giving the final reaction products. This mechanism is followed by the pyrolytic elimination of the allylic acetate derivatives.[2,12]

RESULTS AND DISCUSSIONS

The pyrolytic elimination of tricyclo $[7.3.1.0^{2,7}]$ trideca-2-en-13-acetate (I) is subjected not only to the restrictions regarding the cyclic compounds (the existence of a *cis* β-hydrogen for Ei elimination), but also to Bredt's rule,[13] which applies in these reactions as in the E1—E2—E1cB mechanistic spectrum.[14] Bredt's rule, reformulated by Wiseman,[15] predicts isolable bicyclic bridgehead alkenes when the largest of the two rings containing the double bond has at least eight atoms. The elimination of the acetate group from C_{13} carbon atom of I would lead to the introduction of a *trans*-double bond in a six-membered ring. That is why the elimination of this group cannot occur without the isomerization of the bridged bicyclic system.

The unsaturated acetate I, obtained by dehydration and acetylation of tricyclo $[7.3.1.0^{2,7}]$ tridecane-2,13-diol (II) with zinc chloride and acetic anhydride,[1] has been subjected to pyrolytic elimination in flow system at temperatures ranging from 410 to 470°. The conversion has been determined by titrating the acetic acid resulted from the reaction as well as by IR spectroscopy, using the carbonyl band of the ester which appeared at 1723 cm^{-1}. The calibrating curve extinction, E, in terms of concentration — Pirlot method[16] — has been plotted for that, using the carbon tetrachloride as solvent (fig. 1). The results are in good agreement with those obtained from acetic acid titration (table 1). The highest conversions were obtained at 470°, which was selected as reaction temperature.

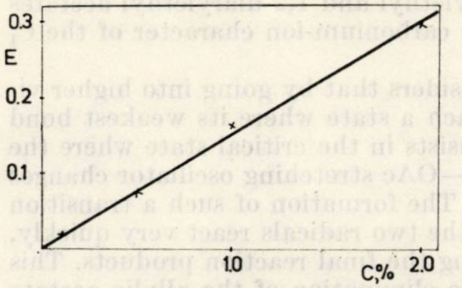

Fig. 1. — The calibrating curve extinction, *E*, in terms of concentration.

The analysis of the elimination products has been made by gas-liquid chromatography on the following columns, after removing the polymers and the unreacted acetate : SE—30 on chromosorb W, diethyleneglycol succinate on celite C_{22}, carbowax 20M on teflon and carbowax 20 M on celite C_{22}. The best resolution was obtained with the last column (fig. 2). Six (*a* - *f*) among the 26 peaks of the chromatogram, which represent 79.3 per cent of the total, were separated by preparative gas-liquid chromatography. The last two peaks, *e* and *f*, were not well resolved on the preparative column, so that they were collected together.

Table 1

Degree of conversion obtained for the pyrolytic elimination of acetate I by acetic acid titration and IR spectroscopy

n_D^{20} of the elimination products	Conversion, %	
	AcOH titration	$E = f(c)$
1.5410	71.6	73.5
1.5447	89.3	91.1
1.5549	98.2	100.0

The peaks *a* - *f* were analysed by MNR, IR, and mass spectroscopy.

The following structure were assigned for these compounds on the basis of mass, NMR, and IR spectra :

The mass spectrum of the peak *a* gives for the parent ion the value 132 and 104 for the principal ion. There are also peaks at m/e 117, 91, 65, 51, 39, and 27. The mass spectrum of this compound is represented in figure 3a, beginning from m/e = 50, and it is identical with that of tetrahydronaphthalene (III). [17,18]

Its NMR spectrum (fig. 3*b*) also presents the tetrahydronaphthalene signals : one quintet at δ 1.77 ppm, J = 2.25 Hz, one multiplet centered at

[18] G. Spiteller, "Massenspektrometrische Strukturanalyse organischer Verbindungen", Verlag Chemie, GmbH, Weinheim/Bergstr., 1966, p. 149—150.

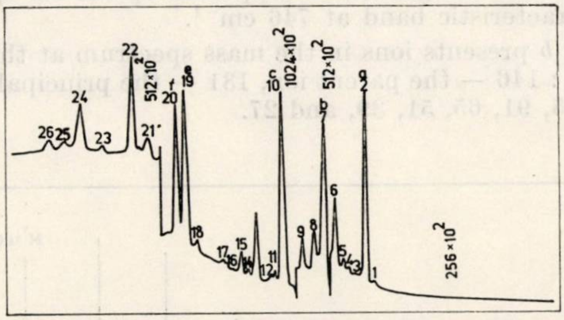

Fig. 2. — The pyrolytic elimination products chromatogram of the acetate I at 470° on carbowax 20M on celite C_{22}.

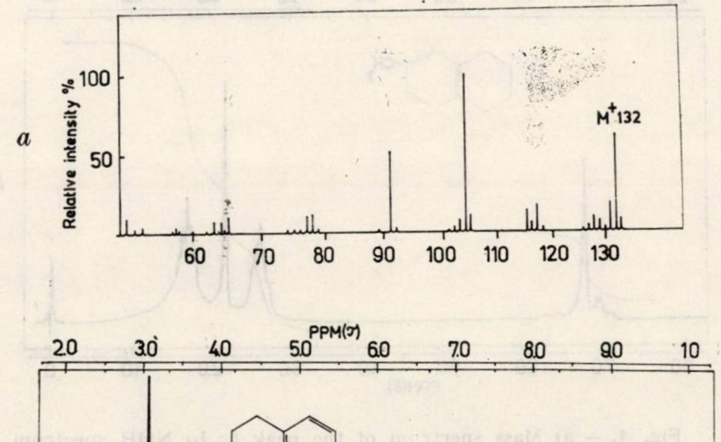

Fig. 3. — a) Mass spectrum of the peak a; b) NMR spectrum of the peak a.

δ 2.715 ppm, and one complex absorption from δ 6.62 to 7.30 ppm centered at δ 6.92 ppm. This assignment is supported by the IR spectrum, which presents a characteristic band at 746 cm^{-1}.

The peak *b* presents ions in the mass spectrum at the following m/e ratios (fig. 4a) : 146 — the parent ion, 131 — the principal ion, and other ions at 118, 105, 91, 65, 51, 39, and 27.

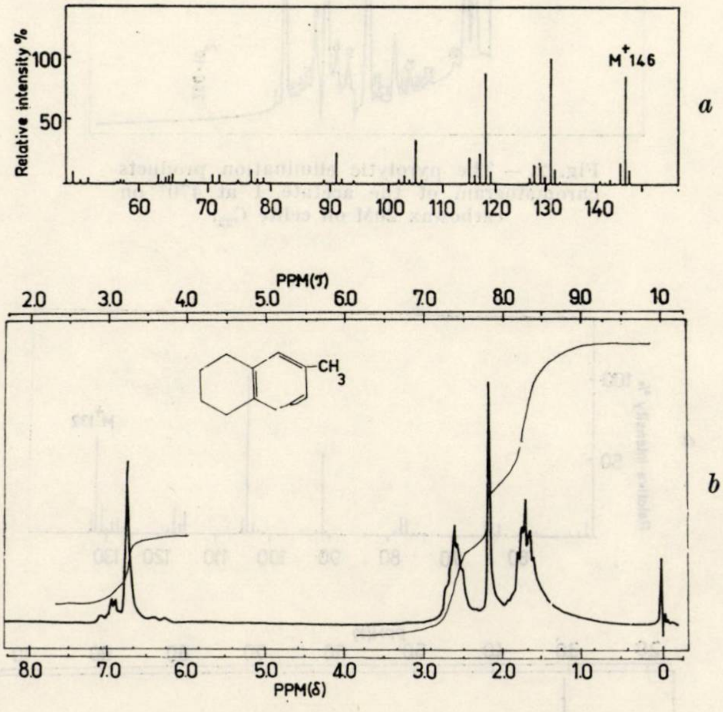

Fig. 4. — a) Mass spectrum of the peak *b* ; b) NMR spectrum of the peak *b*.

There are signals in the NMR spectrum (fig. 4b) at the following δ values : one multiplet centered at 1.72 ppm corresponding to four aliphatic protons, one singlet at 2.21 ppm specific of the CH_3-Ar system, one multiplet centered at 2.62 ppm with an area corresponding to four protons adjacent to benzene nucleus, and one complex absorption to 7.17 ppm for three aromatic protons. The β-methyl-tetrahydronaphthalene (IV) structure has been assigned to the peak *b* on the basis of the parent ion m/e value, of the way of molecule fragmentation which demonstrates the presence of the tetrahydronaphthalene skeleton, and of the NMR spectrum.

There are peaks in the mass spectrum of the compound *d* at the m/e values 174 — the parent ion, 145 — the principal ion, 131, 117, 105, 91, 65, 51, 39, 28, and 27 (fig. 5a). This demonstrates that the peak *d* is a tetrahydronaphthalene derivative.

The NMR spectrum (fig. 5b) presents one triplet at δ 0.92 ppm, J = 7 Hz, specific of the $CH_3 - CH_2 -$ system, one multiplet centered at δ 1.765 ppm corresponding to six aliphatic protons, one multiplet from δ 2.30 to 3.00 ppm with an area corresponding to six protons adjacent to benzene ring in which a triplet at δ 2.47 ppm can be distinguished, J = 7.5 Hz, which can be assigned to the $-CH_2-CH_2-$Ar system, and one multiplet from δ 6.66 to 7.00 ppm for three aromatic protons. The β-propyl-tetrahydronaphthalene (VI) structure was assigned to the peak *d* taking account of the facts presented above.

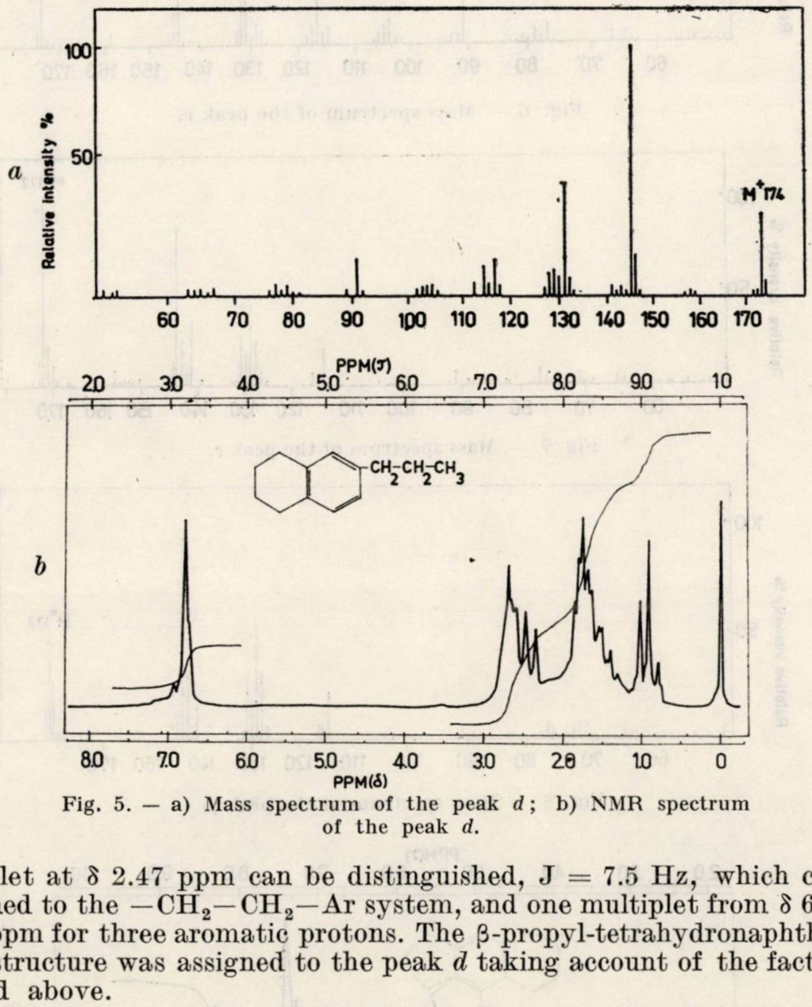

Fig. 5. — a) Mass spectrum of the peak *d*; b) NMR spectrum of the peak *d*.

The peak *c* was not well resolved on the preparative chromatographic column, and the gas-liquid chromatographic analysis shows that the collected product was not pure. The refractionation gives a very small quantity of product, which does not allow a conclusive NMR spectrum. The existence of some aliphatic protons can be seen from the spectrum, grouped in three wide signals from δ 1.30 to 1.90, 2.00 to 2.25, and 2.50 to 2.90 ppm, as well as of some aromatic protons centered at δ 6.80 ppm. The mass spectrum (fig. 6) gives a M^+ parent ion at m/e 174, showing that the peak *c* (V) and *d* are isomers.

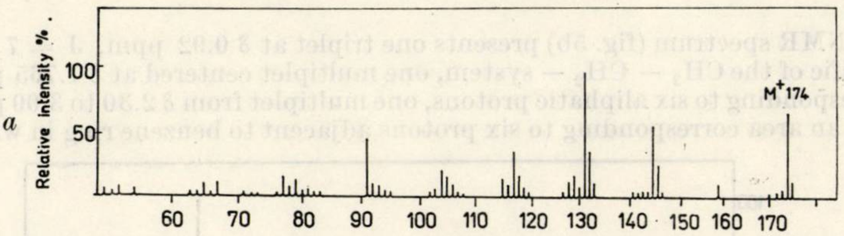

Fig. 6. — Mass spectrum of the peak *c*.

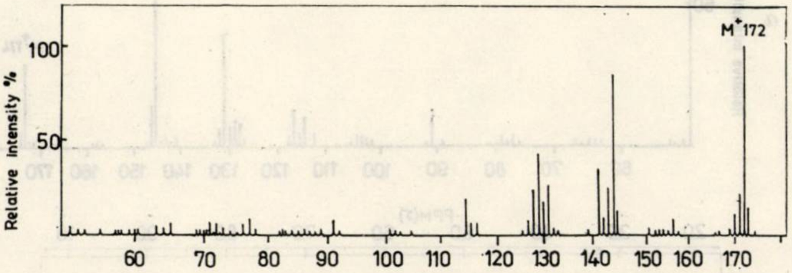

Fig. 7. — Mass spectrum of the peak *e*.

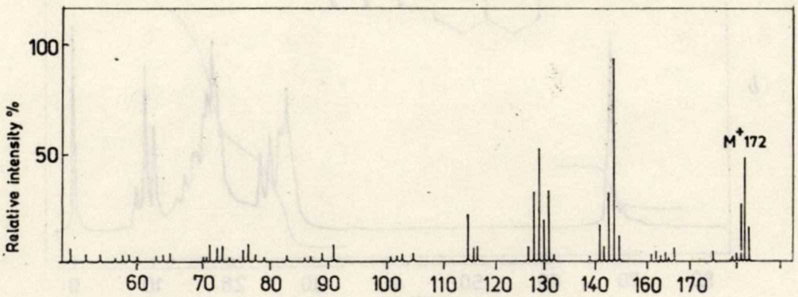

Fig. 8. — Mass spectrum of the peak *f*.

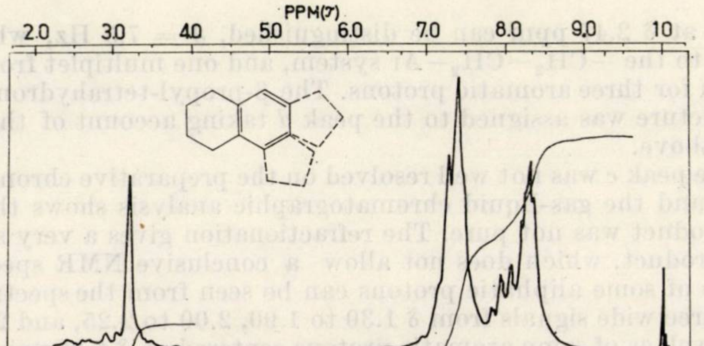

Fig. 9. — NMR spectrum of the mixture of the peaks *e* and *f*.

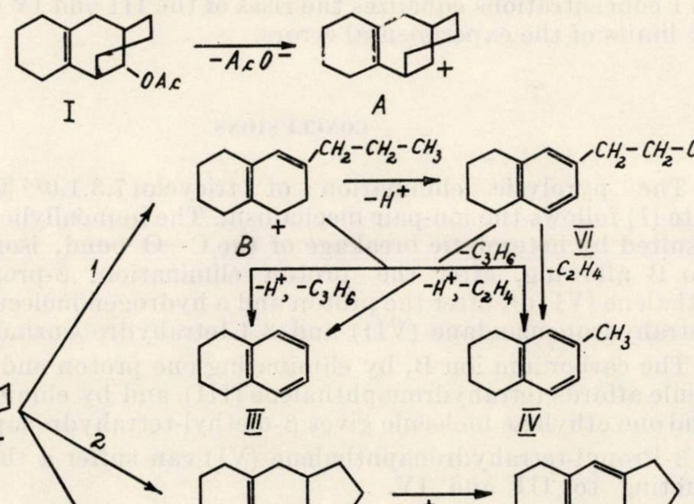
In contrast to the last one, the principal ion is at m/e 131, the 145 ion being not so abundant. There are also ions at m/e 117, 91, 65, 51, 39, and 28, proving that the peak *c* is also a tetrahydronaphthalene derivative.

The mass spectrum of the peak *e* (fig. 7) gives the value 172 for the parent ion, this being at the same time the principal ion. There are ions at m/e 144, 141, 131, 129, 105, 91, 65, 51, 39, and 28.

The peak *f* presents ions at the following m/e ratios (fig. 8) : 172 — the parent ion which is also the principal ion, 144 — an ion almost as intense as the preceding one, other ions at 131, 129, 105, 91, 65, 39, and 28. The NMR spectrum of the peaks *e* and *f* mixture (fig. 9) is identical with that of 2,3-tetrahydrobenzindane (VII) and 3,4-tetrahydrobenzindane (VIII) mixture. [1] The gas-liquid chromatographic analysis gives the value 1.2 : 1 for the VII : VIII ratio.

The pyrolytic elimination of tricyclo$[7.3.1.0^{2,7}]$trideca-2-en-13-acetate (I), taking account of the main reaction products, can be depicted by the ion-pair mechanism as follows :



The homoallylic carbonium ion A, resulted from heterolytic dissociation of the C—O bond, isomerizes probably to B, C, and D. The carbonium ion A is transformed into carbonium ion B by homolytic breakage of the allylic C_1-C_{12} bond. The ion B can eliminate one proton giving *n*-propyl-tetrahydronaphthalene (VI) identified as

7.1 per cent in the reaction products, or affords tetrahydronaphthalene (III) and β-methyl-tetrahydronaphthalene (IV) by thermal cracking. The last two compounds form 4.4 and 8.5 per cent, respectively, of the reaction products.

The radical-ion resulted by the C_1-C_{12} bond breakage may also become stable following the ways 2 and 3, leading to VII and VIII which represent 18.7 and 15.7 per cent, respectively, of the total reaction products.

β-Propyl-tetrahydronaphthalene (VI) can suffer a thermal cracking, too, under the reaction condition (470°), allowing for the formation of III and IV. This is supported by the fact that the ratio of III and IV rises when the elimination products are reintroduced in the elimination column, and the ratio of V and VI diminishes. Reintroducing the above elimination mixture in the column, the concentration of III rises at 11.2 and that of IV at 12.7 per cent. The concentration of V decreases at the same time from 25.9 to 8.5 per cent, and of VI to 5.1 per cent. The increasing of the ratio of another unidentified compound from 1.5 to 6.5 per cent is also observed, its retention time being between that of V and VI. The decreasing of V and VI concentrations equalizes the rises of the III and IV concentrations, in the limits of the experimental errors.

CONCLUSIONS

The pyrolytic elimination of tricyclo[$7.3.1.0^{2,7}$]trideca-2-en-13-acetate (I) follows the ion-pair mechanism. The homoallylic carbonium ion A, resulted by heterolytic breakage of the C—O bond, isomerized probably to B allowing, after the proton elimination, β-propyl-tetrahydronaphthalene (VI) or, after the proton and a hydrogen molecule elimination, 2,3-tetrahydrobenzindane (VII) and 3,4-tetrahydrobenzindane (VIII).

The carbonium ion B, by eliminating one proton and one propylene molecule affords tetrahydronaphthalene (III), and by eliminating one proton and one ethylene molecule gives β-methyl-tetrahydronaphthalene (IV).

β-Propyl-tetrahydronaphthalene (VI) can suffer a thermal cracking conducting to III and IV.

EXPERIMENTAL PART

The preparation of tricyclo[$7.3.1.0^{2,7}$]*trideca-2-en-13-acetate* (I) has been described in an earlier paper. [1]

Pyrolytic elimination of tricyclo[$7.3.1.0^{2,7}$]*trideca-2-en-13-acetate* (I). The equipment for pyrolytic elimination of acetate I consisted of a 245 mm vertical Rasotherm tube, 28 mm in diameter, filled with porcelain bits 205 mm in height, equipped with a separating funnel at the upper side to introduce the compound and a two-necks round bottomed flask at the lower side to collect the reaction products. The second neck had a reflux refrigerator attached, to avoid the volatile compounds loss. The filled part of the glass column was entirely inserted into a 205 mm high electric oven, the temperature being adjusted using an autotransformer. The calibrating curve temperature was plotted in terms of voltage. The temperature was verified with the aid of a thermometer which was introduced up to the middle of the column. The asbestos fibres were used as thermal insulator.

There were introduced 0.12 ml of acetate per minute at temperatures ranging from 410 to 470°. The reaction products were collected in water, the organic portion was extracted with petroleum ether, the extract washed with water and dried with natrium bicarbonate. The resulted solution was chromatographed on aluminium oxide to remove the polymers. The row product, resulted after the petroleum ether removal, was characterized by a total refractive index, by the height of the IR absorption band from 1723 cm^{-1} using carbon tetrachloride as solvent, and by gas-liquid chromatography on carbowax 20M.

The aqueous layers were combined and the acetic acid resulted from the reaction was titrated using 1N natrium hydroxide to calculate the acetate conversion. For example, there were obtained the following results using a portion of 6.25 g acetate at 470 ± 3°: elimination products 3.8 g, $n_D^{20} = 1.5447$, after the chromatography on aluminium oxide, 23.8 ml 1N natrium hydroxide which correspond to 1.428 g acetic acid (theoretically 1.600 g, 89.3% conversion).

The unreacted acetate can be removed by careful elution with petroleum ether on aluminium oxide column.

Analytical chromatography has been performed by employing a Becker 401 type gas-liquid chromatograph, using a 6 mm o.d. copper column, 4 m in length. Packing material was 12% carbowax 20M on 60–80 mesh celite C_{22}. The flame ionization detector was used, with nitrogen as carrier gas. The conditions were as follows:

injection temperature	210°
column temperature	100–210°, with 6°/min programming
detector temperature	240°
gas flow rate	40 ml/min
injected quantity	2–2.5 µl.

The pyrolytic elimination products chromatogram of the above example, after the acetate removal, consists of 26 peaks (fig. 2).

Preparative chromatography was carried out on a Carlo Erba GT type chromatograph by employing a 10 mm o. d. stainless steel column, 2 m in length, and 20% carbowax 20 M on 30–60 mesh chromosorb W as packing material. The thermal conductivity detector was used with hydrogen as carrier gas. The conditions were:

injection temperature	300°
column temperature	195°
detector temperature	280°
hydrogen flow rate	500 ml/min
auxiliary gas flow rate	60 ml/min
injected quantity	170 µl.

The purity verification of the collected samples was made using a 4 mm o.d. stainless steel column, 2 m in length and 20% carbowax 20M on 60–80 mesh chromosorb W as packing material, on an analytic Carlo Erba GT chromatograph under the following conditions:

injection temperature	220°
column temperature	120–180°, with 4°/min programming
detector temperature	240°
nitrogen flow rate	30 ml /min
injected quantity	0.2 – 0.3 µl

The mass spectra were run using a Perkin-Elmer 900 type gas-liquid chromatograph coupled with a Perkin-Elmer RMU–6M type mass spectrometer; the coupling system is shown in figure 10.

A 2.5 m length and 3 mm i. d. stainless steel chromatographic column was used to separate the compounds, having 15 % carbowax 20M on chromosorb W 80–100 mesh as packing material.

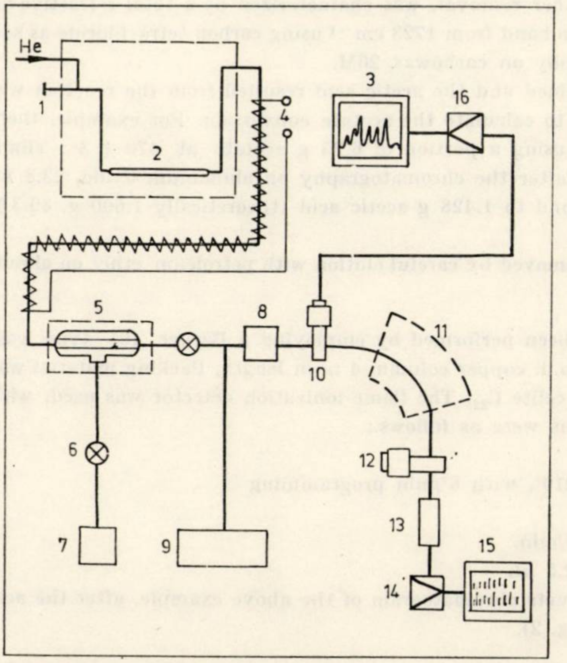


Fig. 10. – Schematic diagram of gas-chromatograph – mass spectrometer system :
1, injection point; *2*, chromatographic column; *3*, gas-chromatograph recorder; *4*, heated pipes; *5*, molecular separator; *6*, valve; *7*, diffusion pump; *8*, ionization source; *9*, diffusion pump; *10*, total ion detector; *11*, magnetic sector 60°; *12*, collector slit; *13*, multiplicator detector; *14*, amplifier; *15*, mass spectrum recorder; *16*, amplifier.

The conditions were: column temperature 100–210°, 10°/min programming, helium as carrier gas – 12 ml/min flow rate – using the total ion detector. The mass spectra were recorded under the conditions

molecular helium separator (Bicman type glass)	250°
ionization energy	70 eV
ion acceleration tension	1 500 kV
vacuum	2×10^{-7} mm Hg
mass number marking system (calibrated with perfluorobutylamine, with respect to 614 mass number)	2–900 mu
exploration speed	1 sec/decade

The following IR bands were used for the structural assignments of the collected peaks: peak *a* : 746 cm^{-1}; peak *b* : 878, 868, 860 cm^{-1}; peak *c* : 878 cm^{-1}; peak *d* : 878, 868, 860 cm^{-1}; peak *e* : 865 cm^{-1}; peak *f* : 833 cm^{-1}.

ALUMINIUM CHLORIDE CATALYZED CONDENSATIONS OF UNSATURATED ACIDS WITH BENZENE *

ALICE MARIE GLATZ

Institute of Organic Chemistry, Bucharest, Spl. Independenţei 202 B

Received September 18, 1973

The present paper reviews the aluminium chloride catalyzed condensation reactions of unsaturated acids with benzene. The behaviour of acyclic acids with one and two double bonds and of alicyclic unsaturated acids is discussed. The reaction products of these condensations are isomeric phenylated acids and cyclic ketones. The mechanism of the reactions taking place through carbocationic intermediates is presented. This paper deals largely with the occurrence of intramolecular hydride ion shifts and formation of lactoid ions in these intermediates, as well as with intermolecular hydride ion shifts. Both hydride ion acceptors and donors involved in the latter processes have proposed.

I. INTRODUCTION

The present review deals with the aluminium chloride condensation reactions of unsaturated acids with benzene, under the conditions of the Friedel-Crafts reaction.

As is well known, these reactions, largely studied in literature, due to their great theoretical interest and numerous industrial applications are the subject of excellent books [1–3] and monographs. [4–9]

[9] J. Hine "Physical Organic Chemistry", McGraw-Hill Book, New York, 1962, p. 353

The alkylation of aromatic hydrocarbons with alkenes is one of the most important industrial applications of the Friedel-Crafts reactions. Large quantities of ethylbenzene, cumene, dodecyl- and tridecylbenzene are thus obtained from the corresponding olefins.

Although only a small area of this immense field is discussed in this paper, the paper reviews the experimental research covering a period of more than forty years.

Considering the published works in this field, two periods may be distinguished : a pioneering period until 1960 [8,9] and a more recent one, developed as a result of the introduction of modern investigation methods in experimental research, thus permitting the formulation of new theories and perspectives for new works. In both periods, Nenitzescu and his coworkers had an important contribution in the understanding of these reactions.

The earlier works, from the first period, will be discussed herein only in order to indicate the starting point of the research, with the corresponding original discoveries, which generated more recent studies in the field, greater attention being paid to the evolution of the research in the last period, starting with 1960 until now.

The condensation of acyclic [10] and alicyclic [11,12] unsaturated acids with benzene and different aromatic compounds has been studied. There are known condensations of unsaturated esters, ethers and ketones with benzene. The present review is restricted to the condensation of different types of unsaturated acids with benzene. The condensations of functional derivatives of the unsaturated acids or other unsaturated compounds with benzene will be only incidently mentioned, if necessary, for a better understanding of the phenomena.

A survey of the results of the different works in this field enables the recognition of some general rules, governing the condensations of the different types of unsaturated acids.

II. CONDENSATIONS OF SOME ALKENOIC ACIDS WITH A SINGLE DOUBLE BOND WITH BENZENE

A. SOME GENERAL CONSIDERATIONS

All the condensation reactions of unsaturated acids, with a linear chain, longer than four carbon atoms involve intramolecular hydride ion shifts. This kind of reaction was known in litterature as early as 1907. Eijkman was the first to describe the addition of benzene and toluene to acrylic [13] and dimethylacrylic [14] acids. The formation of a single product was observed, with the aryl group situated in β position with respect to the carboxyl group. In the mentioned cases, no hydride ion shift was possible and thus no isomers of the arylated acids were formed.

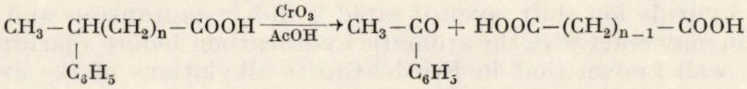
From 1935, Nenitzescu and his coworkers have observed rearrangements during the Friedel-Crafts reactions of alicyclic α,β-unsaturated acids,[15] α,β-unsaturated ketones and α-chloroethers,[16] in the condensation of 1,2-dibromocyclohexanes[17-19] as well as in the condensation of dibromoalkanes with benzene.[20]

In the condensation of either α,β-unsaturated ketones or acids with benzene, at moderate temperatures, Nenitzescu and his coworkers[21-26] have demonstrated in earlier works that the phenyl group is attached to the last but one carbon atom, related to the carbonyl, respectivly, carboxyl group, that means in the remotest possible position from the carboxyl group, and not at the atoms of the initial double bond. No substitution at the marginal primary carbon atom has ever been observed. This observation has a general character and was the starting point of other research in this field. Through modern investigations, a series of phenomena involved in the process has been observed.

B. α,β-UNSATURATED ACIDS

Condensations of 2-pentenoic,[25,27] 2-hexenoic,[22,25,28] 2-nonenoic[25,27] acids with benzene are well known in literature. The reactions were performed at 40—45 °, in 4 hours.

1. In these works, the formation of phenylated acids with the phenyl group in the last but one position, has been observed.[23,25,27-29] The oxidation with chromic acid[25] of the reaction products evinced the presence of acetophenone undoubtedly bearing out the existence of such isomers.



$$\underset{\substack{|\\ C_6H_5}}{CH_3-CH}(CH_2)_n-COOH \xrightarrow[AcOH]{CrO_3} \underset{\substack{|\\ C_6H_5}}{CH_3-CO} + HOOC-(CH_2)_{n-1}-COOH \qquad (1)$$

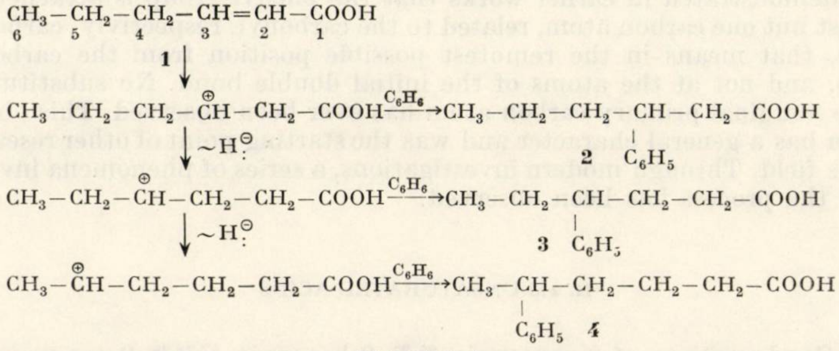
2. The formation of a mixture of isomeric phenylated acids [28] has been demonstrated through vpc of the resulted methylic esters obtained from the reaction product; the structure of each component of the reaction mixture has been established through comparison with authentic samples, obtained in other ways.

In the case of 2-hexenoic acid a reaction mechanism has been formulated



$$\begin{aligned}
&\underset{6}{CH_3}-\underset{5}{CH_2}-\underset{4}{CH_2}-\underset{3}{CH}=\underset{2}{CH}-\underset{1}{COOH}\quad \mathbf{1}\\
&\downarrow\\
&CH_3-CH_2-CH_2-\overset{\oplus}{C}H-CH_2-COOH\xrightarrow{C_6H_6}CH_3-CH_2-CH_2-\underset{C_6H_5}{CH}-CH_2-COOH\quad \mathbf{2}\\
&\downarrow\sim H^{\ominus}\\
&CH_3-CH_2-\overset{\oplus}{C}H-CH_2-CH_2-COOH\xrightarrow{C_6H_6}CH_3-CH_2-\underset{C_6H_5}{CH}-CH_2-CH_2-COOH\quad \mathbf{3}\\
&\downarrow\sim H^{\ominus}\\
&CH_3-\overset{\oplus}{C}H-CH_2-CH_2-CH_2-COOH\xrightarrow{C_6H_6}CH_3-\underset{C_6H_5}{CH}-CH_2-CH_2-CH_2-COOH\quad \mathbf{4}
\end{aligned}$$

SCHEME 1

The protonation of the double bond occurs in the first step of the reaction, leading to a carbocation * with the charge located in position 3. This carbocation suffers hydride ion shifts with the formation of two other carbocations, able to react with benzene. Each of the resulted carbocations may condense with benzene, forming thus the isomeric acids **2**, **3** and **4**.

The hydride ion shift, even if rapid is not instantaneous and thus a carbocation may react with the aromatic hydrocarbon before rearranging.[31]

It is well known that in Friedel-Crafts alkylations of the aromatic nucleus two types of isomerisations [32] may occur within the alkyl group. The isomerisation of the alkylating reagent, before the condensation with the aromatic hydrocarbon and the isomerisation within the resulted alkylation product, after the condensation.

The first types of isomerisation occur in the intermediate formed carbocation and involve 1,2-hydride ion shifts according to the well-known scheme of Whitmore.[33] These processes with low activation energies and entropies (unimolecular processes) are by far more rapid than the condensation (bimolecular reaction) and are catalysed by Friedel-Crafts catalysts (H_2SO_4, HF, BF_3, $FeCl_3$ and even $CH_3NO_2 \cdot AlCl_3$).

---

* Recently Olah [30] has proposed the generic name of *carbocation* for the organic cations with a fully or partially charge located at a carbon atom. The *classical* or tricovalent carbocations, should be named *carbenium ions*, whereas for the unclassical tetra- or pentacovalent carbocations the old nomenclature *carbonium ions* should be applied.

[33] F. C. Whitmore, *Chem Eng. News*, **26**, 668 (1948).

Geiseler, Herrman and Kürzel, [34] through kinetic measurement (in the alkylation of benzene with heptene in the presence of sulfuric acid) showed that the isomerisation rates of the carbocations is about 6 times faster than the alkylation rate.

The reactions of the formed alkylated product involve three steps :

a. hydride ion abstraction (bimolecular process),
b. isomerisation of the formed carbocation,
c. hydride ion abstraction (bimolecular process).

The overall reaction rate of such reactions is much lower than the isomerisation rate in the alkylating reagent, they are favoured by increasing temperature and involve thermodynamic controlled processes. These reactions are catalyzed by the complex acid $H[AlCl_3OH]$ which abstracts a hydride ion from the saturated hydrocarbon giving raise to carbocations able to rearrange.[35] It should be remarked that the stability of the isomeric phenylalkanes is different from the stability of the alkylcarbocations involved in the Friedel-Crafts alkylations. In the latter case the isomerisations of the carbocations occur irreversibily towards the most stable ions [32]

$$R^+_{prim} \rightarrow R^+_{sec} \rightarrow R^+_{tert}$$

whereas the stability of the phenylalkanes decreases in the order [36] primary > secondary >tertiary. This fact explains why during the intramolecular rearrangements of di- and poly-alkylbenzenes the normal chain is able to migrate without branching, the alkylated benzenes with uubranched chain being thermodynamic stable isomers.

3. Studying the condensation of some acids with different length of the chain, the general character of the rearrangement has been proved.

It has been proposed [25] that the hydride ion shift is determined by the inductive effect, electron attracting of the carboxyl group. This observation seems to be true for unsaturated acids with a six or shorter carbon atom chain. It is known that the inductive effect, in longer than a six carbon atom chain, is not sufficiently strong to affect the hydride ion shift. This effect decreases rapidly with the increasing length of the chain. [37] It has been shown [38] that the inductive effect of the carboxyl group can be resented up to the 4th carbon atom of the acid chain.

4. Thus, generally, the aluminium chloride condensation of α,β-unsaturated acids with benzene occurs through intramolecular hydride ion shift, the phenyl group being attached in a single position of the aliphatic chain, but, in different positions, in all possible positions, beginning with carbon 3 and ending with the last but one carbon atom.

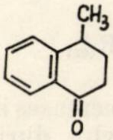
[38] P. Four and D. Lefort, *Tetrahedron Letters*, **1968**, 6143.

The phenyl group is never attached to the last (marginal) carbon atom (the formation of a less stable carbocation would be needed in that case) or in position 2, as the electron attracting inductive effect of the carboxyl group is opposing against to the hydride ion shift from that position.

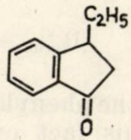
C. FORMATION OF KETONES

1. During the condensations of α,β-unsaturated acids, Nenitzescu, Glatz, Răzuş, [28] modyfying only a little the reaction conditions (higher temperatures, longer reaction times), have observed, without isolating the products, the formation of cyclic ketones corresponding to the phenylated acids. 2-Pentenoic and 2-hexenoic acids yield in these conditions, beside a mixture of phenylated acids, a mixture of cyclic isomeric ketones.

Ansell and Whitfield [27] working in the same conditions with 2-pentenoic acid have identified two ketones ; 4-methyltetralone **(5)** and 3-ethylindanone **(6)**



5

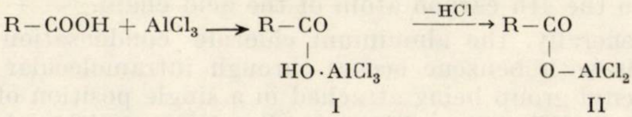


6

2. In the case of unsaturated acids with longer chain, such as 2-nonenoic acid, [39] the ketones are formed only from the phenylated acids with the phenyl group in the positions 3 and 4, substituted indanones or tetralones being thus formed. The isomeric acids with a remoter phenyl group react intermolecular with benzene yielding dihphenyl ketones (Scheme 2) *

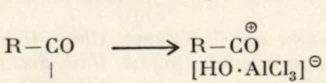
---

* In the condensation of saturated acids with benzene [40] result aliphatic aryl ketones. A high excess of aluminium chloride [41] is used in that case. The high excess of the catalyst is necessary to decrease as much as possible the activity of the water molecules resulted in the reaction. It is difficult to decide if the reactive intermediate has the structure I or II



$$\mathrm{R-COOH} + \mathrm{AlCl_3} \longrightarrow \underset{\substack{|\\ \mathrm{HO\cdot AlCl_3}\\ \mathrm{I}}}{\mathrm{R-CO}} \xrightarrow{-\mathrm{HCl}} \underset{\substack{|\\ \mathrm{O-AlCl_2}\\ \mathrm{II}}}{\mathrm{R-CO}}$$

If structure I is admitted, then the reaction proceeds through ion pairs



$$\underset{\substack{|\\ \mathrm{HO\cdot AlCl_3}}}{\mathrm{R-CO}} \longrightarrow \mathrm{R-C\overset{\oplus}{O}}\ [\mathrm{HO\cdot AlCl_3}]^{\ominus}$$

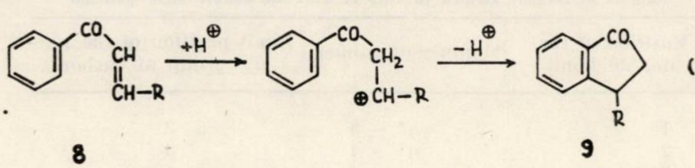
SCHEME 2

3. The cyclic ketones, obtained in that way do not isomerize even in very energetic conditions [28] (16 hrs in refluxing bezene with aluminium chloride). Thus, 5-phenyl-caproic acid was prepared from the lactone of 5-hydroxy-caproic acid [42] with benzene. This acid was then cyclized in the presence of aluminium chloride to 5-methylbenzosuberone (**7**), identical with that obtained by Julia and Bonnet [43] in another way. Ketone **7** does not isomerize in the above mentioned conditions.

4. Baddeley, Holt and Makar [44] have described cyclisations of aryl-vinyl-ketones (**8**; R=H or alkyl) and unsaturated acids (**8**; R = COOH) which proceed in the following manner



CO
CH
CH-R
+H⊕
CO
CH2
⊕CH-R
-H⊕
CO
R

(2)

8 **9**

As in the condensation of unsaturated acids, unsaturated ketones are not formed, the reaction must certainly proceed in another way, namely through cyclisation of the phenylated acids, resulted in the first step of the reaction.

D. UNSATURATED ACIDS WITH A REMOTER POSITION OF THE DOUBLE BOND

1. A series of researchers has studied the effect of the carboxyl group and of the position of the double bond upon the condensation products between benzene and unsaturated acids with six or more carbon atoms in the molecule.

2. In order to establish the effect of the carboxyl group on the condensations of the unsaturated acids, Four and Lefort [29] have compared the condensation products of 4-pentenoic and 10-undecenoic acids with the condensation products of 1-decene and of 9-octadecene. They have observed that in the case of the unsaturated acids, due to the inductive effect of the carboxyl group, the number of the phenylated isomers is less than for the mentioned alkenes.

3. Based on the fact that the phenyl group is never attached to the marginal methyl group, Four and Lefort [38] have shown that the number of the resulted phenylated isomers depends also on the position of the double bond in the chain of the starting unsaturated acid (table 1) :

Table 1

Number of isomers formed in respect with the double bond position

Position of the double bond	Number of isomers	Limit position of the phenyl group at carbon
1 ,	$n^* - 3$	3
2 ,	$n - 4$	4
3 beyond	$n - 5$	5

* n = number of the carbon atoms of the chain of the unsaturated acid.

In the latter case, the limit position of the phenyl group is Cδ, the inductive effect of the carboxyl group being no further felt beyond that atom.

Thus, considering the results obtained in that field the above mentioned authors have concluded that, generally from acids with the double bond located in α, β, if n is the number of carbon atoms of the chain, n-3 isomers are formed ; from β, γ-unsaturated acids, result n-4 isomers, whereas from unsaturated acids with the double bond beyond the δ position (without respect to the distance) $n - 5$ isomers are formed.

Ansell and Whitfield [39] have studied the condensation of pentenoic acids (2-, 3- and 4-) obtaining results in agreement with those observed with the six and nine carbon atoms acids. In the case of 2-nonenoic acid they proved the formation of different phenylated acids. The same authors have completed the condensations performed by Four and Lefort, arriving at similar results with respect to the inductive effect and the effect of the position of the double bond. In table 2 are given the known results obtained until now in the condensation of alkenoic acids with benzene, at 40–45°.

Table 2

Phenyl-alkane-carboxylic acids: position of the phenyl group in the chain

Starting acid	Position of the double bond	Resulted isomers Position of the phenyl group	Ref.
Pentenoic	2,3	3 4	38,39
	3,4	4	38
	4,5	4	38,39
Hexenoic	2,3	3 4 5	28,39
	3,4	4 5	39
	5,6	5	39
Heptenoic	2,3	3 4 5 6	39
	4,5	traces 5 6	38
	6,7	5 6	39
Octenoic	2,3	3 4 5 6 7	39
	3,4	4 5 6 7	39
	7,8	5 6 7	39
Nonenoic	2,3	3 4 5 6 7 8	39
	8,9	3 4 5 6 7 8	39

4. Four, [45] studying the aluminium chloride catalyzed condensation of benzene with unsaturated acids and nitriles established that the number of phenylated isomers depends equally on the position of the double bond with respect to the functional group and on the nature of that group.

5. The acids with a remote double bond (8-nonenoic acid) [39] do not yield cyclic ketones in the conditions discussed above (chap. II, C. 1.) as no isomers, able to cyclize to indanone or tetralone, are formed. These acids give only diphenylketones (see Scheme 2).

E. OLEIC ACID

1. The aluminium chloride condensation of oleic acid with benzene was known and discussed[45-52] long since in the literature, even if the structure of the products resulted in this reaction was not established. Most of the authors considered that the reaction mixture consists of 9- and 10-phenyl-stearic acids. [53-56]

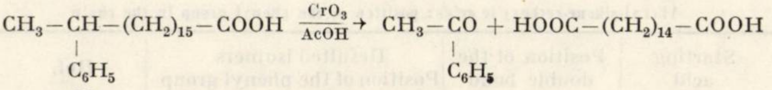
[52] N. P. Buu Hoï and P. Cagniant, *Bull. Soc. chim. France*, **10**, 477 (1943).

Nenitzescu and Glatz [23,25,57] have demonstrated that in the intermediate carbocation, generated from the unsaturated acids with a longer chain than a six carbon atoms chain, hydride ion shifts occur up to the last but one carbon atom. This has been borne out in the case of oleic acid too, when 17-phenylstearic acid was detected among the reaction products. Its existence has been proved through oxidation of the reaction mixture with chromic acid and the indentification of acetophenone and 1,14-tetradecanedicarboxylic acid.

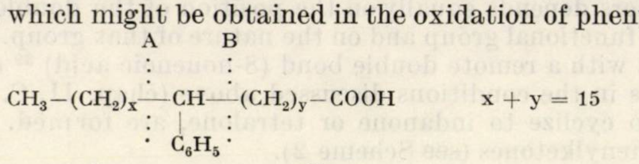


$$\mathrm{CH_3-\underset{\displaystyle C_6H_5}{\underset{|}{CH}}-(CH_2)_{15}-COOH \xrightarrow[AcOH]{CrO_3} CH_3-\underset{\displaystyle C_6H_5}{\underset{|}{CO}} + HOOC-(CH_2)_{14}-COOH} \qquad (4)$$

10

The lack of modern investigation methods has not permitted, at that time, the performance of exact quantitative measurements.

2. Later, Smith, Stirton, Kenney and Doodley [58,59] have treated oleic acid with different aromatic hydrocarbons (benzene, toluene, xylene etc.). They tried to determine, through vpc, the number of the resulted arylated isomers, after converting the reaction products in a mixture of the corresponding methyl esters. The method proved to be tedious and inconclusive, since the esters of phenylstearic acids cannot conveniently be separated. Through chromic acid oxidation of the mixture of the arylated acid obtained in the reaction, Smith, Kenney and Stirton, [58] succeeded in the identification of the arylated acids present in the reaction mixture. Using the scheme of Cason, Fesenden and Agree [60] advanced for the oxidation of some alkanoic acids, substituted with mehyl groups in the chain, the above mentioned authors have formulated a scheme of all possible products which might be obtained in the oxidation of phenylstearic acids



$$\mathrm{\underset{I}{CH_3-(CH_2)_x}\overset{A}{\vdots}\underset{\displaystyle C_6H_5}{\underset{|}{CH}}\overset{B}{\vdots}\underset{II}{(CH_2)_y-COOH}} \qquad x + y = 15 \qquad (5)$$

A – I $\mathrm{CH_3-(CH_2)_{x-1}-COOH}$ B – I $\mathrm{C_6H_5-CO-(CH_2)_x-CH_3}$

A – II $\mathrm{C_6H_5-CO-(CH_2)_y-COOH}$ B – II $\mathrm{HOOC-(CH_2)_{y-1}-COOH}$

[59] F. D. Smith, A. J. Stirton and C. J. Doodley, *J. Amer. Oil Chemists Soc.*, **45**, 747 (1968).

[60] J. Cason, J. S. Fesenden and C. L. Agree, *Tetrahedron*, **7**, 289 (1959).

From a molecule of phenylstearic acid, three types of acids might be formed, i.e. a very complex reaction, whereas only a single neutral product (B — II) accompanies the acids in the mixture (phenone). Thus, the gas-chromatographical analysis of the neutral oxidation products, might give correct information about the mixture of isomeric phenylstearic acids. The method gave the expected results : 12 ketones were found. Through vpc-comparison with authentical samples were identified : acetophenone, propiophenone, valerophenone and laurophenone ; thus, the existence of the corresponding phenylstearic acids in the mixtures has been proved.

3. According to Smith, Kenney and Stirton [58] the condensation of oleic acid proceeds similarly to the reaction of the other unsaturated acids : in the first step, the formation of a carbocation through proton addition to the double bond, then a series of hydride ion shifts follows in which 12 carbocations are formed. The limit position of the location of the position charge is at C_6 and C_{17}, each of these carbocations gives raise to phenylated acid, altogether 12 isomers. The above authors postulated that the proton is transferred from the complex acid $H^+[AlCl_4]^-$. It has been long since established [61–63] that this acid does not exist. Nenitzescu, Avram and Şiliam [35] have demonstrated that in those cases, the proton is given up by the initial acid $H^+[AlCl_3OH]^-$.

F. FORMATION OF LACTOID IONS

The number of the formed phenylated isomers, in the above discussed reaction, is limited by the formation of lactoid ions.

1. Fittig [64,65] and later other authors have shown that in strong acid medium, [60,66–68] the unsaturated acids converted in γ-and δ-lactones, respectively their stability depending on the structure of the acid and on the rection conditons. The analysis of the condensation products of oleic acid [58] indicates the absence from the reaction mixture of the phenylstearic acids with the phenyl group located in positions 5, 4, 3 or 2. In agreement with what was shown above, the absence of these isomers was ascribed to the formation of a δ-lactone which does not further allow the hydride ion shift from the neighbouring positions and implicitly the condensation with benzene

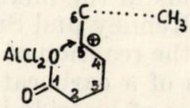
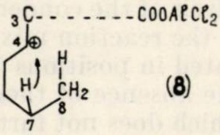
2. Four and Lefort[38] have demonstrated the dependence of the location of the phenyl group on the position of the double bond from the unsaturated acid namely, if the double bond is placed at Cδ or further remote from the carboxyl group, the phenyl group might be attached in all possible positions between the last but one carbon atom and C_5, that is in this position the isomerisation is restricted. This restriction has been ascribed by Four and Lefort to the formation of pseudo-δ-lactonic cycle



(7)

hindering the migration of a hydride ion from C_4 to C_5 and thus the formation of a carbocation with the positive charge at C_4.

The formation of only 5-phenyl-caproic acid from δ-caprolactone[28] in Friedel-Crafts condensations, pleads in its turn for the formation of a lactoid intermediate in the condensation reactions of unsaturated acids. It would have been expected that in the case of 3-octenoic acid the formation of a pseudo-δ-lactonic cycle would restrict the isomerisation at C_5 and would prevent the formation of phenylated acids with phenyl groups in positions 6 and 7. Actually these isomers do exist in the reaction mixture. Four and Lefort have explained the observed disagreement by admitting a hydride ion shift from C_6 to C_5 (nondependent on the inductive effect (7)), or less probably, through a transannular shift[69] (8) from C_7 to C_4 leading to the formation of carbocations with the positive charge at C_6 and C_7:



(8)

Ansell and Whitfield,[39] studying the reaction products with respect to the position of the double bond, obtained results in good agreement with Four and Lefort, but explained their results in a different manner. They do not admit the hypothesis of a transannular hydride shift ascribing the limitation of a number of phenylated acids to the different ease of the carbon atoms from the chain to form carbocations. They suggest the following sequence of this easiness

$C_\omega < C_{\omega-1}$	$C_{\omega-2} \sim C_7 \sim C_6 \sim C_5$	$> C_4 \gg C_3 \ggg C_2$
decreasing ease of formation	the same ease of formation	decreasing ease of formation
⟵	⟵⟶	⟶

---

[69] Reference 9, p. 320.

How can this sequence be explained? The carboxyl group reacts, in the first step, with aluminium chloride yielding an ion pair, as in the acylation of benzene

$$-CO_2.AlCl_2 \rightleftharpoons -\overset{\oplus}{C}O^{\ominus}OAlCl_2 \qquad (9)$$

In a similar way, the above mentioned authors consider that the intermediates involved in the rearrangements that occur in those reactions are not carbocations but light ion pairs with a certain covalent character between the carbocation center and the tetrachloro-aluminate ion. The 1,2-shifts, involved in these nucleophilic rearrangements, are stereochemically controlled, [70] since the hydride ion attacks the neighbouring carbon atom on the opposite side to that of the displaced $AlCl_4^-$ ion.

Accordingly, there will exist only a few preferential conformations in which the hydride ion shift could be possible. Using Newman's projections, Ansell and Whitfield propose two types of conformations.

The decrease of the tendency of formation of the carbocations with the positive charge located in position 4 is due to the inductive effect of the carboxyl group.

3. Another fact that pleads in the favour of the formation of lactoid ions is the difference in the observed behaviour in the condensation of some α, β-unsaturated ketones as compared with that of the α, β-unsaturated acids. Nenitzescu and Gavăt [21] observed in the condensation of hexene-3-one the formation of a phenylated ketone in the position 5, identified through the isolation of a solid compound, whereas Ansell and Mahmud [17] (with modern investigation methods) found ketones **11** and **12** in a relative ratio of respectivly 38 and 62 % that is in a different ratio (reverse order) than that determined in the condensation of unsaturated acids with the same number of carbon atoms in the chain. [28,29] This difference might have the following explanation : the inductive effect of carbonyl group is product-controlling in the condensation of unsaturated ketones, whereas in

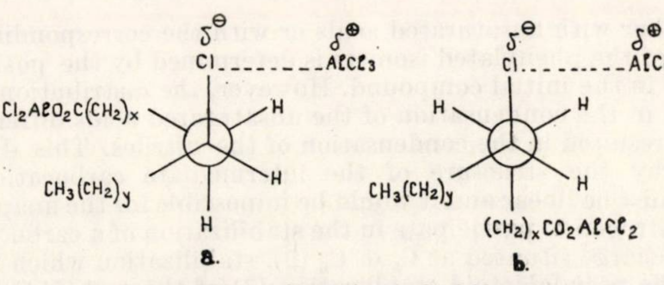


Fig. 1. *a.* Favourable conformation to hydride shift ; *b.* Unfavourable conformation to hydride shift.

---

[70] D. J. Cram and F. D. Green, *J. Amer. Chem. Soc.*, **75**, 6005 (1953) ; reference 25, p. 270.

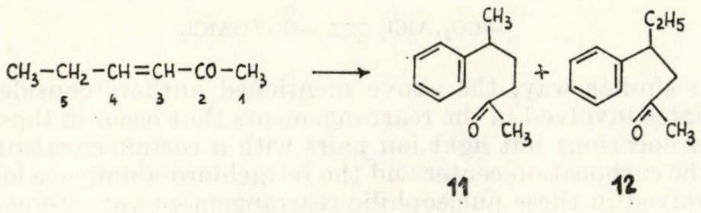
the similar reaction of the unsaturated acids, another factor determining the stability of the cationic intermediate is involved : the formation of a more stable ion than a carbocation, a lactoid ion.

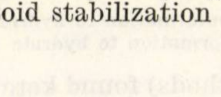


G. EFFECT OF THE FUNCTIONAL GROUP

1. Smith, Stirton and Doodley[59] observed that the distribution of the phenylated isomers is about the same either starting from the nitrile, ester, octadecylic alcohol or from oleic acid.

Comparing unsaturated acids with the corresponding nitriles Four[45] has demonstrated that the number and the relative ratio of the phenylated isomers is equelly determined by the position of the double bond and the nature of the functional group. Thus he has shown that in all the considered cases, the isomer formed in overwhelming weight is the isomer with the phenyl group situated at the last but one carbon atom, due to the stabilization through hyperconjugation of the sp^2 carbon atom with the methyl group.

2. Either with unsaturated acids or with the corresponding nitriles, the number of the phenylated isomers is determined by the position of the double bond in the initial compound. However, the distribution of the isomers formed in the condensation of the unsaturated acids differs from the distribution resulted in the condensation of the nitriles. This difference is determined by the structure of the intermediate carbocations. Thus, $C_2-C_1\equiv N$ must be linear and it would be impossible for the unapaired electrons from nitrogen to participate in the stabilization of a carbocation with the positive charge situated at C_5 or C_6 (9), stabilization which would correspond to the pseudolactoid stabilization (7) of the carbocations derived from unsaturated acids



(10)

Table 3 includes comparative results of the phenylation of three unsaturated acids and their corresponding nitriles. It shows that with one exception (which hardly could be named so) the number of the formed isomers does not change from acids to nitriles. However, the remotest position of the phenyl group, is preferred in the case of the nitriles. The different isomers distribution might be explained through the more powerful in

Table 3

Comparative data between phenylated product formed from unsaturated acid and nitriles

	Ethylenic acids and nitriles	% of different phenylated isomers Phenyl bonded at carbon atom

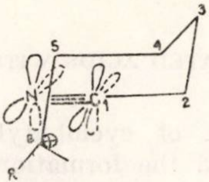
ductive effect of the CN group,* or, probably, through an extra stabilization of the positive charge in one of the different conformation of the carbocation** (11)



III. CONDENSATIONS OF SOME UNSATURATED ALICYCLIC ACIDS WITH BENZENE

A. GENERAL CONSIDERATIONS

In the series of alicyclic unsaturated acids will be discussed the results obtained in the condensation of alicyclic α, β-unsaturated acids containing an exocyclic double bond with a four-, five- and six-membered ring, each example being represented by a single compound. Occasionally, some related results, observed with the corresponding endocyclic double bond in the unsaturated acids, will be mentioned. Generally, these condensations have been performed in the same conditions as in the case of aliphatic α,β-unsaturated acids. Mixtures of isomeric phenyl-alicyclic acids have been obtained, in which the phenyl group is located to different cyclic carbon atoms up to the remotest carbon atom from the carboxyl group. [15,21,72]

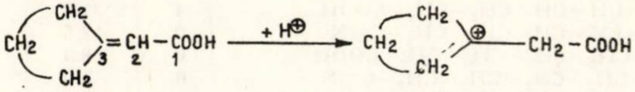
---

* We may consider as measure of the inductive effects, the σ-values (s. for exemple J. E Leffler and E. Grunwald, "Rates and equilibria of organic reactions", John Wiley, New York 1963, p. 223). The σ_{CN} values are definitely higher than the σ_{COOH} values.

** In solution, the conformations requiring the smallest volume (such as in (11)) are preferred.

[72]. A. M. Glatz, A. C. Răzuş, F. Badea and C. D. Nenitzescu, *Rev. Roumaine Chim.*, **16**, 1567 (1971).

As in all similar reactions, the first step is the formation of a carbocation through proton addition to the alkenic double bond. This carbocation may further isomerize in a more stable lactoid ion or in another carbocation yielding different isomeric phenylated acids. Cosequently, no acid with t he phenyl group located in position 3 has ever been observed



Beside the already mentioned reactions, the intramolecular hydride ion shifts, with the formation of lactoid ions, the formation of benzo-bicyclic ketones, hydrogenating ring-openings, through intermolecular hydride ion transfer (cyclobutane-derivatives) have been also observed.

B. ALICYCLIC UNSATURATED ACIDS WITH CYCLOBUTANIC RING

1. In the condensation of cyclobutylideneacetic acid [73,74] with benzene [75] has been observed the formation of a mixture of $C_{12}H_{16}O_2$ acids (branched phenyl-hexanoic acids)together with a $C_{12}H_{14}O_2$ acid (*trans*-2 phenyl-cyclobutylacetic acids), a diphenylated acid $C_{18}H_{16}O_2$ and a small proportion of ketones $C_{12}H_{14}O$ (table 4). The identification of the isomeric

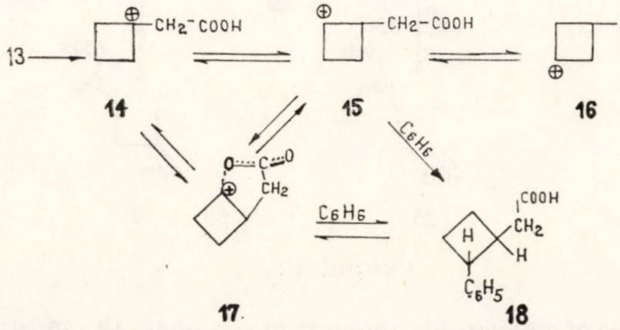
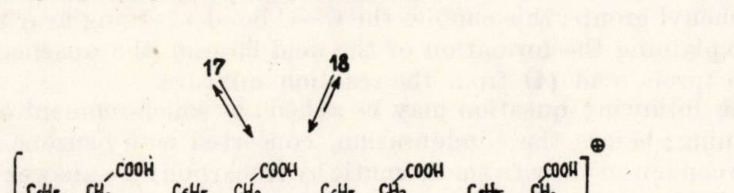
acids in the reaction mixture has been done through gas-chromatographic comparison of the corresponding methyl esteres with authentic samples.

2. Thus, as in all similar reactions, the first step, implies the addition of a proton to the alkenic double bond of the acid **13**, forming the carbocation **14**. In this ion, hydride ion shifts are possible, with the subsequent formation of the carbocations **15** and **16**.

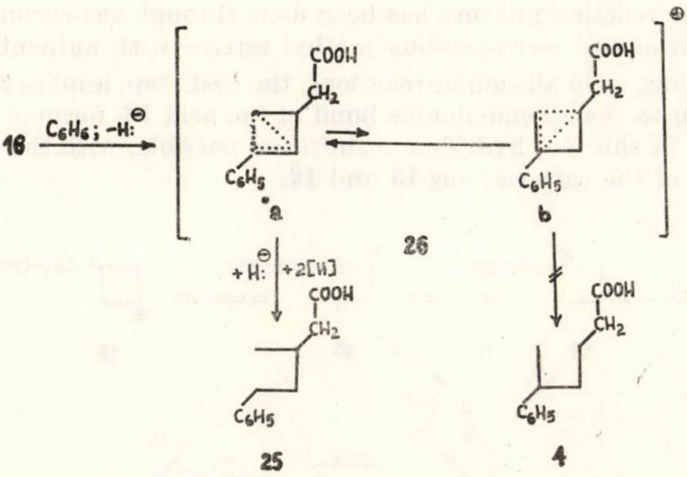


Each of these intermediate ions might suffer different transformations. Thus, the carbocation **15** rearranges in a more stable lactoid ion **17**.[61] That intermediate, through a stereospecific attack of benzene, should yield *trans*-2-phenyl-cyclobutylacetic acid (**18**).

3. *Ring openings*. The acid **18** is the single reaction product preserving the initial cyclobutane ring. The formation of $C_{12}H_{16}O_2$ acids occurs through ring opening (Schemes 3 and 4):



SCHEME 3



SCHEME 4

The presence of comparable amounts of the acids **19**, **20**, **21**, suggests a common intermediate, which might be the cyclobutonium ion **22**, represented in the four structure *a*, *b*, *c* and *d* (Scheme 3). These structures generate the acids **19**, **20**, **21** and, probably, the acid **23**, in small amounts.

The major component is 3-methyl-5-phenyl-valeric acid (**25**), formed from the carbocation **16**. That ion, through simultaneous benzene attack and hydride ion abstraction gives the bicyclobutonium ion **26** represented in structures *a* and *b* (Scheme 4). The equilibrium between structure *a* and *b* is favourable to structure *a*, having the maximum charge delocalization in the phenyl group ; this enables the C—C bond breaking near the pheny group explaining the formation of the acid **25** and the absence of the 5-iphenyl-caproic acid (**4**) from the reaction mixture.

The following question may be asked : at which moment occurs the ring opening : before the condensation, concerted with benzene attack or after the condensation with the aromatic hydrocarbon? To answer this question, a sample of acid **13** in carbondisulfide was refluxed in the presence of aluminium chloride several hours, without any change in its structure. This fact, together with the absence of 5-phenyl-caproic acid from the reaction mixture indicates that the ring opening does not take place before the condensation of the acid 13 with benzene. The presence of 5-phenyl-caproic acid would have confirmed the ring opening before the condensation and its formation from the bicyclobutonium ion **26** *b*.

The bicyclobutonium ions may arise either through benzene attack at the lactoid ion **17** or after the formation of the acid **18** or 3-phenyl-cyclobutylacetic acid simultaneously with the abstraction of hydride ions. To distinguish between these two alternatives, *trans*-2-phenyl-cyclobutylacetic acid (**18**) has been submitted to the same conditions described above for the acid **13**. In that case, 4-phenyl-caproic (**19**) and 3-methyl-4-phenyl-valeric (**20**) acids were identified through vpc, pleading thus for a ring opening after the formation of acid **18**.[76] The question, however, has not been completly elucidated.

4. *Intermolecular hydride ion transfers*

a. General considerations

It is well known that the intermolecular hydride ion transfers [23,77,79*] occur according to certain rules : [77,78,80]

1. In the reactions in which hydride ion changes its position, the hydride ions never become free. 2. In such reactions, in the reaction mixture, hydride donors and acceptors must exist. Compounds able to generate stable carbocations are powerful hydride donors; unstable carbocations (or their precursors) are efficient hydride acceptors. 3. intermolecular hydride ion transfers are stepwise reactions.

The theory of carbocation intermediate in the intermolecular hydride ion transfer was proposed by Bartlett, Condon and Schneider[61] and demonstrated through an intermolecular hydrogen-halogen transfer. The driving force of an intermolecular hydride ion transfer consists usually in the energy of formed acceptor-hydrogen bond and the disappearence of the carbocation.[81]

There are known a large number of intermolecular hydride ion transfer reactions occurring in condensations catalysed by aluminium chloride; these reactions were observed for the first time by Nenitzescu and Ionescu[77,82,83] in the reaction of alkyl halides with cyclohexane and aluminium chloride. Similar reactions were also observed by Nenitzescu and Isăcescu[84,85] in Anschütz type condensations of phenyl-chloro-propane and in acetylation and benzoylation of 9,10-dihydroanthracene.[86]

In the reaction of cyclohexane and acetyl chloride, catalyzed by aluminium chloride, Nenitzescu and Cantuniari[87] observed, beside the ring contraction and the formation of saturated ketones, the appearance of unsaturated cyclic ketones with a five-membered ring.

Nenitzescu and Ciorănescu,[88] in the condensation of cyclohexane with acetyl chloride in cyclohexane in the presence of aluminium chloride, have shown that the saturated hydrocarbon is able to hydrogenate the reaction products between the alkene and the acylating agent; similar results have been also obtained with other cycloalkenes.[89] These acylation reactions involve the intermolecular hydride ion transfer from the added saturated hydrocarbon to the intermediate carbocation resulted in the acylation. Such reactions are known in the literature as "Nenitzescu's reductive acylations".[90,91]

---

* According to an earlier nomenclature the hydride ion transfer is named "hydrogen transfer"; see reference 79.

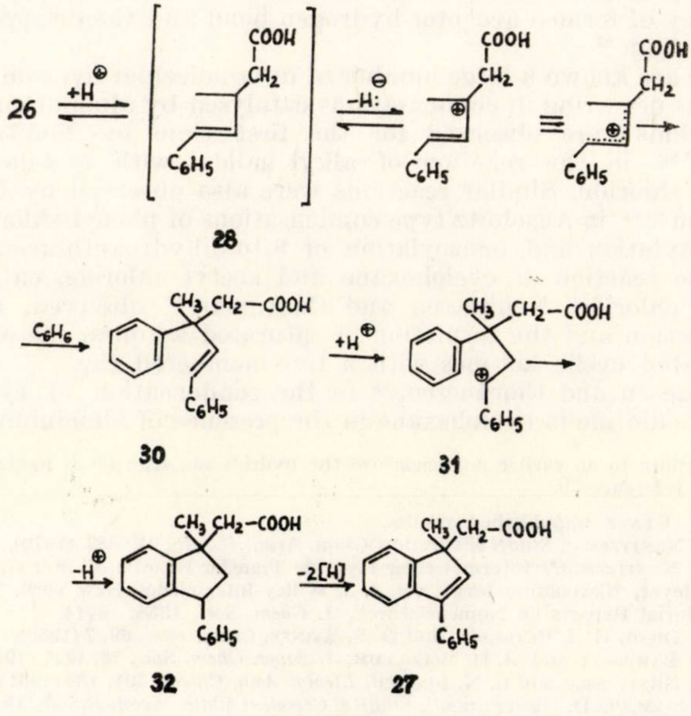
b. The formation of the acids $C_{12}H_{16}O_2$, instead of the expected acids $C_{12}H_{14}O_2$, containing no four-membered ring products, in the condensation of cyclobutylideneacetic acid,[75] was explained by a ring opening followed by hydrogenation occurring through intermolecular hydride transfer. The presence in the reaction mixture of a crystalline acid (m.p. 140°), poor in hydrogen, $C_{18}H_{16}O_2$, indicated this acid as stabilization product of some intermediate hydride-donors. Its structure was established through IR, UV, NMR. The structure corresponds to 1-methyl-3-phenyl-indenylacetic acid **(27)**, formed from a common intermediate **(26)** with the acid **25** (Scheme 5).



SCHEME 5

[90] Reference 6, b. p. 376.

[91] J. E. Gowan and T. S. Wheeler, "Name Index of Organic Reactions", Longmans, London, 1962, p. 179.

This sequence of reactions involves a series of intermolecular hydride transfers. In the Friedel-Crafts reaction conditions the hydride abstractions are much favoured. The great proton mobility in these substituded indenes is well known, it has been studied and measured.[92-94] In the case of the formation of the acid **27**, the extention of the conjugation (facilitated by a quaternary carbon atom) **(32→27)** as well as the presence of some unsaturated intermediate in the reaction medium, are the motor of hydride abstraction. These intermediates (the bicyclobutonium ions **22** and **26**) act as hydride acceptors which allow the intermolecular hydride transfer.

5. *Formation of ketones*

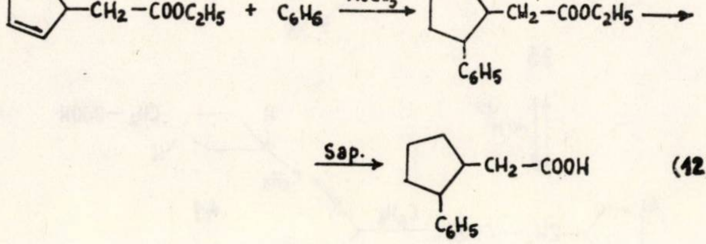
In the condensation of cyclobutylideneacetic acid **(13)** the formation of ketones (Table 4) $C_{12}H_{14}O$ was pointed out, a mixture of ketones similar to that obtained from the cyclisation of the isomeric phenyl-hexanoic acids, obtained in the first step of the reaction. The ketones were not identified.

C. ALICYCLIC UNSATURATED ACIDS WITH CYCLOPENTANIC RING

1. The first observation that in the condensation of 1-cyclopentenyl carboxylic acid a phenylated acid is formed in which the phenyl group is bound to the remotest carbon atom with respect to the carboxyl group (position 3) belongs to Nenitzescu and Gavăt. [21]

Later, the formation of a mixture of two isomeric phenylated acids [95] has been reported by Baker and Leeds.

Buu Hoï and Cagniant[96] have condensed the ester of 2-cyclopentenyl-acetic acid with benzene and after hydrolysis have obtained a phenylated acid which they considered to be 2-phenyl-cyclopentylacetic acid



(42)

---

[92] C. D. Nenitzescu, I. Necşoiu and M. Adlersberg, in "Lucrările Consfătuirii Româno-Sovietice din 3–4 dec. 1959", Acad. R.P.R., Bucureşti, 1959, p. 213.

[93] A.M. Weidler and G. Bergson, *Acta Chem. Scand.*, **17**, 862, 1798, 2724 (1963); **18**, 1487 (1964).

[94] C. K. Ingold and R. Piggott, *J. Chem. Soc.*, **123**, 1469 (1923).

[95] W. Baker and W.G. Leeds, *J. Chem. Soc.*, **1948**, 974.

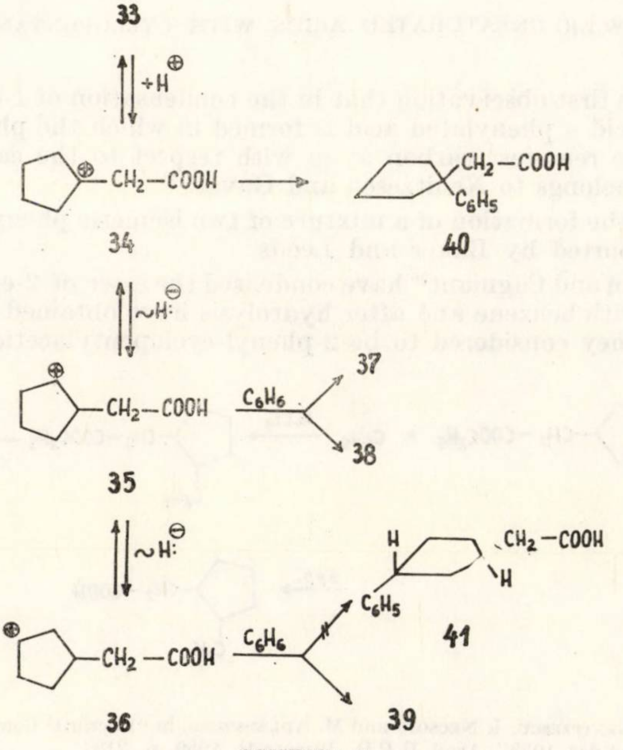
[96] N. P. Buu Hoï and P. Cagniant, *Compt. rend.* **220**. 744 (1946).

Repeating this reaction, Mousseron, Winternitz and Rouzier[97–99] have shown that the reaction product obtained by the above authors is actually a mixture of *cis* and *trans*-3-phenyl-cyclopentyl-acetic acids, together with a small amount of the 2-phenyl-cyclopentylacetic acid.

These disagreements, as well as the results obtained with acyclic α,β-unsaturated acids, [28] determined new investigations in the series of alicyclic α,β-unsaturated acids, namely cyclopentyldeneacetic acid.

2. *Formation of lactoid ions*

In the condensation of the cyclopentylideneacetic acid (**33**) with benzene, [72] in the usual conditions, [22] a mixture of three acids was obtained: *cis*-2-(**37**), *trans*-2-(**38**) and *cis*-3-phenyl-cyclopentylacetic (**39**) acids, in molar ratio **37** : **38** : **39** = 3 : 47 : 50. The absence of a phenylated acid at position 1 (**40**) must be remarked in that case too, as well as the absence of *trans*-3-phenyl-cyclopentylacetic acid (**41**) and the preferential formation of acids **37** and **38** (Scheme 6)



SCHEME 6

The involvement of carbocations **34**, **35** and **36**, as reaction intermediates, cannot explain the stereoselectivity of the reaction as well as the

SCHEME 7

The absence of a phenylated acid in position 1 (of the cyclopentane ring) is due to the formation of a more stable lactoid ion **42**, which might yield, in stereospecific attack [100] of benzene the acid **38**. The procursor carbocation **35**, in a nonstereospecifical reaction, forms the *cis*-isomer **37** (beside **38**). The formation of a benzylic ion **45** or a phenonium ion **46**, sterically unfavourable, explains the small amount in which **37** is present in the reaction mixture.

3. *Other unsaturated acids with cyclopentane ring*

Cyclopentylacrylic acid has been condensed, in the usual manner, with benzene, [101] at 40—45°. Phenylated cyclopentyl-propionic acids, besides phenylated cyclohexylacetic acids were obtained, the cyclohexane derivatives being in overwhelming ratio in the reaction mixture (molar ratio : cyclohexane derivatives : cyclopentane derivatives = 6 : 1). The formation of phenylated acid in the β position of the initial unsaturated acid was also observed. These facts point out to the following conclusions

---

[100] J. I. Brauman and A. J. Pandell, *J. Amer. Chem. Soc.*, **89**, 5421 (1967).

[101] A. M. Glatz, V. Wertheimer and F. Badea, *Rev. Roumaine Chim.*, **19**, 87 (1974).

a. The presence or absence of a β-phenylalkanoic (or cycloalkylalkanoic) acid in the reaction mixture must be determined by the nature of the β-carbon atom (secondary or tertiary). If tertiary, as in cycloalkylideneacetic acids, the β-carbon atom never attacks a phenyl group in the condensation.*

This observation could be rationalized admitting steric hindrance, as obvious from the examination of models.

b. The preference for the formation of cyclohexyl derivatives, in the mentioned reaction, and the total absence of a cyclohexyl derivative in the condensation of cyclopentylideneacetic acid, demonstrated in its turn that hydride ion shift, in such reactions, never occurs from the α-position. The strong inductive effect, felt in that position, must be responsible and it overwhelms the higher stability of the cyclohexane-derivatives.

4. *Isomerization of phenylated acids*

cis-3-Phenyl-cyclopentylacetic acid **(39)**, the major component of the reaction mixture resulted in the condensation of cyclopentylideneacetic acid, might be directly formed from carbocation **36** or from acid **38**, through the intermediate formation of a phenonium ion,[102] **43** and a benzylic ion **44**.

The isomerization of acid **38** was experimentally confirmed. A mixture of acids **37**, **38** and **39**, treated in the condensation reaction conditions with aluminium chloride, was enriched in acid **39** at the cost of isomer **38**, the ratio of isomer **37** being practically unchanged.

The absence of *trans*-3-phenyl-cyclopentylacetic acid **(41)** is explained either by the impossibility of a *cis* attack of a hydride ion in benzylic ion **44**, or by the low stability of *trans*-1,3-disubstituted cyclopentane derivatives.[103-107]

cis-3-Phenyl-cyclopentylpropionic acid is readily isomerized into the *trans*-2-phenyl-cyclopentylpropionic acid, whereas phenyl-cyclopentylpropionic acids never isomerize into cyclohexyl derivatives.[101] The absence of the equilibration between five- and six-membered ring derivatives, in those conditions, even if equilibrium is attained in the five membered ring derivatives, must be considered as a clear demonstration of the importance of inductive effects of the carboxyl group in those reactions. As the carboxyl group, judging from the σ-values, seems not to be a very powerful electron attracting group, the result points out that the carboxyl group is transformed, in the reaction conditions, in a more efficient group, that is in anion pair in agreement with equation (9), which explains also the cyclisation reaction, which will be discussed in the following section.

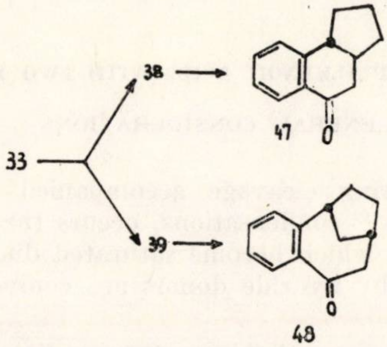
5. *Formation of benzobicyclic ketones*

If the condensation of the unsaturated acid **33** is performed in refluxing benzene, instead of the phenylated acids **38** and **39**, the benzobicyclic ketones **47** and **48** are obtained in a similar mechanism as that described for the acyclic α, β-unsaturated acids (Chapter II C)



(13)

6. The condensation reaction of acid **33** with benzene might be used in preparative purposes, for the preparation of acids **38** and **39** as well as for ketones **47** and **48**. All these compounds might be obtained in that way with pure and relatively good yields.

D. ALICYCLIC UNSATURATED ACIDS WITH CYCLOHEXANE RING

The Friedel-Crafts condensations of acids of that type, although known long since (1937) were only scarcely studied.[108] Ghosh [109] has described the condensation reaction of 1-cyclohexenylacetic acid with benzene in the presence of aluminium chloride and has indicated 2-phenylcyclohexylacetic acid as the single reaction product.

Simultaneously, Cook and Goulden [110, 111] and Nenitzescu and Gavăt [15] isolated in the same reaction, 4-phenyl-cyclohexylacetic acid, whose structure was proved through an independent synthesis of the compound

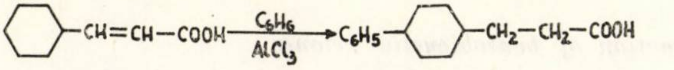
(14)



(15)

They have shown that cyclohexylacrylic acid, in the same conditions forms a phenylated product with the phenyl group situated in position 4 of the cyclohexane ring.

IV. CONDENSATIONS OF ALKENOIC ACIDS WITH TWO DOUBLE BONDS

A. GENERAL CONSIDERATIONS

The cyclobutane ring cleavage accompanied by hydrogenation during the Friedel-Crafts [75] condensations, occurs through allylic carbocations as intermediates, which become saturated due to intermolecular hydride transfers, whereby hydride donors are compounds with indane skeleton.

Based on the assumption that some intermediates of these reactions may be unsaturated acids with two double bonds containing six carbon atoms, the behaviour of sorbic acid in such kind of reactions has been studied.

B. SORBIC ACID

1. In an earlier paper, Nenitzescu and his coworkers [22] have prepared 5-phenyl-caproic acid **(4)** (as an authentical sample) with sorbic acid as starting material. The scope of this reaction was at that time a pure preparative one.

2. Later [112] it has been established that the acid 4 resulted from the condensation was one of the major reaction products, as comparable amounts of 4-phenyl-caproic **(19)** and 3,5-diphenyl-caproic **(53)** acids besides smaller quantities of *cis*- and *trans*-methylindenylacetic acid **(50** and **51)** and 5-phenyl-hex-3-ene-oic acid **(52)** (table 5). The neutral products of this reaction are hydrocarbons and not, as usually,[20,21,27,61] mixtures of ketones and hydrocarbons. Among these products two unsaturated hydrocarbons with indene skeleton (**54** and **55**) were isolated and identified.

SCHEME 8

The relative high and comparable yields of the reaction products **4**, **15** and **53** show that in this case alkylation of benzene and hydrogenation are the main reactions.

The acids **56** and **57** react with benzene only in the 4 and 5 positions, respectively, because inductive and allylic conjugation effects act together. The resulted acids **58** and **59** are hydrogen acceptors and give rise to the acids **4** and **19**.

Another fact which points the two combined effects is the absence of a monophenylated acid in position 3, as well as the absence of 4- and 5-diphenylated acids, whose presence should have involved, in the first step, a carbocationic center at the position 3.

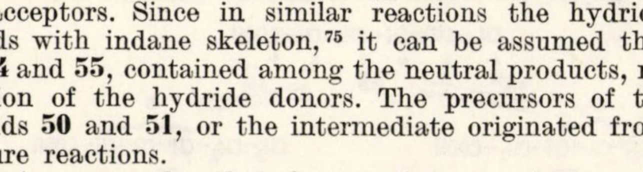
3. A hydride ion abstraction from the unsaturated acid **58**, favoured by the formation of an allylic benzylic carbocation **60**, leads by benzene condesation to the 3,5-diphenyl-capronic acid **(52)**.

4. The hydrogenation of the acids **58** and **59** represents an example of intermolecular hydride ion transfer, from donor compounds to unsaturated acceptors. Since in similar reactions the hydride donors are compounds with indane skeleton,[75] it can be assumed that the hydrocarbons **54** and **55**, contained among the neutral products, result from the stabilization of the hydride donors. The precursors of these could be either acids **50** and **51**, or the intermediate originated from **59** through yet obscure reactions.

5. It is noteworthy, that the secondary reactions promoted by intermolecular hydride transfers (which were taken into account in all cases of the present paper) take place only if the main reaction requires this, as in the case of cyclobutylidene [75] or sorbic acids. [112]

A valuable proof of this observation was achieved in the condensation of a phenylated unsaturated acid with one double bond, [113] able to generate an indane skeleton, namely the 3-phenyl-5-hexenoic acid **(61)**.

Among the condensation products of acid **61** there were only three acids identified: *cis*- and *trans*-methyl-indaneacetic acids **(50** and **51)** and 3-methyl-phenyl-indaneacetic acid **(62)**, their molar ratio being: 50 : 51 : 62 = 43.9 : 52.8 : 3.4 %



(16)

61 60 and 51 62

6. In the case of acids with two double bonds the course of the condesation becomes more complex. In the present stage of research the following facts could be established: formation of mono-plenylated acids saturated by intermolecular hydride transfer, formation of diphenylated acids, indane and indene compounds (acids and hydrocarbons, respectively).

---

[113] A. M. GLATZ, unpublished data.

Unlike the condensation of unsaturated acids with one double bond, neither intermolecular hydride transfer, nor ketone formation was observed during these condensations.

According to the observations, the rate of cyclisation to compounds with indane skeleton exceeds the rate of condensation with benzene (the case of diphenylation). Knowing that indane compounds are generally good hydride donors it can be noticed that hydride donation occurs only if is required by some unsaturated compounds present in the reaction mixture; under the same conditions they do not undergo any change if such unsaturated products are not present.

V. CONCLUSIONS

During the researches concerning aluminium chloride-catalyzed condensations of unsaturated acids with benzene, several data regarding the complex pathways of these reactions were established.

1. The condensation of alkanoic and alicyclic unsaturated acids, at 40—45°, takes place through intramolecular hydride ion transfer to the carbocation formed in the first step of the reaction.

In this way other carbocations are formed, able to generate a number of isomeric phenylated acids. This observation has a general character regarding the acids with one duble bond.

2. The phenylation of alkenoic acids takes place not only in one position of the alkanoic chain, but, with different proportions, in all possible positions (depending on the position of the double bond [27, 28, 38]). Herein the last carbon atom and the C_2 (the case of α, β- unsaturated acids) are excepted.[28]

3. The formation of pseudo-cyclic, lactoid type ions, restricts the number of isomeric phenylated acids which may arise from unsaturated acids containing six carbon atoms and where the double bond lies in a different position from α, β.[38,58]

4. In alicyclic α, β-unsaturated acids with an exocyclic double bond (between a carbon atom belonging to the ring and one to the chain), the tertiary carbon atom does not undergo phenylation, though the tertiary carbocation is the first one formed. The formation of a more stable lactoid ion also prevents the condensation at this position.[72]

5. In the case of acrylic acid substituted with a five-membered ring [101] predominantly ring enlargement (about 82%) leading to isomeric phenyl-cyclohexylacetic acids has been observed, besides the formation of phenyl-cyclopentylpropionic acids. The irreversibility of the rearrangement of the five-membered ring has been established.

6. The condensations of α, β-unsaturated acids lead to mixtures of cyclic ketones, [27, 28, 39, 72] resulted through cyclizations of the phenylated acids at higher temperature (80°).

7. The hydrogenolysis of cyclobutane ring, [75] through bicyclobutonium ions as intermediates, has been reported. In this case several other unstable unsaturated intermediates are also involved, which stabilize by intermolecular hydride transfer.[80] The unstable intermediates are thereby hydride acceptors.

8. Indane compounds are the stabilization products of the hydride donors.[75,112] Correlation between intermolecular hydride transfer and cyclization to indane compounds has been revealed.

9. A general remark is that during the condensations of unsaturated acid with benzene the formation of diphenylated acids was made evident only in the case of an advanced unsaturation (cyclobutylideneacetic[75] and sorbic[112] acids).

10. Generally, a distinction of the different rate reactions which are involved is possible. The fastest reaction is the protonation, followed by intramolecular hydride transfer (if possible), condensation with benzene, intermolecular hydride transfer (if required by the reaction pathway). The last reaction affords cyclic compounds with indene skeleton. The slowest reaction is the cyclization of phenylated acids giving rise to the cyclic ketones.

The author is deeply indebted to Professor Ecaterina Nenitzescu-Ciorănescu for helpful discussions and to Professor Florin Badea for his assistance during the last years.

METHODS FOR THE DETERMINATION OF 2-AMINOPYRIDINE. VISIBLE AND INFRARED SPECTRA OF THE COMBINATION WITH AMMONIUM REINECKATE

GRIGORE TEODORESCU

Polytechnic Institute — Bucharest,
Department of Inorganic and Analytical Chemistry,
str. Polizu 1, Bucharest, Romania

Received May 8, 1973

The present paper presents methods for the determination of 2-aminopyridine based upon its combination with ammonium reineckate, the dissolving of the obtained compound in acetone followed by the precipitation of the reineckate anion as silver reineckate and the titration of the silver nitrate excess with ammonium thiocyanate. Since the obtained compound is also soluble in ethanol, forming a coloured solution, 2-aminopyridine has been determined spectrophotometrically as well.

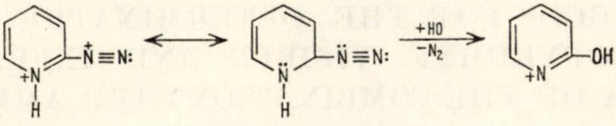
The structure of the compound has been proved by the determination of the molecular weight, by means of visible spectra for ammonium reineckate and for the reineckate of 2-aminopyridine. In order to determine the structure of 2-aminopyridine reineckate, the infrared spectra of 2-aminopyridine and of its reineckate have been recorded.

1. INTRODUCTION

2-Aminopyridine is an intermediate for the manufacture of many dyes, pesticides, and pharmaceuticals.

The quantitative determination of 2-aminopyridine is therefore of interest. The well-known method for the determination of amines and of 3-aminopyridine itself cannot be used in the case of 2-aminopyridine and 4-aminopyridine. Indeed, like 2-aminobenzothiazole, 2- and 4-aminopyridine can be diazotized only in concentrated acidic media, such as concentrated sulphuric acid over 60% or nitrosylsulphuric acid.

On dilution with water, hydroxy-pyridine is formed, and no diazonium salt can be detected. The reason for its absence is probably the fact that diazonium salts of 2-and 4-aminopyridine have law electron densities in the 2- and 4-positions and are therefore more sensitive to the nucleophilic attack of water :

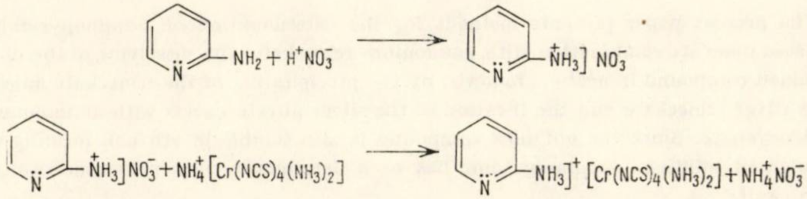


The failure of the usual method determined us to study the reaction of 2-aminopyridine (AP) in an aqueous solution in which onium ions predominate with ammonium reineckate ($NH_4^+ R_c^-$), which was also used by the author for the determination of other compounds. [1–5]

The present method may be applied to 4-aminopyridine as well as to 3-aminopyridine.

This procedure is simple and rapid and may be applied to the amine in technical mixtures.

The complex is formed from the ammonium salt (as it results in acidic media), according to the following sequence :



$NH_2 + H^+NO_3^-$
$\overset{+}{N}H_3] NO_3^-$
$\overset{+}{N}H_3]NO_3^- + NH_4^+[Cr(NCS)_4(NH_3)_2]$
$NH_3]^+[Cr(NCS)_4(NH_3)_2] + NH_4^+NO_3^-$

This reaction was used for the determination of AP by volumetric and spectrophotometric methods.

2. DETERMINATION METHODS

2.1. *Volumetric method.* The aqueous solution of AP was acidified with nitric acid and precipitated with 2% $NH_4^+R_c^-$.

The resulting violet-pink precipitate is filtered, washed with water and dissolved in acetone.

The acetone solution is treated with silver nitrate solution in excess. Silver reineckate precipitates according to the equation :

$NH_3][Cr(NCS)_4(NH_3)_2] + AgNO_3$
$NH_3]^+NO_3^- + Ag[Cr(NCS)_4(NH_3)_2]$

[5] Gr. Teodorescu, *Rev. Roumaine Chim.*, **17**, 1621 (1972).

The precipitate is filtered and washed, then the excess of silver nitrate is titrated with thiocyanate in presence of iron (III) alumen and ammonium as an indicator.

EXPERIMENTAL PART

2-Aminopyridine, a brown crystalline compound, is easily soluble in water. 2g of technical AP are weighed, dissolved in distilled water, the solution is filtered and is taken with distilled water in a standard flask of 250 ml.

From this solution, aliquots containing between 0.0480 and 0.1200 g AP are taken out. Each aliquot is acidified with 2–3 drops of a 2 n solution of nitric acid and then treated dropwise under continuous stirring, with a freshly prepared 2% solution of $NH_4^+ R_c^-$ until the solution above the precipitate darkens to violet-red. The crystalline, nacreous violet-red precipitate is filtered on a G_4 filtrable crucible, carried along by means of 0.1 %$NH_4^+ R_c^-$ solution, washed with cold (5°C) distilled water until the solution becomes colourless, and in the end washed with two 5 ml ether portions.

The compound is dissolved with 15–20ml acetone directly on the filtrable crucible which is then washed with 10–15 ml distilled water, all filtrates being collected in a 250 ml flask. 100 ml distilled water, 20 ml 0.1 n silver nitrate and 2 drops 2 n nitric acid are then added. The silver reineckate is precipitated. The precipitate is filtered, then washed with distilled water by decanting and the filtrate is collected together with the washing water in a 750 ml titrating decanter. In the same decanter 3–4 ml saturated solution of iron (III) ammonium alumen (about 40%) and 2 ml 2 n nitric acid are added, then the excess of silver nitrate is titrated by means of 0.1 n ammonium thiocyanate of factor = 1.0152.

To 0.1 n silver nitrate corresponds 0.0094 g AP. The results are given in table 1.

Table 1

Volumetric determination of 2-aminopyridine with $NH_4^+ R_c^-$

0.1040	10.50	9.50	0.0893	85.86
0.1120	9.85	10.15	0.0954	85.35
0.1200	9.15	10.85	0.1020	85.00

[a] 20 ml 0.1 n $AgNO_3$ are previously added.

[b] Mean value : 85.11 ± 0.36; by the diazotation method the purity of the technical AP was found to be 85%.

2.2. *Spectrophotometrical method.* AP is precipitated with $NH_4^+ R_c^-$ in the same way as by the volumetric method.

The compound formed is dissolved in 95% ethanol. The concentration of AP is obtained from a standard curve. In addition, the spectrophotometric method can be used to check the molecular weight.

The standard curve is obtained from different solutions with a known content of $AP^+ R_c^-$. The absorbance (A) is determined at $\lambda = 525$ nm which corresponds to the absorption maximum of $NH_4^+ R_c^-$, as in the following examples:

% $AP^+ R_c^-$	0.3	0.25	0,2	0.15	0.1
Absorbance	0.425	0.358	0.275	0.205	0.130

The standard curve is shown in figure 1.

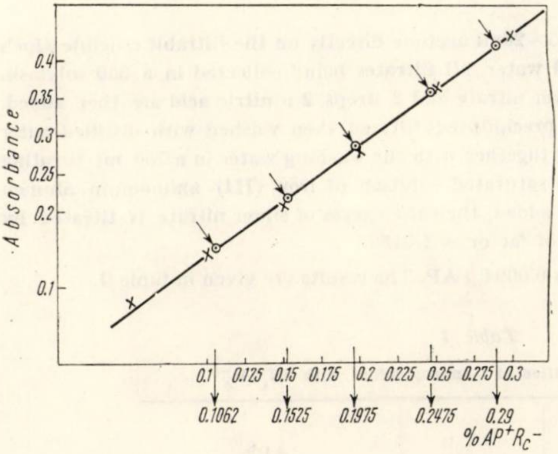

Fig. 1. — The absorbance of $NH_4^+ R_c^-$ *vs* the concentration of the corresponding ethanolic solution.

A V.S.U.-1 spectrophotometer was used with a 0.5 cm cell.

The determination of the AP in the technical product was performed as follows:

2.0475 g technical AP are dissolved in about 150 ml distilled water, filtered and washed, and the solution is collected in a 250 ml standard flask which is filled up to the mark with distilled water. One ml of this solution contains 0.0081 g technical AP. Aliquots of 3.5 ; 5 ; 6.5 ; 8 ; 9.5 ml are withdrawn (they correspond to 0.02866 ; 0.4095 ; 0.05323 ; 0.06552 and respectively 0.07780 g technical AP), acidified with 2—3 drops of 2 n nitric acid and precipitated with a freshly prepared 2% $NH_4^+ R_c^-$, added dropwise, under continuous stirring, until the solution above the precipitate is dark violet-red. The product obtained is filtered on a G_4 filtrable crucible, carried along by means of 0.1% $NH_4^+ R_c^-$, washed with two 5 ml portions of cold distilled water (about + 5°), and finally with two 5 ml portions of ether.

The compound is directly dissolved in 95% ethanol on the filtrable crucible, the crucible is washed with 95% ethanol, the filtrates being collected in a 100 ml standard flask which is filled up to the mark with solvent.

The absorbances for each solution are measured and these values plotted in fig. 1 enable the determination of the concentration in $\mathrm{AP^+ R_c^-}$. The per cent values are calculated from relation :

$$\frac{94 \cdot a}{412 \cdot b} \cdot 100 = \%\mathrm{AP}$$

where 94 is the molecular weight of AP ;

412 is the molecular weight of $\mathrm{AP}^+ R_c^-$;

a is the per cent concentration of $\mathrm{AP}^+ R_c^-$ obtained as above ;

b is the weight (g) of technical AP used in the run.

The results obtained are given in table 2.

Table 2

Per cent concentration of AP in a technical sample

Technical AP in aqueous solution		Absorbance	$\mathrm{AP^+ \overline{R_c}}$ in a 100 ml ethanolic solution	AP* in technical AP
ml	g(b)	A	g(a)	%
3.5	0.02866	0.150	0.1062	84.5
5.0	0.04095	0.215	0.1525	84.4
6.5	0.05323	0.285	0.1975	84.2
8.0	0.06552	0.355	0.2475	85.5
9.5	0.07780	0.413	0.2900	84.4

* The mean value, 84.5 ± 0.3%

3. SPECTRAL STUDY

3.1. *Checking of the molecular weight of 2-aminopyridine reineckate.* For compounds like 2-aminopyridine, containing more than one nitrogen atom, it is necessary to verify if the complex contains one or more reineckate anions.[6] For this purpose, the values of the absorbance (A) for $\mathrm{NH_4^+} R_c^-$ and $\mathrm{AP}^+ R_c^-$ and the absorptivity (K) for $\mathrm{NH_4^+} R^-$ (fig. 2) are used.

The absorptivity was calculated from the relation :

$$K = A/c \cdot l$$

---

[6] Kum-Tatt-Lee, *J. Pharm. and Pharmacol.*, **12**, 666 (1960).

With $c = 0.0297$ moles of $NH_4^+ R_c^-$ in 95% ethanol, the length of the cell, $l = 0.5$ cm, and the absorbance, $A = 0.155$ (from figure 2 at $\lambda_{max} = 520 - 525$ nm), the absorptivity is $K = 104$.

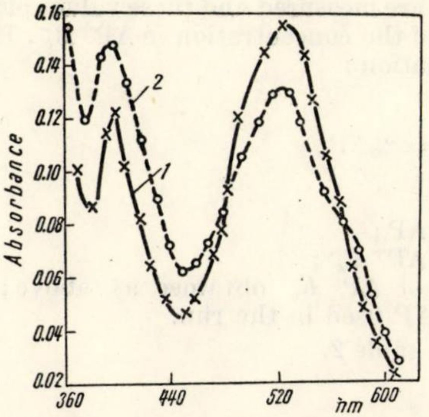

Fig. 2. – Visible spectra of $NH_4^+ R_c^-$ (1) and $AP^+ R_c^-$ (2) in 95% ethanol ($l = 0.5$ cm).

Since the two reineckates, $NH_4^+ R_c^-$ and $AP^+ R_c^-$, have nearly the same $\lambda_{max} = 525 - 530$ nm, we assume that the absorptivity, K, obtained for $NH_4^+ R_c^-$ is also valid for $AP^+ R_c^-$.

The molecular weight is calculated from the relation :

$$M_d = g_1/100 \times K/A \times l/1000$$

when $g_1 = 0.1\%$, the relation becomes :

$$M_d = K \cdot l/A$$

With $\lambda_{max} = 525 - 530$ nm for $AP^+ R_c^-$ and a concentration of 0.1%, the absorbance is $A = 0.130$ ($l = 0.5$ cm). Hence the molecular weight is :

$$M_d = \frac{104}{0.130} \cdot 0.5 = 400$$

The value for the monoreineckate is 412. The comparison of the two values allows us to assume that the compound is a monoreineckate ; it does not contain two reineckate groups.

3.2. *Infrared spectrum of 2-aminopyridine reineckate.* The infrared spectrum of AP reineckate has also been recorded for the structural characterization of the compound. [7–11]

The IR spectrum of AP reineckate has been interpreted by comparing it with the $NH_4^+ R_c^-$ spectrum (table 3).

The IR spectrum of the complex presents bands found in the spectrum of ammonium reineckate, which can be attributed to the NH_3 and NCS groups in the reineckate anion; they appear at 493 cm^{-1} (δNCS), 1262 cm^{-1} (δ^{sym}_{N-H} NH_3), 2090 cm^{-1} (ν_{C-N}) and 3160 – 3290 ν^{sym}_{N-H} NH_3. It also shows bands corresponding to the organic base (table 4). These bands, at 750 cm^{-1}, 1172 cm^{-1}, 1480 cm^{-1}, 1620 cm^{-1}, 1670 cm^{-1}, appear also in the spectrum of the compound, where they are slightly altered in their positions and intensities.

Получена 12 февраля 1973 г.

Путем морфологических исследований объясняется влияние режима распылительной сушки на характеристики порошков эмульсионного поливинилхлорида. В зависимости от температуры и величины капель латекса образуются сухие частицы ПВХ разного пористого строения, которые ведут себя неодинаково по отношению к пластификатору. Свойства паст определяются количественными соотношениями структур разного типа в порошке.

В предыдущем сообщении [1] были представлены экспериментальные данные относительно влияния условий распылительной сушки на свойства порошкообразного поливинилхлорида и его способность к образованию паст с пластификатором.

Было найдено, что главным фактором, с точки зрения способности образовывать пасты, является температура сушки ПВХ, которая влияет на:

— величину частиц сухого порошка (чем выше температура сушки, тем больше средняя величина частиц порошка);

— седиментацию паст (осаждаются из пасты только частицы, полученные при температуре сушки выше 80°, в то время как пасты, приготовленные из частиц той же величины, но высушенные при более низких температурах, не осаждаются);

— консистенцию паст и изменение вязкости во времени. Понижение температуры сушки благоприятствует получению паст с низкой начальной вязкостью, но которая возрастает во времени, в то время как повышение температуры сушки уменьшает способность порошков к образованию паст вплоть до совершенного несвязывания их в пасты. Напротив, вязкость таких паст снижается во времени;

---

[1] Первая часть см. в *Rev. Roumaine Chim.*, **18**, *2* (1973).

— реологические свойства паст. Повышение температуры сушки благоприятствует дилатансии, а понижение температуры—псевдопластичному течению.

Уменьшение размеров частиц порошка оказывает влияние на;

— стабильность вязкости паст во времени;

— уменьшение псевдопластичности.

С точки зрения замеченных закономерностей теряет свою важность гранулометрическое распределение порошка, из которого приготовлены пасты, т.к. при одном и том же гранулометрическом составе пасты имеют различные реологические свойства, если порошки были высушены при разных температурах (см. рис. 2 из сообщения I[1]).

В специальной научной литературе были даны различные объяснения образования паст определенной вязкости и устойчивости. Так, разница в поведении паст во времени объясняется разницей в форме частиц (ценосферы и пленосферы [2]), в их твердости [3], характере поверхности, от которой зависит адгезия и образования агрегатов в среде пластификатора [4], в образовании поверхностной труднорастворимой корки [5] и т.п.; многие авторы считают очень важным широкое гранулометрическое распределение величины частиц и их абсолютные размеры[6–9], принимая или не принимая во внимание те изменения, которые происходят в величине частиц в контакте с пластификатором. Штаркман с сотрудниками [10,11] объясняют разницу в поведении порошков ПВХ разницей в морфологии частиц, а механизм образования различных структур во время сушки латексов в распылительной сушилке был представлен в работе Ульянова и Овчинникова [12].

На основе литературных данных и собственных наблюдений относительно связи между условиями получения порошков ПВХ и свойствами самих порошков и образованных из них паст, авторы настоящей статьи дают следующее объяснение феноменов.

Считаем, что фактором, определяющим поведение порошка поливинилхлорида, полученного в различных условиях распылительной сушки, является структура зерен, или, вернее, сочетание различных структур в отношении к пластификатору.

Пасты — это дисперсии твердых частиц в жидкости. Поскольку идет речь о дисперсиях, т.е. о множестве частиц, должны действовать теории множества.

Одна частица того или другого строения отдельно не может оказать никакого влияния, в то время как сочетание различных структур дает определенный эффект, зависящий от количества различных структур и вероятного поведения каждой из них.

В ходе превращения множества латексных частичек в твердые зерна ПВХ на них действует целый ряд факторов (температура сушки, время сушки, тонкость распыления, гранулометрический состав латексных частиц в каждой капле латекса), который направляет образование частиц с тем или иным пористым строением. Может идти речь только о возможности образования какой-то определенной основной структуры, которая в наибольшей мере влияет на средние абсолютные величины при анализах порошков и паст.

Образование каких же структур является возможным при формировании частиц ПВХ в процессе распылительной сушки?

Электронно-микроскопическое изучение частиц методом реплик позволило установить следующее.

— Все частицы ПВХ полученные из латекса путём распылительной сушки представляют собой агломераты сферической или овальной формы, объединяя множество латексных глобул разных размеров (см. рис. 1).

Если эти сферические агломераты размолоть, они распадаются на индивидуальные латексные частицы или на агломераты меньших размеров (рис. 2).

Степень сближения и слипания латексных частиц в сухом зерне ПВХ зависит от природы латекса, размеров сухих зерен, расстояния изучаемого слоя от поверхности зерна и от температуры сушки. На рис. 3(а, б) представлены две частицы одной и той же пробы ПВХ, из которой половина была размолота (б). Видно, что латексные частицы из поверхностного слоя неразмолотого зерна располагаются очень близко друг к другу, как бы входят одна в другую, в то время как в размолотом зерне, в котором был снят верхний слой и представлена внутренняя часть зерна, можно видеть, что пространство более разрежено и латексные частицы менее связаны между собой.

На зернах порошка, высушенного в определенных условиях, на поверхности появляются впадины и трещины, которые ведут во внутреннюю разреженную зону частицы, что можно видеть из рис. 4—6.

Внутреннее строение зерен изучалось с помощью оптического микроскопа, применяя объектив с имерсионной жидкостью. В качестве имерсионной жидкости использовался диоктилфталат.

При рассмотрении в оптический микроскоп было обнаружено несколько видов внутреннего строения зерен ПВХ (рис. 7): зерна полные и зерна голые внутри, с каналом, ведущим во внутреннюю голую полость или без него, наконец, с внутренней полостью, заполненной более мелкими сферическими частицами, которые в определенный момент при контакте частицы с пластификатором выходят из нее через имеющийся канал.

Изучение порошков ПВХ, полученных при различных температурах, показало, что каждому температурному режиму соответствует определенная преобладающая структура частицы, но в то же время помимо нее имеются и другие типы структур.

Частицы различного строения ведут себе неодинаково по отношению к пластификатору, это можно заметить из серии фотографий, представленных на рис. 8—10.

На рис. 8 (а, в, с) показаны превращения частиц ПВХ, полученных при $T = 60^0$ в контакте с пластификатором ДОФ в течение 15 минут. Были сделаны фотографии через 1, 7 и 15 мин. после нанесения капли пластификатора на порошок ПВХ.

Очень хорошо видно, что зерна со сплошным строением и некоторыми вмятинами на поверхности через 7 мин. взаимодействия с ДОФ начинают набухать и распадаться в латексные частички, которые некоторое время еще сохраняют форму шаровых скоплений. Через 15 мин. благодаря броуновскому движению латексные частицы покидают места своего первоначального скопления и распределяются по всему видимому пространству, подобно рыбьей икре. Только два первоначальных зерна ПВХ уцелили в этом скопище латексных частиц взвешенных в пластификаторе, но и они, вероятно, не продержутся долго.

При приготовлении паст, когда используются механические силы для перемешивания, процессы разрушения зерен ПВХ происходят еще быстрее.

На рис. 9 (а, в) показаны превращения зерен порошка поливинилхлорида, высушенного при $T = 80°$. Видно, что в течение 15 мин. только несколько зерен распалось на латексные глобулы, некоторые едва набухли, а большинство не претерпело никаких изменений. Освободившиеся латексные частицы расползлись по всему свободному объему между зернами ПВХ.

На рис. 10 (а,в) представлено поведение в пластификаторе порошка ПВХ, высушенного при $T > 90°$. В течение 15 мин. ни одно зерно не распалось, и свободное пространство между ними осталось заполненным только пластификатором. Размеры частиц не имели никакого значения.

Отсюда видно, какое огромное значение при взаимодействии с пластификатором имеет внутреннее строение зерен порошка поливинилхлорида, степень спайки латексных глобул в каждом зерне. Латексные частицы, слабо связанные между собой, при воздействии пластификатора распадаются быстро, а те, что успели сплавиться во едино во время сушки при повышенной температуре, под воздействием пластификатора при комнатной температуре не изменяются.

Микроскопическое изучение поведения размолотых порошков ПВХ показало, что размол способствует более быстрому растворению осколков, полученных из сердцевины зерен, в то время как частицы, происходящие из поверхностной зоны, растворяются в пластификаторе в соответствии со степенью спекания латексных глобул во время сушки.

Чем выше температура в сушилке, тем быстрее происходит испарение воды из капель латекса, что видно из рис. 11, в которой представлены рассчитанные кривые времени испарения воды ($\tau_{\text{сек}}$) в зависимости от размеров капель и Δt процесса сушки.

Рис. 12. — Сухая частица ПВХ, происходящая из трех первоначальных частиц.

$\tau_{\text{сек}}$ была рассчитана по формуле[13]

$$\tau_{\text{сек}} = \frac{r \cdot \gamma \cdot \Phi_m^2 \cdot 3600}{4\ \text{Nu} \cdot \lambda \cdot \Delta t},$$

где:

r — теплота испарения воды, $r = 575$ ккал/кг при $T = 42°$;
γ — плотность испаряемой жидкости, $\gamma = 1000$ кг/м^3;
Φ_m — средний диаметр разбрызгиваемых капель;
λ — теплопроводность воздуха, $\lambda = 0{,}0234 \dfrac{\text{ккал}}{\text{м. час}^0\ C}$;

Nu — критерий Нуссельта, $\text{Nu} = 2$

$$\Delta t = \frac{T_1 - T_2}{2{,}3 \lg \dfrac{T_1 - T_c}{T_2 - T_c}},$$

T_1 — температура горячего воздуха на входе в сушилку;
T_2 — то же — на выходе из сушилки;
T_c — температура влажной поверхности капли (в наших условиях

$$T_c = T \text{ мокрого термометра} = 42°.$$

Пары воды из латексных капель в первые моменты сушки направляются наружу из капли, но в следующие моменты, когда вокруг капли начинает образовываться сухая корка из латексных глобул, движение жидкости изнутри становится затруднительным и водяные пары могут задержаться внутри зерна, в полостях, образовавшихся за счет перемещения латексных частичек в верхние слои вслед за испаряющейся жидкостью. Если давление водяных паров внутри зерна велико, что может иметь место при высоких температурах сушки и при скоплении больших количеств паров в каплях относительно крупных размеров, пары прорывают стенки полусухой частицы, образуя выход-канал наружу. Эти каналы хорошо видны под микроскопом с имерсионной жидкостью.

Когда же температура сушки относительно низка, за счет более медленного испарения воды в капле происходят более равномерные процессы уплотнения латексных глобул при свободном движении воды из внутренних слоев к поверхности. В этом случае образование внутренних пустот менее вероятно, что видно из фотографии рис. 8, где частицы ПВХ предстают в виде сплошных шаров.

В порошках, полученных при более высоких температурах (рис. 9—10), напротив, велико число частиц с внутренними пустотами и связывающими их с поверхностью каналами.

Таким образом, можно сделать вывод, что по мере роста температуры сушки происходят изменения во внутреннем строении зерен ПВХ. Повы-

[1] H.G.Kessler, *Chem. Ing. Technic*, **39**, 601 (1967).

шение температуры способствует переходу от зерен, построенных из равномерно распределенных, но менее связанных между собой латексных глобул, к зернам пористым, с твердой оболочкой из спаянных глобул и наличием внутренних пустот.

Существование этих пустот, помимо микроскопических наблюдений, можно доказать и с помощью разницы в плотностях зерен ПВХ, которые будут тем ниже, чем выше температура сушки порошка.

Плотности зерен вычислялись из плотностей свежеприготовленных паст. Простым расчетом, принимая во внимание весовые соотношения между полимером и пластификатором и плотность пластификатора, была рассчитана средняя плотность зерен ПВХ по формуле:

$$\gamma_{\text{пасты}} = 0{,}6\ x + 0{,}4\ \gamma_{\text{дсф}},$$

где x — плотность зерен ПВХ в пасте.

При одинаковой скорости подачи латекса, но разных температурах сушки были получены следующие величины рассчитанных плотностей зерен ПВХ:

$T = 92°$, $x = 1{,}264$ г/см^3,

$T = 80°$, $x = 1,\ 271$ г/см^3,

$T = 70°$, $x = 1{,}302$ г/см^3.

Следует, что частицы в основном являются пористыми, имея плотность меньшую, чем плотность расплава полимера ($\gamma = 1{,}4$ г/см^3); пористость больше у частиц, полученных при более высоких температурах.

Температура сушки в большей степени влияет на строение более крупных зерен. Как было показано в первом сообщении, сжатие латексных капель во время сушки наблюдается только при температурах ниже 90° (см. рис. 1 из сообщения 1[1]), а при $T > 90°$ средние размеры зерен порошка оказываются даже крупнее первоначальных капель, что можно объяснить слипанием зерен, возможным при температурах выше точки стеклования (см. рис. 7 и 12).

Более резкое сжатие наблюдается у мелких частиц, потому что при небольших размерах зерна является менее вероятным образование внутренних пустот, латексные глобулы стремятся к сближению даже и после испарения воды благодаря равномерному прогреву всего зерна и вязкому течению латексных глобул, закрывающих все пустоты.

Внешняя оболочка более крупных зерен, как видно из рис. 4—6, покрыта трещинами и впадинами. Трещины можно объяснить неравномерным сжатием оболочки благодаря неодинаковому притяжению между собой латексных глобул. Впадины — это следы паров воды и всасывания размягченной массы полимера во внутрь. Как видно из рис. 4, и вмятины покрыты трещинами.

При соприкосновении порошка поливинилхлорида с пластификатором через трещины открывается доступ ко внутренним зонам частиц. Благодаря проникновению молекул пластификатора во внутренние пустоты порошка, объем жидкости вокруг частиц уменьшается. Если число полых частиц велико, порошок поглощает большое количество пластификатора, и паста не образуется совсем или образуется очень густая паста.

Во времени происходит растворение оболочек ПВХ в пластификаторе, как с наружной, так и внутренней стороны. Когда благодаря растворению оболочка прорывается в каком-нибудь месте, через образовавшееся отверстие выходит пластификатор, увеличивая тем самым объем свободной жидкости в пасте.

Чем быстрее идет растворение, паста становится все жиже. Механические силы перемешивания помогают разрушению стенок зерна. Этим объясняются случаи, когда некоторые порошки ПВХ образуют пасты только после длительного перетирания в ступке, смесителе или на вальцах. Жидкость, оставшаяся свободной между частицами порошка, и та, что выливается из пустот при разрушении зерен, действует как смазка при перемешивании паст. Если пасты подвергаются очень энергичному перемешиванию, частицы удаляются быстро друг от друга и между ними может не оказаться достаточно жидкости для смазки; движущиеся частицы сталкиваются друг с другом и тогда вязкость возрастает с повышением скоростей сдвига, т.е. создается дилатансия.

В случае поливинилхлоридных партий, полученных при низких температурах, число зерен со внутренними пустотами невелико и пластификатор не исчезает из пространства между частицами, благодаря чему такие порошки образуют пасты с первого момента перемешивания. По мере разрушения зерен до уровня латексных глобул пасты начинают загустевать, потому что каждая латексная частица, обладая сродством к полярному пластификатору, оказывается окруженной слоем молекул пластификатора, адсорбированного на поверхности глобул за счет проникновения молекул пластификатора между макромолекулярными цепями и частичного растворения полимера в пластификаторе.

Растворение ПВХ в пластификаторе можно доказать, измеряя показатели преломления смесей ПВХ + ДОФ во времени. Например, для смесей 10% ПВХ в ДОФ через 24 и 48 часов после приготовления были найдены следующие величины $n_{\text{д}}^{20}$ (см. табл. 1).:

Таблица 1

Величины показателей преломления для смесей ПВХ 10% + ДОФ

Пробы ПВХ	Показатель преломления $n_{\text{д}}^{20}$	
	через 24 часа	через 48 часов
ПВХ, высушенный при 90°	—	1,4881
при 80°	1,4883	1,4889
при 60°	1,4903	1,4908
диоктилфталат	1,4876	

Видно, что величины $n_{\text{д}}^{20}$ растут во времени, удаляясь от значения показателя преломления пластификатора и этот рост тем больше, чем температура сушки полимера была ниже.

Латексные глобулы, разбухшие благодаря адсорбированному на поверхности пластификатору, при высоких концентрациях полимера в пасте (C = 60% вес. или 46% об.) соприкасаются друг с другом, образуя сетчатую структуру во всей массе пасты. Но это структурирование значительно только в состоянии покоя пасты. В смесителях, когда действуют силы сдвига, образовавшиеся связи рвутся, латексные глобулы начинают движение по предпочтительным путям, и таким образом вязкость падает, появляется феномен псевдопластичности.

У проб ПВХ, высушенного при средних температурах, когда образуются несколько видов внутреннего строения зерна, вид течения — псевдопластичное или дилатантное — зависит от того, какой вид строения в порошке преобладает, а также зависит от величины приложенных сил сдвига. Таким образом может наблюдаться течение чисто дилатантное, псевдопластичное или смешанный характер течения: дилатантный + псевдопластичный.

Таким образом, анализируя различное поведение порошков ПВХ в зависимости от температуры распылительной сушки, можно сделать следующие заключительные выводы:

1. Увеличение средних размеров частиц с ростом температуры сушки объясняется быстрым испарением воды, которая затрудняет перегруппировку латексных глобул и ведет к образованию пустотелых зерен тех же или даже больших размеров, чем распыляемые капли, а также слипанием сухих частиц между собой, возможным при высоких температурах.

2. Седиментация паст, полученных из порошков ПВХ, высушенных при относительно высоких температурах, объясняется преобладанием в таких порошках зерен с застеклованной внешней оболочкой, которая трудно растворяется в пластификаторе и потому происходит выпадание зерен из общей массы и оседание их благодаря разнице в плотностях полимера и пластификатора.

Когда же пасты приготовлены из порошка, в котором преобладающими являются зерна, легко распадающиеся на латексные глобулы, адсорбирующие на своей поверхности пластификатор, в этой общей вязкой массе остаются во взвешенном состоянии и те немногие частицы, что имеют застеклованную поверхность.

3. Высокая вязкость паст или даже несвязывание в пасты порошков, высушенных при температуре на выходе из сушилки выше 90°, и падение вязкости во времени одъясняется преобладанием в таких порошках зерен со внутренними пустотами, которые через имеющиеся на поверхности трещины быстро поглощают пластификатор, а потом отдают его обратно по мере растворения стенок пустотелых зерен.

Характер прямо противоположного поведения (возрастания вязкости во времени) паст, приготовленных из ПВХ, высушенного при относительно низких температурах, объясняется преобладанием в таких порошках частиц, которые распадаются легко до уровня латексных глобул, а потом структурируются во времени.

4. Реологические свойства паст зависят также от физического состава порошка поливинилхлорида — соотношения между разными типами структур зерен. Пустотелые частицы с застеклованными оболочками дают дилатантное течение паст, а частицы, легко распадающиеся в пластификаторе до уровня латексных глобул, благоприятствуют псевдопластичному течению паст. Путем комбинирования различных типов структур можно получить желаемые кривые течения.

SPEKTROPHOTOMETRISCHE UNTERSUCHUNG DES SYSTEMS VANADIUM (V)-SOLOCHROMVIOLETT RS

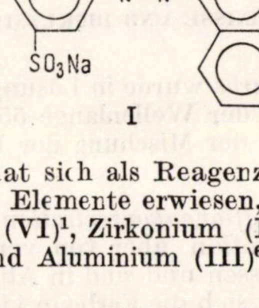
DIE SPEKTROPHOTOMETRISCHE BESTIMMUNG DES VANADIUMS

IOAN BURNEA, MARIA PLENICEANU und LUCIA BURNEA
Universität Craiova, Chemische Fakultät, Calea Bucureşti, 165

Eingegangen am 8. Mai 1973

In der vorliegenden Arbeit wurde das System Vanadium(V)-Solochromviolett RS (I) spektrophotometrisch untersucht. Es wurde die Zeitbeständigkeit des gebildeten Komplexes, und der Einfluß der Konzetration des (I) und der H^+-Ionen verfolgt und das Absorbtionsspektrum des Komplexes registriert. Bei pH 3.1 bildet sich eine Komplexverbindung im Verhältnis 1 V(v) : 2(I), dessen Dissoziation durch ein $pK = 12.43 \pm 0{,}20$ charakterisiert ist. Es wurde eine Methode zur spektrophotometrischen Bestimmung des V(v) mit (I) ausgearbeitet für den Konzentrationsbereich 0.203–10.185 μg V(v)/cm^3 ($\lambda = 550$ nm).

Das Solochromviolett RS (I) ist das Natriumsalz der 2-Hydroxynaphthyl-azo-1-phenol-4-sulphonsäure :



I

Diese Verbindung hat sich als Reagenz für die spektrophotometrische Bestimmung einiger Elemente erwiesen, ohne spezifisch zu sein. So konnten mit I Molybden (VI)[1], Zirkonium (IV)[2], Thorium (IV)[3], Chrom (III)[4], Gallium (III)[5], und Aluminium (III)[6] bestimmt werden.

In der vorliegenden Arbeit wurde die Reaktion der Bildung des dunkelroten V(v)-I-Komplexes spektrophotometrisch untersucht.

Um die besten Bedingungen der Vanadiumbestimmung mit I zu erforschen wurde die Beständigkeit der Farbe sowie der Einfluß der Konzentration der Reaktionspartner und der Wasserstoffionen untersucht. Ferner wurde die optimale Wellenlänge für die Analyse, die Zusammensetzung des Komplexes und seine Instabilitätskonstante durch die Methoden der isomolaren bzw. nichtisomolaren Mischungen von Job bestimmt sowie die Grenzen der Gültigkeit des Lambert-Beerschen Gesetzes.

Es ist noch zu bemerken, daß Vanadium (V) auch mit anderen organischen Reagentien Verbindungen bildet, die auch zu einer spektrophotometrischen Bestimmung herangezogen werden können, so z. B. Solochromschwarz RN[7].

EXPERIMENTELLER TEIL

Zur Herstellung der 10^{-3}M Stammlösungen wurde Amoniummetavanadat (Merck) und Solochromviolett RS (Serva) ohne weitere Reinigung verwendet. Die Pufferlösungen von pH 1 bis 5.6 wurden nach Walpole[8] aus 0.2 M Essigsäure und 0.2 M Natriumazetat, während die von pH 6 bis 9 nach Kolthoff und Vleeschhouwer[8] aus 0.1 Monokaliumphosphat und 0.005 M Natriumtetraborat hergestellt.

Aus den Stammlösungen wurden jeweils die angegebenen Mengen genommen und entweder im Gemisch, oder allein mit der entsprechenden Pufferlösung auf 25 cm^3 verdünnt. Die Referenzlösung für die spektrophotometrischen Messungen war – wenn nicht anders angedeutet eine I-Lösung gleicher Konzentration und vom gleichen pH wie die zu untersuchende Lösung. Das gilt auch für die Job-Kurven. Da die V(v)-Lösungen unter den gegebenen Bedingungen keine Absorption aufweisen, erhielt man auf diese Weise unmittelbar die Abweichung der gemessenen Größe von der Additivität.

Die Extinktionsmessungen wurden mit einem Zeiss VSU 1-Spektrophotometer, und die pH-Messungen mit einem Clamann-Grahnert pH-Meter mit Glaselelektrode ausgeführt.

ERGEBNISSE UND DISKUSSION

Zeitbeständigkeit der Farbe wurde in Lösungen von 8.10^{-5}M V(v) und 24.10^{-5} M I von pH 3.1 bei der Wellenlänge 550 nm verfolgt. Die Farbe erscheint augenblicklich bei der Mischung der Lösungen und ändert sich nicht mit der Zeit.

Einfluß der Wasserstoffionenkonzentration. Die Extinktionen von Lösungen obiger Konzentration aber von verschiedenem pH, wurden zwischen 1.42 und 6.1 gemessen und sind in Abb. 1 aufgetragen. Bei pH-Werten größer als 6.1 ändert sich die Farbe in violett und hat eine kleinere Extinktion als reines I. Ein ausgeprägtes Maximum wird bei pH 3.1 beobachtet, bei welchem die analytischen Messungen optimal ausgeführt werden können.

[8] C. Luca, „pH-ul şi aplicaţiile lui“ Ed. tehnică, Bukarest 1964, S. 57.

Einfluß der I-Konzentration. Aus Tafel 1 ist ersichtlich, daß für eine V(v)Konzentration von 4.10^{-5} M ein dreifacher Überschuß von I 12.10^{-5} M genügt um die Unabhängigkeit der Extinktion von der I-Konzentration zu erreichen.

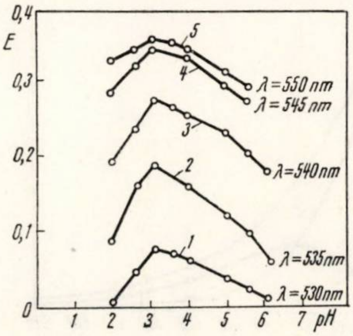

Abb. 1. — Die Abhängigkeit der Extinktion vom pH (8.10^{-5} M V (v) + + 24.10^{-5} MI).

Tafel 1

$[V(v)] = 4 \cdot 10^{-5}$ **M; pH** 3·1 λ = 550 nm

[Solochrom] × 10^{-5}M	Extinktion
2.0	0.062
4.0	0.112
6.0	0.164
8.0	0.220
10.0	0.225
12.0	0.230
14.0	0.232
16.0	0.233

Die Absorptionskurve. Um die optimale Wellenlänge für die spektrophotometrischen Messungen zu finden wurden die Absorptionskuven für a) V(v)-I gegen I, b) I gegen Wasser und c) V (v)-I, gegen Wasser registriert. Die Ergebnisse sind in Abb. 2 wiedergegeben. Die größte Extinktion der Mischung gegen reines I entspricht der Wellenlänge 550 nm.

Beim optimalen pH ist die Farbe des Reagens rosarot. In der Lösung von pH 3.1 ist das V(v) in derForm VO_2^+ vorhanden, da das stark vom pH und der Konzentration abhängende Gleichgewicht [9] :

$$[V_{10}\,O_{28}]^{6-} + 16\,H^+ \rightleftarrows 10\,VO_2^+ + 8H_2O$$

---

[9] R. Ripan und I. Ceteanu, „Chimia metalelor“, Ed. didactică și pedagogică Bukarest, 1969, S. 160.

unter den gegebenen Bedingungen praktisch vollständig nach rechts verschoben ist. Deshalb werden die Messungen durch der Absorption anderer V(v)-Formen nicht gestört.

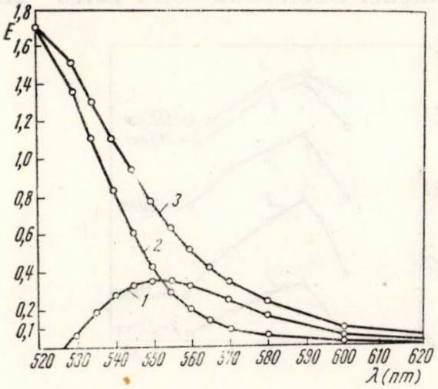

Abb. 2. — Extinktionskurven: 1.V (v) + I gegen I; 2. I gegen Wasser; 3. V(v) + I gegen Wasser (8.10^{-5} M V (v) + 24.10^{-5} MI); pH 3.1

DIE SPEKTROPHOTOMETRISCHE BESTIMMUNG DES VANADIUMS MIT SOLOCHROMVIOLETT RS

Die obigen optimalen Bedingungen der Extinktionsmessung wurden zur Bestimmung des V(v) benützt.

Die Gültigkeit des Lambert-Beerschen Gesetzes wurde unter optimalen Bedingungen für V (v)-Konzentrationen von $0.4.10^{-5}$M bis 20.1^{-5} M und der gleichen Reagenzkonzentration von 64.10^{-5} M erforscht. Wie Abb. 3 zeigt ist die Extinktion der Mischungen eine lineare Funktion der V(v)-Konzentration zwischen 0.203 — 10. 185 μg V(v)/cm³. Der relative molare Extinktionskoeffizient—gegen reines I — ist 5 000, so daß die Methode zu den empfindlichen V-Bestimmungsmethoden gezählt werden kann.

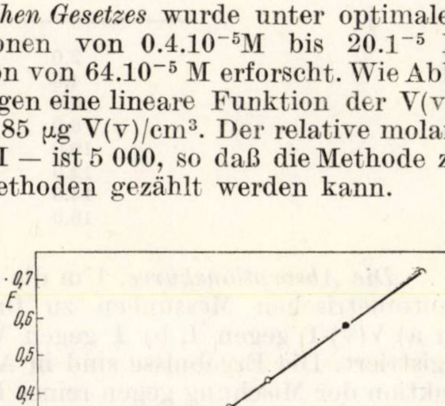

Abb. 3. — Abhängigkeit der Extinktion von der V(v)-Konzentration

Die Neigung der Lambert-Beerschen Geraden wurde durch die Methode der kleinsten Quadrate aus 16 Messungen zu m = $(69.0 \pm 1.2).10^{-3}$ berechnet, unter Berücksichtigung der Studentverteilung für eine Wahrscheinlichkeit von 95%.

DIE ZUSAMMENSETZUNG DES KOMPLEXES

Die Untersuchung der Absorptionsspektren unter verschiedenen Bedingungen führte zum Schluß dazu, daß nur eine Komplexverbindung zwischen V(v) und I gebildet wird.

Die Zusammensetzung des Komplexes wurde anhand der Extinktion isomolarer Reihen sowie anhand der Methode des molaren Verhältnisses ermittelt. Die Abb. 4 gibt die Abweichungen von der Additivität der Extinktion $\triangle E$ für die Job-schen isomolaren Reihen verschiedener Konzentrationen wieder, bei pH 3.1 und 550 nm, xR bezeichnet den Molenbruch des I im V(v) -I- Gemisch.

In Abb. 5 und 6 sind die Ergebnisse der Methode des molaren Verhältnisses wiedergegeben. Abb 5 zeigt die Änderung der Extinktion von Lösungen gleicher Konzentration von V(v) 4.10^{-5} M (Kurve 1) und 2.10^{-5} M (Kurve 2) und wachsender I-Konzentration, während Abb. 6 die Extinktionsänderung von Lösungen gleicher I—(8.10^{-5} M) aber wachsender V(v)-Konzentration enthält.

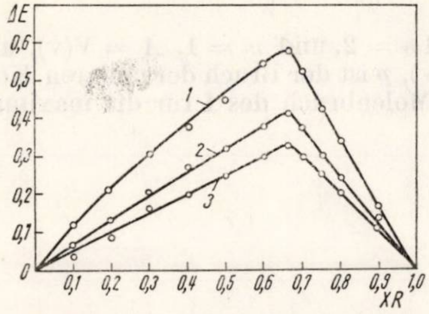

Abb. 4. — Die Bestimmung der Zusammensetzung des Komplexes durch die Methode der isomolaren Reihen: verschiedener Gesamtkonzentrationen:

1. $1.0.10^{-3}$ M; 2. $6.66.10^{-4}$; 3. $5.6.10^{-4}$ M—.

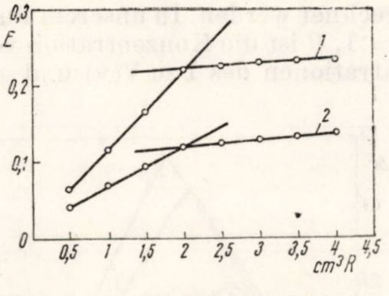

Abb. 5. — Die Bestimmung der Zusammensetzung des Komplexes durch die Methode des molaren Verhältnisses:

1. $1.0.10^{-3}$ M; 2. $5.0.10^{-4}$ M.

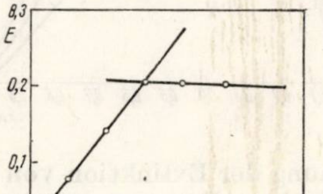

Abb. 6. — Die Bestimmung der Zusammensetzung des Komplexes durch die Methode des molaren Verhältnisses: $6.66.10^{-4}$ M.

Beide Methoden führen eindeutig zum selben Schluß : der Komplex bildet sich im Verhältnis 1 V(v) : 2 I.

DIE BESTIMMUNG DER INSTABILITÄTSKONSTANTE DES V(v)-I - KOMPLEXES

Zu der Bestimmung der Instabilitätskonstante des Komplexes wurde die Methode der nichtisomolaren Reihen von Job herangezogen.

Wird das Massenwirkungsgesetz auf das Gleichgewicht

$$\mathrm{Am\,Bn} \rightleftarrows \mathrm{mA} + \mathrm{nB}$$

angewendet, so kann für die Gleichgewichtskonstante der Ausdruck

$$K = \frac{C^{m+n-1}\, p^{n-1}\, [(pm+n)\,x - n]^{m+n}}{[m^{n-1}\, n^{m-1}\, (p-1)^{m+n-1}]\,[n - (m+n)\,x]}$$

berechnet werden. In unserem Fall sind $n = 2$, und $m = 1$, $A = \mathrm{V(v)}$, und $\mathrm{B} = 1$, C ist die Konzentration von V(v), p ist der Bruch der molaren Konzentrationen des I zu V(v) und x der Molenbruch des I für die maximale Abweichung der Extinktion von der Additivität, so daß die obige Formel eine einfachere Form annimmt :

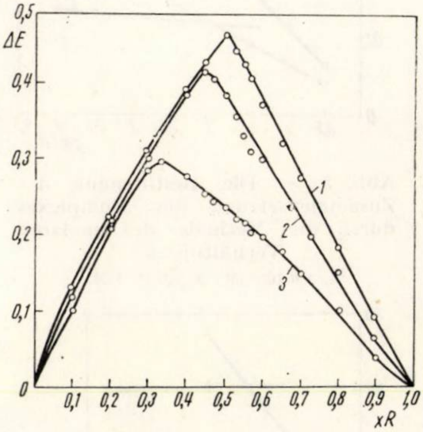

Abb. 7. — Die Bestimmung der Instabilitätskonstante des Komplexes mit Hilfe der nichtisomolaren Reihen.

$$K = \frac{C^2\, p\, [(p+2)\,x - 2]^3}{(p-1)^2\,(2 - 3x)}$$

Die Berechnung der Instabilitätskonstante erfolgte für folgende Reihen von nichtisomolaren Lösungen.

Die Kurven für die ersten drei Reihen wurden in Abb. 7 wiedergegeben, R bedeutet den Volumenbruch der I - Lösung im Gemisch.

Die berechneten pK-Werte sind in Tafel 2 enthalten. Der Sicherheitsbereich ist durch die mittlere quadratische Abweichung in der Studentverteilung für eine Wahrscheinlichkeit von 95% angegeben.

Tafel 2

Die Werte der Instabilitätskonstanten (für sechs Reihen von nichtisomolaren Lösungen berechnet)

Nichtisomolare Reihe	C	p	x	pK	$\overline{pK}$
I	$9.90 \cdot 10^{-5}$	2.0	0.505	12.50	12.43 ± 0.20
II	$8.80 \cdot 10^{-5}$	2.5	0.450	12.68	
III	$6.55 \cdot 10^{-5}$	4.0	0.345	12.18	
IV	$7.39 \cdot 10^{-5}$	5.8	0.270	12.55	
V	$7.90 \cdot 10^{-5}$	8.0	0.210	12.32	
VI	$6.60 \cdot 10^{-5}$	10.0	0.175	12.44	

Die Fehlerfortpflanzungsrechnung gibt einen Fehler der selben Größenordung an, so daß die Abweichungen vom Mittelwert als zufällig angesehen werden können und die Berechnung eines Mittelwertes berechtigt ist. Bei 25° und für die Ionenstärke $\mu = 2.0$ wurde der Mittelwert $\overline{pK}$ gleich 12.43 ± 0.20 gefunden. Dieser Wert deutet auf eine große Stabilität des Komplexes hin.

SCHLUSSFOLGERUNGEN

Die spektrophotometrische Untersuchung des Systems V (v)-I führt zu folgenden Schlußfolgerungen :

1. Vanadium (V) bildet mit Solochromviolett RS eine tiefrote Verbindung die eine leichte spektrophotometrische Bestimmung des Vanadiums gestattet.
2. Die Empfindlichkeit der Methode läßt sie zu den guten Bestimmungsmethoden des Vanadiums zählen.
3. Das große $\overline{pK}$ des gebildeten Komplexes läßt auf eine große Stabilität schließen.

SPEKTROPHOTOMETRISCHE BESTIMMUNG DES Tl(III) MIT ORTHO-NITRAL UND PARA-NITRALGRÜN

CECILIA CONSTANTINESCU* und SIMON FIŞEL **

*Technische Hochschule für Erdöl, Gase und Geologie, Bukarest, str. Av. Traian Vuia, nr. 6

** Al. I. Cuza Universität Jassy, Calea 23 August nr. 11

Eingegangen am 2. Juni 1973

In der vorliegenden Arbeit wurden die optimalen Reaktionsbedingungen zwischen den basischen Farbstoffen *ortho*-Nitralgrün bzw. *para*-Nitralgrün und dem Thallium Komplexanion $TlBr_4^-$ studiert. Die vom Verfasser gewonnenen Farbstoffe wurden zum Studium der Reaktion mit $TlBr^-$ benutzt und festgestellt, daß sie wasserunlösliche aber benzollösliche Verbindungen bilden, welche dann in Benzol extrahiert werden. Die organischen Extrakte wurden dann spektrophotometrisch untersucht. Außerdem wurden die Verbindungen ausgefällt und einer Elementaranalyse unterworfen. Die Ergebnisse stimmten überein. Die studierte Reaktion ist für die spektrophotometrische Bestimmung des Thalliums geeignet.

In einigen vorherigen Arbeiten wurden die Reaktionen zwischen den Thalliumkomplexionen und basischen Farbstoffen der trimetharischen Klasse spektrophotometrisch studiert.[1-3] Der Mechanismus ähnlicher Reaktionen wurde von Onishi[4] bestimmt und besteht in der Bildung in wäßrigen Medien der komplexen hallogenometallischen Säuren : HMX_4 ; H_2MX_5 ; H_3MX_6 ; die durch die Bindung des komplexen Anions MX_{3+n}^{n-} am Farbstoffskation gefolgt wird. Die in organischen Lösungsmitteln extrahierbare Verbindung ist vom Typus der ionischen Assoziation, dem man nachträglich die optische Dichte bestimmt.

In dieser Arbeit werden die Synthese der basischen Farbstoffe *ortho*- und *para*-Nitralgrün, die Ergebnisse der Forschungen bezüglich der Bildungsreaktion der ionischen Assoziation zwischen dem komplexen Anion $TlBr_4^-$ und der Kationen der Farbstoffe sowie auch die Struktur der erhalte nen Verbindung dargestellt.

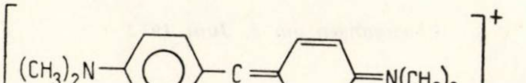
VERSUCHSTEIL

SYNTHESE DER FARBSTOFFE

Ortho- und *para*-Nitralgrün wurden durch Anwendung der geeigneten Methode zur Erhaltung des triphenylmethanischen Farbstoffes Malachitgrüns synthetisiert[5] d.h. durch die Kondensierung der *ortho-* und *para*-Nitrobenzolaldehyde mit Dimethylanilin. Die durch Erhitzung auf dem Wasserbad erhaltene dickflüssige Masse ist mit Wasserdampf angetrieben. Der zurück gebliebene Rückstand ist in Äthylalkohol aufgelöst, woraus die Leukobasis wieder ausgefüllt wird. Durch Oxydation der Leukobasis mit Bleidioxyd erhält man das entsprechende Karbinol oder Pseudobase, welches mit Chlorowasserstoff die Kombination mit folgender Struktur bildet :



— NO_2 in *ortho-* oder *para-* Stellung

Die Farbstoffe werden weiterhin in verkürzter Form bezeichnet : $o-R^+Cl^-$; $p-R^+Cl^-$

Die Reinigung erfolgte durch wiederholte Umkristallisationen, wonach die Reinheit durch die Kaliumdichromatmethode[6] bestimmt und 82,33 % für *ortho*-Nitralgrün bzw. 96,28 % für *para*-Nitralgrün festgestellt wurde.

REAGENZIEN UND LÖSUNGEN

Die wäßrige Lösung des Tl(III) war durch die Auflösung des Thallium (I) Nitrats, Zufügung von konzentriertem Chlorwasserstoff, und Oxydierung mit Bromwasser hergestellt. Nach der Entfernung des Chlorwasserstoffs durch Verdampfen wird eine Eichlösung vorbereitet, die 204 µg Tl(III) enthält. Der Titer der Thalliumlösung wurde durch Fällung in Form von Thalliumjodid bestimmt.[7] Die in dieser Arbeit benutzten Lösungen wurden durch angemessene Verdünnungen vorbereitet.

— Man verwendet 0,05 %ige Lösungen bezogen auf die 100 %ige Reinheit von *ortho-* und *para*-Nitralgrün ;

— Bromwasserstoff 64 %ig.

— Benzol *p.a.*

— Lösungen verschiedener Kationen unter Form von Nitraten, Sulfaten und/oder Chloriden.

EXTRAKTION DES KOMPLEXES

Die 1.10^{-5} M Lösung von Tl(III) in Volumina von 0,5–10 cm³ wird in einen Scheidetrichter von 50 cm³ mit 64 %igen Bromwasserstoff (1 ccm) und 0,05 %ige Reagenzlösung geführt. Man füllt destilliertes Wasser bis zum Volumen von 10 cm³, fügt 10 cm³ organisches Lösungsmittel hinzu und schüttelt 2 Minuten lang. In ähnlicher Weise wird auch die Blindprobe vorbereitet. Man mißt die Extinktionen der gefärbten organischen Phase bei den entsprechenden Wellenlängen $\lambda = 635$ nm ; $\lambda = 645$ nm.

DIE SYNTHESE DER KOMPLEXE

Um das Kombinationsverhältnis in festem Zustand des thallischen Anions mit den untersuchten Reagenzien festzulegen, wurden 0,25 *g* *ortho*- oder *para*-Nitralgrün in 25 cm³ Wasser gelöst und mit 0,25 g in 1 cm³ gelöster Tl(III) gemischt. Es erscheint ein blauer Niederschlag der durch Filtrierung unter Vakuum getrennt und mit Wasser gewaschen wurde. Die Verbindungen wurden bezüglich des Gehalts an Thallium durch die Fällungsmethode (in Form von Thalliumjodid [7]) und an Stickstoff bzw. an Brom analysiert. Die erhaltenen Ergebnisse sind in Tabelle 1 eingetragen, woraus hervorgeht, daß das Kombinationsverhältnis Metall-Ligand 1 : 1ist.

Tabelle 1

Die Analyse der Komplexe

Verbindung	Thallium %		Stickstoff %		Brom %	
	Ber.	Gef.	Ber.	Gef.	Ber.	Gef.
$[o\text{-}R^+][TlBr_4]^-$	22,7	22,1	4,67	4,62	35,6	34,9
$[p\text{-}R^+][TlBr_4]^-$	22,7	22,2	4,67	4,61	35,6	35,0

ERGEBNISSE UND DSKUSSIONEN

Die Wahl des Lösungsmittels. Es wurden folgende Lösungsmittel erprobt : Benzol, Toluol, Chloroform, Aceton, Zyklohexanol, Benzol gemischt mit Methyläthylceton und Benzol gemischt mit Äther. Man stellt fest, daß die Benzolmischung mit kleinen Mengen von Methyläthylceton zur größten Extinktion führte, gefolgt von Benzol. Da die Benzol-Methyläthylceton Mischung auch eine Menge Farbstoff mitextrahiert, wurde in unseren Forschungen nur das Benzol als Lösungsmittel für beide Komplexverbindungen verwendet.

ABSORPTIONSSPEKTREN IM SICHTBAREN BEREICH

Bei Bestimmung der elektronischen Absorptionsspektren der wäßrigen Lösungen von *ortho*-Nitralgrün (Abbildung 1) als Kurve C_1 und von *para*-Nitralgrün als Kurve C_3 wird festgestellt, daß das erste Spektrum ein Absorptionsmaximum bei $\lambda_{max} = 635$ nm und das zweite bei $\lambda_{max} =$

$=645$nm haben. Die mit Tl(III) in 10 cm^3 Benzol erhaltenen Verbindungen haben ein Absorptionsmaximum bei $\lambda_{max} = 645$ nm für das *ortho*-Nitralgrün (C_2) und bei $\lambda_{max} = 655$ nm für *para*-Nitralgrün (C_4). Wir erwähnen, daß die Benzolextrakte der Kontrollproben ohne Gehalt an Tl(III) überhaupt keine Färbung ergeben. Aus Abbildung 1 ist ersichtlich, daß die Maxima der Absorptionsbänder der Komplexe mit Tl batochrom verschoben sind, in Verhältnis zu den Farbstoffspektren, Verschiebung, die der Bildung einiger Komplexe mit Ladungsübertragung vom Typus $\sigma - \pi$ zugeschrieben werden kann.

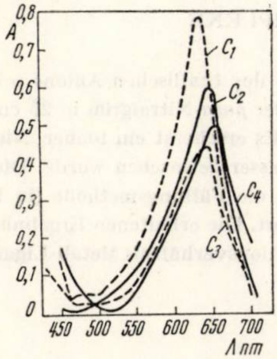

Fig. 1. — Absorptionsspektren : C_1 : Farbstoff : *ortho*-Nitralgrün ; C_2 : Komplex : Thallium-*ortho*-Nitralgrün ; C_3 : Farbstoff : *para*-Nitralgrün ; C_4 : Complex : Thallium-*para*-Nitralgrün.

DIE IR ABSORPTIONSSPEKTREN

Diese Spektren werden in einem Bereich von 400— 4 000 cm^{1-} erforscht. Bei Vergleichung der IR Spektren der freien Verbinder mit denen der entsprechenden Komplexverbindungen mit Thallium, wurde festgestellt, daß die Lagen und die Größen der Vibrationsbänder nach der Reaktion sich nicht verändert haben, ein Hinweis dafür, daß sich die Komplexe mit Ladungsübertragung bilden. Die charakteristischen Vibrationen der Verbindungen C—N (1 400 cm^{-1}), C—C (1 600 cm^{-1}), C—H (1 000 cm^{-1}) in den Spektren der Komplexe sind gewöhnlich etwas verschoben gegen kleinere Frequenzen wegen der Ausdehnung dieser Verbindungen nach der Komplexierung. Die Verbindungen mit Thallium konnten nicht hervorgehoben werden, weil die betreffenden Vibrationen unter 400 cm erscheinen und dieser Bereich nicht mit dem verwendeten Apparat erforscht wurde (Perkin-Elmer 337).

DIE AZIDITÄT DER LÖSUNG

Die Reaktionen zwischen Thallium (III) und der Reagenzien *ortho*- und *para*-Nitralgrün laufen im Milieu von Bromwasserstoff ab. Bei 1,20 N HBr für das erste Komplex (C_1) und 0,68 N HBr für den das zweite (C_2), erhält man die maximale Absorbanz. Die Versuchsergebnisse werden in der Abbildung 2 vorgeführt. Im Medium von Chlorwasserstoff ist die Extraktionsfähigkeit klein.

DIE REAGENZKONZENTRATION

Bei Veränderung der Farbstoffmenge von 0,2–2,0 cm^3 für *ortho*-Nitralgrün und von 0,2–2,5 für *para*-Nitralgrün wurde eine Erhöhung der Absorption bis zu einer bestimmten Konzentration festgestellt, nach der sie konstant bleiben. Die bestmögliche Konzentration, in Abbildung 3 ersichtlich, ist für das erste Reagens von 1,5 cm^3 0,05% wäßrige Lösung die Kurve C_1) und für das zweite von 2 cm^3 0,05%ige wäßrige Lösung (die Kurve C_2).

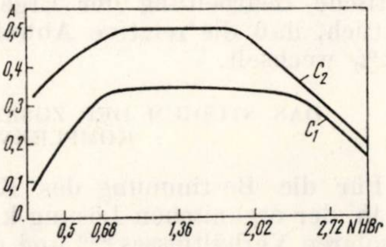

Fig. 2. — Einfluß der Lösungsazidität : C_1 : Tl-*ortho*-Nitralgrün ; C_2 : Tl-*para*-Nitralgrün.

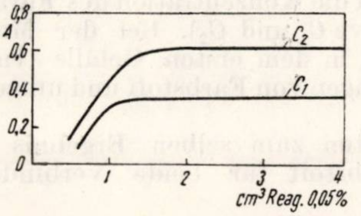

Fig. 3. — Einfluß der Farbstoffskonzentration : C_1 — *ortho*-Nitralgrün ; C_2 — *para*-Nitralgrün.

DIE EICHKURVE

Das Studium der Absorptionvariation in Abhängigkeit von der Konzentration von Thallium (III) hat gezeigt, daß das Bouguer-Lambert-Beer'sche Gesetz zwischen den Grenzen 0,05–6,1 μg Metall/cm^3 Extrakt als wahr erwiesen ist für das Komplex Tl(III)-*ortho*-Nitralgrün (C_1) Abbildung 4, mit einem molaren Extinktionskoeffizient $\varepsilon = 110\,000$ und

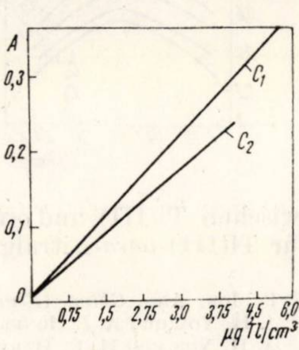

Fig. 4. — Die Eichkurve : C_1 : Tl-*ortho* Nitralgrün ; C_2 : Tl-*para*-Nitralgrün.

zwischen den Grenzen 0,04—4,0 μg Tl(III)/ccm Extrakt für das Komplex Tl(III)-*para*-Nitralgrün (C_2) mit einem molaren Extinktionskoeffizient $\varepsilon = 116\,000$. Es ist ersichtlich, daß die Reaktion zwischen Thallium und *para*-Nitralgrün empfindlicher ist. Die Beständigkeit der komplexen Kombinationen beträgt 48 Stunden.

Die Eichungsgeraden wurden durch Verbesserung der Versuchsdaten mit Hilfe der Methode der kleinsten Quadrate erhalten. Durch die statistische Bearbeitung der Ergebnisse (Wahrscheinlichkeit 0,95) wird ersichtlich, daß die relative Abweichung für beide Methoden zwischen ± 3,2% wechselt.

DAS STUDIUM DER ZUSAMMENSETZUNG GEBILDETER KOMPLEXVERBINDUNGEN

Für die Bestimmung des Kombinationsverhältnisses Metall-Farbstoff in der organischen Lösung kamen die Methode Job [8], die Methode des molaren Verhältnisses [9,10] und die Methode der Gefälle [11] zur Anwendung. Die erhaltenen Ergebnisse bei der Durchführung der Methode Job sind in der Abbildung 5 wiedergegeben, bei Benutzung zweier Paare von Isomolarlösungen : 1.10^{-4} M die Kurve C_1 und C_4 und 2.10^{-4} M die Kurven C_2 und C_3. Bei der Methode des molaren Verhältnisses ist die Konzentration des Metalls konstant geblieben und die Konzentration des Farbstoffs hat sich verändert (Zeichnung 6 die Kurve C_1 und C_2). Bei der Methode des Gefälleverhältnisses verwendet man in dem ersten Gefälle variable Mengen von Thallium und konstante Mengen von Farbstoff und umgekehrt bei dem zweiten Gefälle.

Die angewandten Methoden führten zum selben Ergebnis u.z. : das Kombinationsverhältnis Metall/Farbstoff für beide Verbindungen ist 1 : 1.

DIE BILDUNGSKONSTANTE DER KOMPLEXVERBINDUNGEN

Aus der graphischen Darstellung des molaren Verhältnisses (Abbildung 6) wurde die Bildungskonstante [9,10] K_f errechnet und es wurde für das zwischen Tl(III) und *ortho*-Nitralgrün gebildete Komplex $K = 1{,}1 . 10^5$ und für Tl(III)-*para*-Nitralgrün $K = 1{,}5 \cdot 10^5$ gefunden.

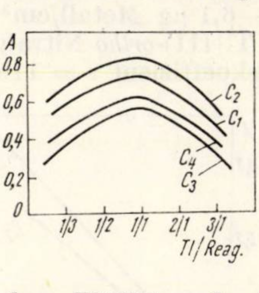

Fig. 5. — Das Kombinationsverhältnis : Die Methode Job ; C_1 : Tl-*o*-Nitralgrün 1.10^{-4} ; C_2 : Tl-*o*-Nitralgrün 2.10^{-4} ; C_3 : Tl-*p*-Nitralgrün 1.10^{-4} ; C_4 : Tl-*p*-Nitralgrün 2.10^{-4}.

Die erhaltenen Ergebnisse zeigen, daß durch Fällung sich Komplexe vom Typus $R^+[TlBr_4]^-$ bildeten. In Lösung wegen der Übermenge an Bromwasserstoff können folgende Gleichgewichte erscheinen :

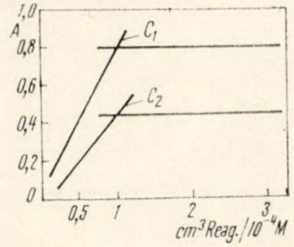

Fig. 6. — Das Kombinationsverhältnis : Die Methode des Molarverhältnisses : Tl-*o*-Nitralgrün ; C_2 : Tl-*p*-Nitralgrün.

$$TlBr_3 + HBr \rightleftarrows HTlBr_4$$

$$HTlBr_4 + HBr \rightleftarrows H_2TlBr_5$$

$$H_2TlBr_5 + HBr \rightleftarrows H_3TlBr_6$$

Unter den obenerwähneten Bedingungen herrscht das Bromkomplex $HTlBr_4$ vor, aus welchem Grund sich die ionische Assoziation bildet :

$$R^+Cl^- + HTlBr_4 \rightleftarrows R^+[TlBr_4]^- + HCl$$

Es ist aber möglich, daß in der Lösung auch andere in Gleichgewicht bleibende Arten existieren wie :

$$R_2^+[TlBr_5]^{2-} ; R_3^+[TlBr_6]^{3-}.$$

DER EINFLUSS FREMDER IONEN

Es wurden die Interferenz jener Ionen geprüft, die gewöhnlich in verschiedenen Materialien Thallium begleiten, so wie : Indium, Gallium, Eisen, Antimonium, Vanadium, Gold und Germanium . Die Reaktion ist vom Wachsen der Absorption in folgender Reihenfolge gestört :

Au(III) >Fe(III) >In(III) >Ge(III) >Ga(III)> Sb (III).

Die erhaltenen Ergebnisse zeigen, daß durch Fällung sich Komplexe vom Typus $R_x[TlBr_y]$ bildeten. In Lösung wegen der [illegible] Bromwasserstoff können folgende Gleichgewichte erscheinen:

$$TlBr_3 + HBr \rightleftharpoons HTlBr_4$$

$$HTlBr_4 + HBr \rightleftharpoons H_2TlBr_5$$

$$H_2TlBr_5 + HBr \rightleftharpoons H_3TlBr_6$$

Unter den obenerwähnten Bedingungen herrscht das Bromkomplex $HTlBr_4$ vor, aus welchem Grund sich die ionische Assoziation bildet:

$$R^+Cl^- + HTlBr_4 \rightleftharpoons R^+[TlBr_4]^- + HCl$$

Es ist aber möglich, daß in der Lösung auch andere in Gleichgewicht bleibende Arten existieren wie:

$$R_2^+[TlBr_5]^{2-} ; R_3^+[TlBr_6]^{3-}$$

DER EINFLUSS FREMDER IONEN

Es wurden die Interferenz jener Ionen geprüft, die gewöhnlich in verschiedenen Mineralien Thallium begleiten, so wie: Indium, Gallium, Eisen, Antimon, Vanadium, Gold und Germanium. Die Reaktion ist [illegible] der Absorption in folgender Reihenfolge gestört:

Au(III) > Fe(III) > In(III) > Ge(III) > Ga(III) > Sb (III)

Revue Roumaine de Chimie, 19, 3, 517–519 (1974)

H. I. ENE und S. GOGONEA ,,*Probleme în teoria filtrației*" (Probleme der Filtrationstheorie), Edit. Academiei, Bukarest 1973, 43 S.

In der vorliegenden Arbeit versuchten die Autoren die wichtigsten Probleme der Filtrationstheorie vorzubringen. Während der Darlegung fiel der Schwerpunkt auf die Entwicklung der mathematischen Modelle, ohne aber auch die konkrete, praktische Seite der Filtrationstheorie zu vernachlässigen.

Die Arbeit besteht aus drei Hauptteilen, die weiter in zehn Abschnitte untergeteilt wurden. Im ersten Abschnitt befassen sich die Autoren mit den Gleichungen der Bewegung der Fluiden in porösen Mitteln. Dieser Abschnitt hat mehr einen Einleitungscharakter. Der erste Teil des Buches beginnt erst mit dem zweiten Abschnitt der über einige Probleme der Bewegung der artesischen Gewässer in homogenen Mitteln handelt. Im nächsten Abschnitt wird dasselbe Thema erweitert und zwar wird, vom mathematischen Gesichtspunkt ausgehend, die Volterra- und Riemanngleichung gelöst. Es folgt ein Abschnitt in dem die Probleme der Bewegung der Fluiden in porösen Mitteln mit Hohlräumen behandelt werden. Es ist der größte Abschnitt des Buches und da die behandelten Probleme sehr verschieden sind, wird dieser Abschnitt in fünf Unterabschnitte geteilt. Ein Schwerpunkt wird auf die rumänischen Beiträge zur mathematischen Modellierung der Bewegung der Fluiden in dünnen Schichten gelegt. In dieser Hinsicht werden die von Prof. Gheorghiță vorgeschlagenen Lösungen besprochen.

Der zweite Teil der Arbeit besteht aus den Abschnitten fünf, sechs und sieben, und behandelt die Magnetohydrodynamik der porösen Mittel. Im fünften Abschnitt wird der Einfluß der porösen Wände auf die Bewegung der elektrizitätsleitenden Fluiden besprochen. Wie in jedem Abschnitt werden zuerst die Gleichungen des Vorgangs untersucht um dann weiter auf mehr praktische Probleme überzugehen. Der nächste Abschnitt befaßt sich mit den Gleichungen der Bewegung der elektrizitätsleitenden Fluiden durch poröse Mittel. In diesem Abschnitt wird weitgehend über den Zusammenhang zwischen den Bewegungsgleichungen und der Elektroosmose berichtet. Der letzte Abschnitt des zweiten Teils wird ,,Die Magnetohydrodynamik der porösen Körper" genannt. Das Hauptproblem in diesem Abschnitt bildet die Untersuchung der hydrodynamischen Wirkung im magnetischen Feld.

Die letzten drei Abschnitte bilden den dritten Teil der Arbeit. In diesem Teil werden die nichthomogenen porösen Mittel behandelt. Der achte Abschnitt, ,,Die Bewegung der Fluide durch nichthomogene poröse Mittel" besteht aus vier Unterabschnitten. Es werden, vom mathematischen Gesichtspunkt aus Probleme, wie z.B. die Bewegung der Fluiden in homogenen und nichthomogenen Mitteln besprochen. Im neunten Abschnitt werden die Reziprozitätsprinzipien für nichthomogene poröse Mittel behandelt. Schließlich, im letzen Abschnitt wird über den Einfluß der Temperatur auf die Bewegungen in porösen Mitteln berichtet. In diesem Abschnitt behandeln die Autoren die Gleichungen der Energie, die natürliche Konvexion in porösen Schichten und andere Probleme die mit dem Einfluß der Temperatur auf die Bewegung in verschiedenen porösen Mitteln in Zusammenhang sind.

Am Ende von jedem Abschnitt bringen die Verfasser ein reiches Literaturverzeichnis aus dem betreffenden Gebiet vor. Übrigens, am Schluß des Bandes befindet sich ein allgemeines Literaturverzeichnis das aus 15 Angaben, über Bücher die über dasselbe Gebiet handeln, besteht. Die Behandlung eines so umfangreichen Materials wird sehr systematisch und klar ausgeführt. Die Gliederung der Arbeit in 10 Abschnitte und fast 130 Unterabschnitte erleichtert wesentlich die Arbeit mit dem Buch. Das hohe wissenschaftliche Niveau der Arbeit setzt besondere mathematische Kenntnisse voraus. Sie wird daher nur einem geringen Kreis von Spezialisten empfohlen.

C. SIMIONESCU, MARGARETA GRIGORAȘ, AGATA CERNĂTESCU ASANDEI und G. ROZMARIN „*Chimia lemnului din România; Plopul și salcia*" (Die Chemie des Holzes aus Rumänien ; Pappel und Weide), Edit. Academiei, Bukarest, 1973, 293 S.

Die Ausbeutung des Holzes der Wälder ist sicher eine der ältesten Beschäftigungen der Menschen. Während der Jahrhunderte nahmen sich die Menschen das nötige Holz aus den Wäldern, denn das verfügbare Holz war immer in größerer Menge als die Nachfrage. In der letzten Zeit hat sich diese Lage grundsätzlich verändert ; die außerordentliche Entwicklung der Zellstoffindustrie und der immer größere Verbrauch von Papier und Pappe, benötigten Holzmengen die vom natürlichen Nachwuchs nicht mehr gedeckt werden konnten. Während ein Tannenwald fast 100 Jahre braucht um ausgebeutet werden zu können, vermindert sich diese Zeit im Fall der Pappel und Weide bis zu höchstens 20 Jahren. Darum gehören diese Baumarten zu denen die im höchsten Maße zur Befriedigung der Holznachfrage beitragen können.

In der vorliegenden Arbeit nahmen sich die Verfasser vor, den Fachmännern ein umfangreiches Studium der physikalisch-chemischen Eigenschaften des Pappel- und Weideholzes vorzubringen. Die Arbeit besteht aus 9 Abschnitten. Der erste Abschnitt behandelt allgemeine pedoklimatische Probleme der Wälder. In diesem Abschnitt werden, zwischen anderen, folgende Hauptthemen besprochen : Die Waldvegetation im Donautal, Waldtypen, die Züchtung der Pappel in der Donauau. Dieser Abschnitt hat mehr einen Einleitungscharakter. Erst mit dem zweiten Abschnitt beginnt das eigentliche Studium der Pappel und Weide. Es werden die Morphologie und Anatomie des Pappelholzes besprochen. Die Autoren meinen, daß ,,ein grundlegendes Kennzeichnen der anatomisch-morphologischen Struktur des Pappelholzes das Vorhandensein in größerem Maßstab, von Zugholz ist, das dieser Holzart eine Anzahl von besonderen Eigenschaften verleiht. Makroskopisch, im Stammquerschnitt ist das Zugholz weißschimmernd, glänzend und dichter als Normalholz".

Im dritten Abschnitt der Arbeit werden die chemischen Eigenschaften des Pappelholzes untersucht. Es ist die Rede über die chemische Zusammensetzung und die chemischen Eigenschaften sowohl des eigentlichen Pappelholzes, als auch der Hemizellulose und des Lignins. Dieser Abschnitt enthält auch einen sogenannten ,,experimentellen Teil" in dem über die Trennung und Reinigung des Lignins berichtet wird.

Im vierten Abschnitt werden die beim Studium des Pappelholzes benützten physikalisch-chemische Methoden besprochen. Zwischen diesen modernen Forschungsmethoden, steht an erster Stelle die Methode der Beugung der Röntgenstrahlen. Andere ebenfalls wichtige Methoden sind die I. R. Absorptionsspektroskopie des Pappelholzes, die I. R. Spektroskopie des Lignins und thermogravimetrische Studien. Dieser Abschnitt ist, vom Gesichtspunkt des Chemikers aus, der Wichtigste, da er die Möglichkeiten der Anwendung von modernen Forschungsmethoden beim Studium des Holzes behandelt.

In den zwei nächsten Abschnitten ist die Rede über die besonderen Eigenschaften des Pappelholzes bei der Papierherstellung, und über dem Pappelflaum. Angefangen mit dem siebenten Abschnitt beginnt das Studium des Weidenholzes. Die untersuchten Probleme sind fast dieselben wie beim Studium des Pappelholzes. Im Abschnitt sieben, acht, und neun wird die Morphologie und Anatomie des Weidenholzes, seine physikalischen und chemischen Eigenschaften und die Möglichkeiten der Papierherstellung aus Weidenholz besprochen.

Nach jedem Abschnitt bringen die Verfasser ein reiches Literaturverzeichnis vor. Am Ende der Arbeit befindet sich eine Zusammenfassung in rumänischer, englischer und deutscher Sprache. Die Darstellung des Materials ist äußerst systematisch unternommen, so daß die praktische Arbeit mit dem Buch sehr leicht vor sich geht. Die Arbeit setzt keine besonderen Chemie- oder Landwirtschaftskenntnisse voraus, und wird daher einem weiten Kreis von Studenten, Technikern und Spezialisten empfohlen.

NOTE POUR LES AUTEURS

La *Revue Roumaine de Chimie* publie des articles en anglais, français, russe, allemand ou espagnol. Les auteurs sont priés d'envoyer des articles, notes, communications et comptes rendus inédits.

Les manuscrits seront dactylographiés à deux intervalles. Les tableaux seront dactylographiés sur des feuilles séparées, de même que la légende des figures. Les diagrammes seront tracés à l'encre de Chine sur papier calque. Les tableaux et les figures seront numérotés par des chiffres arabes, en nombre strictement nécessaire. Prière de ne pas inscrire les mêmes données dans les tableaux et les figures. Les formules chimiques seront incluses dans le texte ; en outre, elles seront transcrites sur des feuilles séparées. Les auteurs sont priés d'indiquer les caractères italiques (en soulignant les lettres au crayon), ainsi que tout autre caractère spécial. L'ordre des références bibliographiques sera celui de leur mention dans le texte ; le nom de l'auteur sera précédé de l'initiale du prénom ; les publications périodiques seront présentées suivant les prescriptions internationales. Les références seront ajoutées à la fin de l'article ; elles paraîtront comme des notes, au bas de la page. Le texte sera précédé d'un résumé comprenant 15 lignes au maximum.

L'entière responsabilité du contenu des articles appartient aux auteurs. On publie des articles dus aux collaborateurs roumains ou étrangers. Les auteurs recevront 50 tirés à part.

THE GALVANOSTATIC STUDY OF THE ELECTROCHEMICAL ADSORPTION PROCESS ON THE IODINE-ACTIVE CARBON ELECTRODE IN MOLTEN SALTS. I

THE CURRENT INTENSITY EFFECT

S. STERNBERG and I. GALASIU

Centre of Physical Chemistry, Str. Galaţi 31, Bucharest

Received May 5, 1973

Anodic and cathodic polarization curves for iodine-active carbon electrode in fused AgI + KI eutectic have been determined by galvanostatic method at several intensities and 300°. The efficiency of iodine deposition on electrode has been measured *versus* intensity for different charges passed through the cell.

In previous papers the halogen-active carbon electrode has been studied by the cathodic polarization curves.$^{1-4}$ In those works the halogen-active carbon electrode has been obtained by a preliminary anodic polarization corresponding to the reversible potential. In this new series of investigations the carbon electrode is anodically polarized under galvanostatic conditions up to a stationary potential which is lower than the reversible potential. This way one can investigate the "charging" of activated carbon surface with the halogen which is electrochemically adsorbed.

EXPERIMENTAL

The deposition of iodine on the active carbon electrode has been effected by electrolysis of an eutectic mixture of AgI + KI. The anode consisted of an active carbon rod with the specific surface of 10–20 m^2/g and a weight of 2.23 g. The cathode was a silver rod of 3 mm diameter. The potential of the $Ag_{(s)}/AgI_{(l)} + KI_{(l)}/I_{2(g)}$ C cell was measured with a remanent trace oscillograph. Both for anodic and cathodic polarizations of carbon electrode a galvanostatic method has been used. The carbon electrode without iodine has been exposed to a gal-

vanostatic anodic polarization until the desired potential was obtained, and the galvanostatic anodic polarization curve has been recorded. Then, the cell was switched on a galvanostatic cathodic polarization circuit until the iodine was completely removed from the electrode; the galvanostatic cathodic polarization curve was recorded, too.

The iodine quantities adsorbed on or desorbed from the electrode by electrolysis have been calculated with the relations:

$$Q = i \cdot t \quad \text{and} \quad a = Q/F$$

where:

Q = quantity of current in coulombs.
F = Faraday constant.
i = current intensity.
t = polarization time.
a = atom-grams of iodine.

During the experiments argon gas has been bubbled through the electrolyte, so that gaseous iodine has continuously been evolved from the cell. The apparatus and the preparation procedure of the active carbon electrodes were described in our previous works.[1-4]

The apparent surface area of the electrode was 11.33 cm². The real surface of the active carbon electrode is much greater but its value is not known since one cannot accurately determine the contact surface between electrode and electrolyte; hence no reliable value of the current densities used can be given.

RESULTS AND DISCUSSIONS

In fig. 1 the anodic polarization curves obtained at the deposition of iodine on an active carbon electrode at 300° are plotted. The anodic polarization has been effected with currents of 20, 50, 100 and 200 mA. The reversible potential of the iodine electrode in the same mixture and at the same temperature, calculated according to the equation[5]

$$E = 0.5885 - 0.225 \times 10^{-3} (T - 873)$$

has been chosen as reference potential.

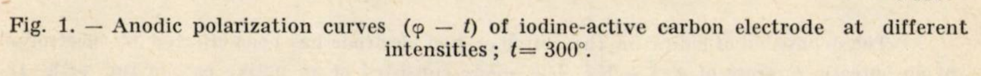

Fig. 1. — Anodic polarization curves ($\varphi - t$) of iodine-active carbon electrode at different intensities; $t = 300°$.

---

[5] S. Sternberg, I. Adorian and I. Galasiu, *Electrochim. Acta*, **11**, 385 (1966).

The general behaviour of the potential (φ)-time curves is as follows :

At a given value of the current intensity the electrode potential increases in time and reaches a stationary value which is lower than the reversible potential.

Following the galvanostatic anodic process, a galvanostatic cathodic polarization was always effected at a current equal to that used at the anodic polarization in order to measure the iodine adsorbed on the electrode. The anodic polarization has also been effected "in steps". After the anodic polarization (duration t_1) the cathodic polarization was effected, and the charging efficiency calculated according to the equation :

$$\eta = \frac{Q \text{ (cathodic polarization)}}{Q \text{ (anodic polarization)}} \cdot 100$$

After the first cathodic polarization, the anodic polarization has been resumed for a duration $t_2 > t_1$, and so on. The "in steps" anodic polarization curve was found to superimpose very well on that obtained in a single period.

This behaviour may be explained as follows :

The potential of the active carbon electrode is determined by the quantity of halogen adsorbed on carbon, that is by the degree of coverage θ. To exemplify we have studied the charging curve corresponding to $i = 100$ mA.

On the AB portion of the curve a discharging reaction of the iodine ions with formation of adsorbed iodine, probably in atomic state, takes place.

$$I^- = I_{(\text{ads})} + e^- \tag{1}$$

On this portion all the anodic polarization current is practically used for the "charging" of the electrode with adsorbed iodine. Let this current be $i_{(\text{ads})}$ adsorption current. On this portion the efficiency is practically $\eta = 100\%$. On the BC portion the efficiency begins to decrease, owing to the "thermal desorption" process :

$$2\,I_{(\text{ads})} \rightarrow I_{2_{(\text{ads})}} \rightarrow I_2 \text{ (gas or dissolved in the melt)} \tag{2}$$

We will denote as desorption current $-i_{(\text{desorption})}$ – the current used to compensate the iodine losses by "thermal desorption" according to reaction (2). Therefore, in this portion part of the iodine which is deposited on the electrode is used to compensate the "thermal desorbed" iodine. This causes the potential increase in time to become slower. The increase of the potential φ is determined by the adsorption current which is given by :

$$i_{(\text{ads})} = i - i_{(\text{desorption})} \tag{3}$$

where "i" stands for the total current used for the anodic galvanostatic polarization.

On the CD portion of the curve the φ potential becomes practically stationary and in this case the total current $i = i_{(\text{desorption})}$ while $i_{(\text{ads})} = 0$.

All these facts, in agreement with our previous works[1-3] point out a new phenomenon, namely the existence of a thermal desorption current at the polarization of active carbon electrodes in fused electrolytes. Because of high temperatures required by electrolysis processes in molten salts, the "thermal desorption current" can reach high values, *i. e.* several hundreds milliamperes. Actually, this desorption current is equal to the desorption rate of the halogen from the active carbon electrode, $v_{(\text{desorption})}$

$$i_{(\text{desorption})} = v_{(\text{desorption})}\,) = \theta \cdot K_{(\text{desorption})} \tag{4}$$

where $K_{(\text{desorption})}$ represents the desorption constant.

The degree of coverage depends on pressure and implicitly on potential

$$\theta = f(\varphi) \tag{5}$$

The more electropositive the φ potential, the higher the value of θ and consequently, according to eq. (4), the higher $i_{(\text{desorption})}$. This explains the increase of the stationary potential as a function of the charging current, taking into account that under stationary conditions $i = i_{(\text{desorption})}$ as may be seen in table 1.

Table 1

The potential dependence of Q_{charging} and $Q_{\text{discharging}}$ (reference potential: silver electrode): t = 300°

$i_{\text{charging}} = i_{\text{discharging}} = 20\text{mA}$			$i_{\text{charging}} = i_{\text{discharging}} = 50\text{ mA}$			$i_{\text{charging}} = i_{\text{discharging}} = 100\text{mA}$

Fig. 2 represents the dependence of the potential φ on the charge required for the anodic polarization. The Q quantities were calculated from the φ *vs.* anodic polarization time curves. Only the AB portion of the anodic polarization curves has been plotted, because in this range the efficiency is 100% for different currents. Examination of these curves shows that they do not overlap. Therefore, the same potential φ is obtained with different amounts of halogen adsorbed : the higher the current, the smaller the Q quantities at $\varphi =$ constant. The explanation could be the following : the value of the degree of coverage remains the same for a given potential, but the electrochemically active surface is larger as the charging current "i" is smaller. For smaller currents the charging time is larger and the halogen diffuses into the inner pores of the active carbon bulk. It is also possible that, in this case, the wetting of the electrode by the electrolyte is better. Under these conditions, the surface which participates in the electrochemical process is larger, and to obtain a φ potential a larger charge is necessary.

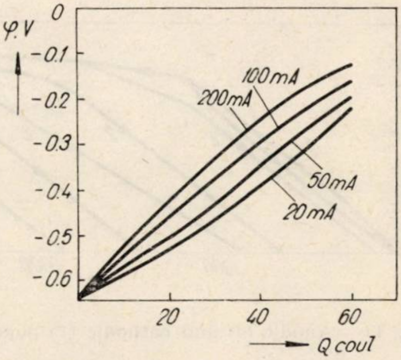

Fig. 2. — Anodic polarization curves (φ — Q) of iodine-active carbon electrode at different intensities ; $t = 300°$.

Fig. 3 shows the anodic polarization curve obtained by "steps" corresponding to $i = 100$ mA. At the end of every anodic polarization a cathodic polarization has been effected. It has been found that for short anodic polarization times the efficiency of the iodine deposition on the electrode is 100% and decreases as the anodic polarization time increases.

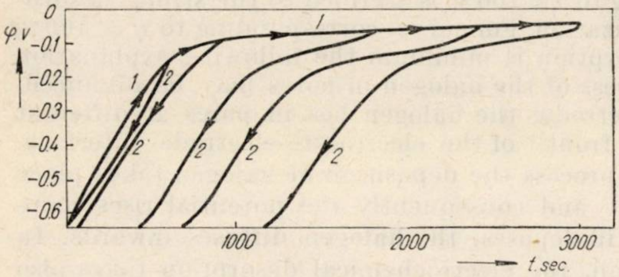

Fig. 3. — Anodic (*1*) and cathodic (*2*) polarization curves at $i = 100$ mA and $t = 300°$.

It has also been found that for higher potentials, close to the reversible potential, on both anodic and cathodic polarization curves there are characteristic plateaus which may be attributed to a capillary condensation of iodine in the active carbon pores. This is plausible because the working temperature, 300°, is below the critical point of iodine, *i. e.* 511°. The curves for anodic-cathodic polarization with $i = 50$ and $i = 20$ mA have similar shapes (figs. 4 and 5). Some hysteresis existing in case of curves corresponding to $\eta < 100\,\%$ is ascribed to the strong desorption during the anodic polarization. For curves corresponding to $\eta = 100\,\%$ for which the thermal desorption is minimum the following explanation based on the diffusion process of the halogen in pores may be advanced. On the halogen-carbon electrode, the halogen lies in pores at different distances from the "first front" of the electrolyte-electrode interface. At the anodic polarization process the deposition of halogen takes place at first on the "first front" and consequently the potential rises more rapidly in time. Then, as it deposes, the halogen diffuses inwards. In case of cathodic polarization, the electrochemical desorption takes also place at first from the "first front", and the $\varphi - t$ curve has at the beginning a higher slope.

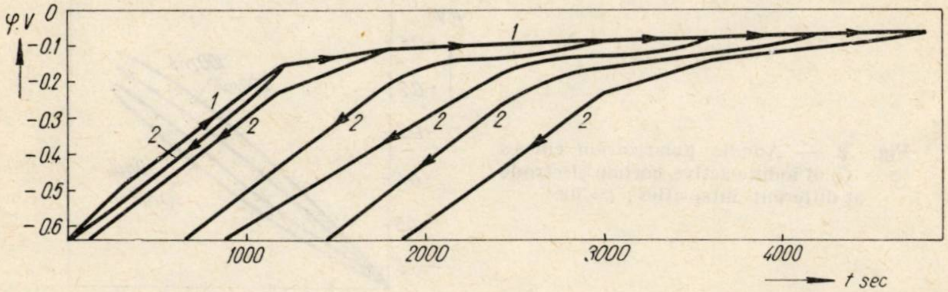

Fig. 4. — Anodic (*1*) and cathodic (*2*) polarization curves at $i = 50$ mA and $t = 300°$.

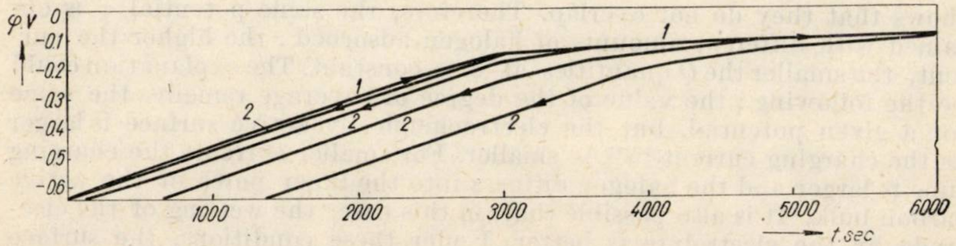

Fig. 5. — Anodic (*1*) and cathodic (*2*) polarization curves at $i = 20$ mA and $t = 300°$.

Figs. 6 and 7 represent the iodine deposition efficiency change *versus* anodic polarization time and the charge involved in anodic polarization, respectively. As expected, one observes that in the η *vs.* time coordinates (fig. 6) the lower the value of the "*i*" current, the higher the location of the curves on plots. On the other hand, if we plot the efficiency *vs.* charge used for anodic polarization (fig. 7) one observes that the positions of the three curves are reversed. In this latter case, passing through the cell some charge with a lower current requires longer times during which the thermal desorption is more important and iodine deposition efficiency lower. Fig. 7 also shows that up to a charge of 60 coulombs passed through the cell, the efficiency of iodine deposition on the electrode is 100%, no matter the current intensity used for charging. For higher charges the efficiencies are lower. Figs 8, 9 and 10 re-

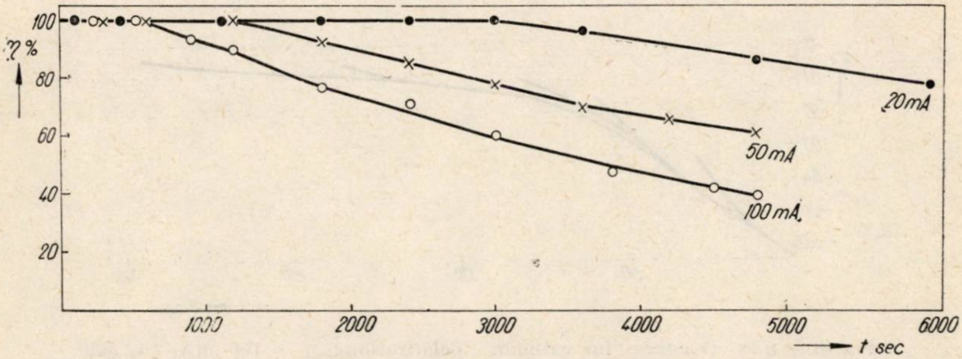

Fig. 6. — The efficiency $\eta = Q_{\text{discharging}}/Q_{\text{chargirg}}$ *versus* anodic polarization duration for several intensities; $t = 300°$.

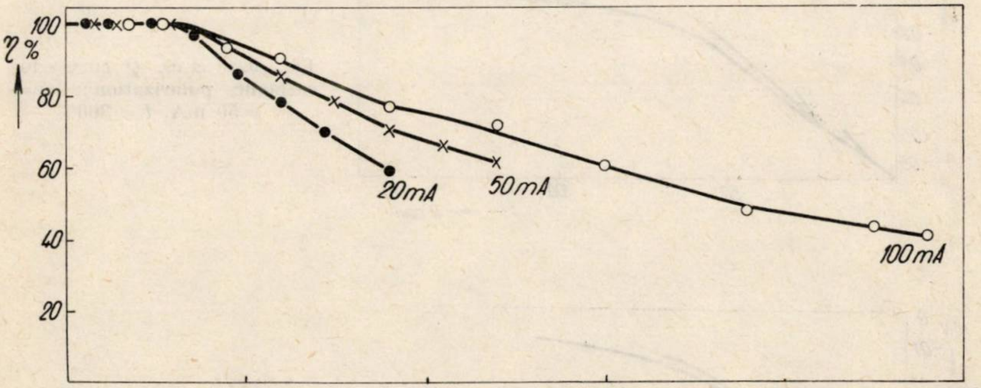

Fig. 7. — The efficiency $\eta = Q_{\text{discharging}}/Q_{\text{charging}}$ *versus* the charge used in anodic polarization at several intensitis; $t = 300°$.

present φ — Q plots based on the cathodic polarization curves. One observes that the initial portions of all the cathodic polarization curves present a faster decrease of the potential, after which all gather together in a "basic curve". The faster decrease of the potential is due either to a quantity of iodine from the electrode surface weakly bound to the carbon atoms and which leaves easier the electrode, or to an overvoltage of the iodine-active carbon electrode. We also note that the higher the cathodic polarization current, the greater the initial variation of the potential.

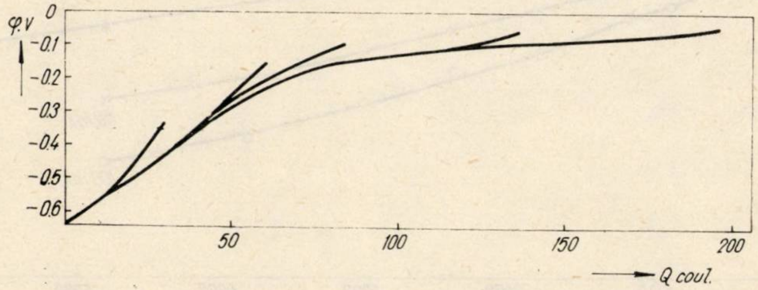

Fig. 8.— φ *vs.* Q curves for cathodic polarization; $i = 100$ mA, $t = 300°$.

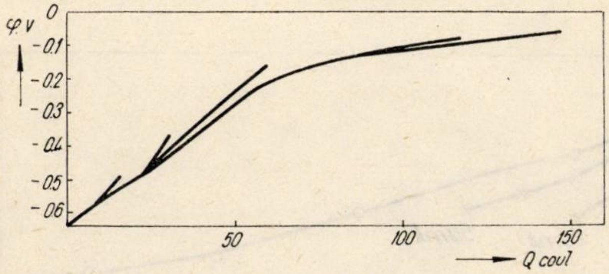

Fig. 9. — φ *vs.* Q curves for cathodic polarization; $i = 50$ mA, $t = 300°$.

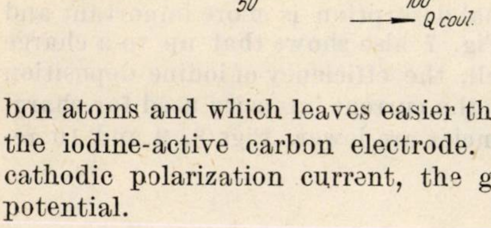

Fig. 10. — φ *vs.* Q curves for cathodic polarization; $i = 20$ mA, $t = 300°$.

The three "basic cathodic polarization curves" are shown on figure 11. Comparison of the curves plotted on fig. 11 with the anodic polarization curves from fig. 2 shows that the differences between the cathodic polarization curves are far smaller than those existing between the anodic polarization curves, while their positions are inverted. This is probably due to the self-desorption phenomena, which are more intensive during the anodic polarization.

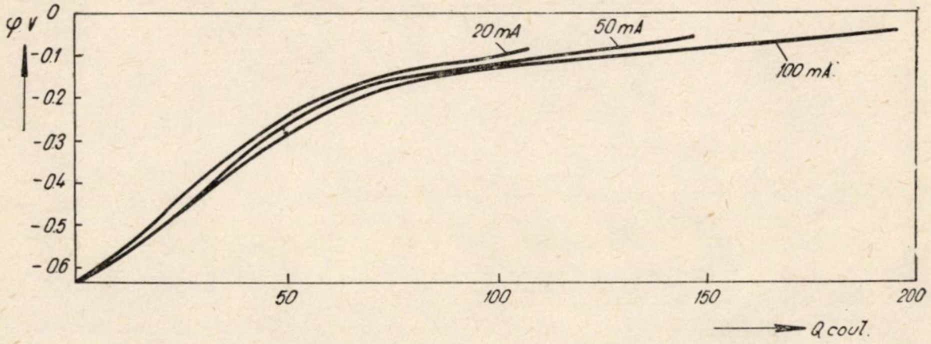

Fig. 11. — φ *vs.* Q curves for cathodic polarization at several intensities; $t = 300°$

For this reason, in the subsequent processing of the data it will be more convenient to use the cathodic polarization curves.

Revue Roumaine de Chimie, **19**, *4*, 533–541 (1974)

ON THE EQUIVALENCE BETWEEN THE CRYSTAL FIELD AND MO PARAMETRIC APPROACHES

C. LEPĂDATU and VERONICA TUFOI

Institute for Physical Chemistry Str. Dumbrava Roşie 23, Bucharest, Romania

Received May 25, 1973

It is shown that the parametric crystal field approximations are nothing else but molecular orbital alternatives with the difference that the first ones do not divide the orbital energies in the molecule according to the chemical bonding type. The quantitative equivalence between the CF and MO theories justifies the applicability and the prediction power of the crystal field approaches widely used by chemists and physicists.

It is well known that the crystal field theory in its different forms, like the operator equivalents, [1] or the strong and weak field coupling,[2] leads to good results in the interpretation of electronic and ESR spectra of the transition metal [3] and rare earth complexes,[4] when semiempirical fitting parameters for the orbital and interelectronic repulsion energies are used. The prediction power of the mentioned theory is somewhat surprising having in view the basic principles which do not take into account the chemical bond formation as the LCAOMO approximations do, the interactions between metal and ligands being reduced to a matter of electrostatic perturbations only.

It was already reported in the related literature the qualitative equivalence between the molecular orbital and crystal field energy diagrams, due to the circumstance that both theories make use of the same symmetry properties of the central atom orbitals.[5] In other words, the postulated MO and CF model hamiltonians fulfil the same invariance requirements in respect to the symmetry group to which the molecule belongs.

Some authors [6–9] have recently suggested the possible correlation between the CF parameters and the parameters used by a contact potential approach developed by Jørgensen and Schäffer [10] under the name of Angular Overlap Model (AOM). As has been shown elsewhere,[11] the AOM may be well included into the category of semiempirical MO approximations which exploits the localizability properties of the chemical bonds.

The aim of the present note is to give a more consistent explanation to the quantitative equivalence between CF potentials and MO energies, and to show that the semiempirical CF approximations are nothing else but parametrized LCAOMO alternatives.

To this purpose, the electrostatic energies were calculated from :

$$\begin{aligned}< \varphi_n |\hat{\mathrm{H}}_{\mathrm{el}}| \varphi_n > &= < \varphi_n |\hat{\mathrm{H}}^0| \varphi_n > + < \varphi_n |\hat{\mathrm{V}}| \varphi_n > = \\ &= E^0 + R_n(0) + \sum_k \sum_m a_k P_k^m (\cos \theta_i) \cos m\varphi_i R_n(k)\end{aligned} \tag{1}$$

where φ_n's are Slater type orbitals, STO, $\hat{\mathrm{H}}_{\mathrm{el}} = \hat{\mathrm{H}}^0 + \hat{\mathrm{V}}$, is the electrostatic model hamiltonian, P_k^m – Legendre polynomials and $R_n(k)$ electrostatic potentials :

$$R_n(k) = \frac{(2\mu)^{2n+1}}{(2n)!\,\mu^{2n}} \left\{ \frac{(2n+k)!}{2^{2n+k+1}\,\alpha^{k+1}} - \alpha^{2n} \left[\underset{2n+k}{A}(2\alpha) - \underset{2n-k-1}{A}(2\alpha) \right] \right\} \tag{2}$$

where μ is the Slater exponent, $\alpha = R\mu/a_0$ (R – interatomic distance, a_0 – Bohr radius), A – incomplete gamma functions,[12] n – the principal quantum number and k, m – indices running over even numbers from 0 to 21 and all integer numbers from –1 to +1, respectively.

Master formulas for bicenter electrostatic integrals $< \varphi_n |\hat{\mathrm{V}}| \varphi_n >$ over real STO's with 1=2, 3 are given in Appendix.

The expressions for molecular orbital energies were estimated using the Generalized Angular Overlap Model,[11] where the antibonding MO energies for a cluster type molecule are of the form :

$$E_i^* = E_i^0 + \sum_k \sum_j {}^kD_{ij}^2\, \mathrm{e}_{\lambda(j)} + \sum_k \sum_{k'} \sum_j {}^kD_{ij}\, {}^{k'}D_{ij}\, \mathrm{e}_{\lambda(j)}^{k\,k'} + \ldots \tag{3}$$

where E_i^0 is the zero-order energy, the indices k, k' running over the ligand orbital set (atomic, hybrid or molecular), D_{ij} – the angular matrix

elements necessary to bring the central atom orbital set from the proper coordinate Cartesian system to that of each ligand :

$$|i| = |{}^{k}D_{ij}||j|,$$

the indices i, j, running over the set of central atom orbitals, closed under the orbital quantum number "1". If the ligand-ligand interactions were neglected, the third term from (3) would vanish.

The quantity $e_{\lambda(j)}$ is the antibonding orbital energy, where λ is the bonding type σ, π, δ or Φ. The detailed expression for $e_{\lambda(j)}$ was given elsewhere,[11] the terms included into $e_{\lambda(j)}$ being in principle easily calculated using a monoelectronic model hamiltonian.

To prove the quantitative equivalence between the electrostatic potentials and the molecular antibonding energies consider both quantities as parameters, express $R_n(k)$ through $e_{\lambda(j)}$ from the CF splitting and differences between AOM levels, express the CF levels not used in calculations substituting $R_n(k)$ function by $e_{\lambda(j)}$ and then compare the results with those obtained directly by the AOM approximation. The calculations were performed for those coordination clusters belonging to lower symmetry groups, such that the number of energy levels be higher than that of $R_n(k)$ potentials.

We give below the energy levels for different clusters, belonging to lower symmetries calculated in both CF and AOM approximations. For the sake of simplicity, the energy expressions do not contain the zero-order energies, neither the $R_n(0)$ terms which do not contribute to the relative energy distances between levels.

The CF energies were calculated using the master formulas given in the Appendix and the Legendre polynomials tabulated in reference. [13]

The AOM energies were calculated by means of formula (3) neglecting the bond-bond interactions and using the angular matrices reported elsewhere.[6,10,14,15]

As may be seen from the cases considered above, the agreement between the predicted and calculated energy expressions for the orbital splittings (the energy differences at the end of each example, the first line indicating the predicted energy and the second one the direct AOM results) justifies the existence of a quantitative equivalence between the electrostatic potentials and the MO energies. In other words, all the crystal field approaches widely spread among the chemists and physicists are nothing else but parametric MO alternatives, with the single difference that the first ones do not take into consideration the chemical bonding types according to which the MO theory classifies the bonding and antibonding orbital energies in the molecule.

THE CORROSION OF CARBON STEEL AND SOME AUSTENITIC STAINLESS STEELS IN SYNTHETIC RIVER WATERS

SULTANA CIOLAC and O. RADOVICI

Institute of Physical Chemistry,
Str. Galaţi 31, Bucharest, Romania

Received May 14, 1973

Gravimetric and electrochemical methods have been used to determine the rate of corrosion of carbon steel and some austenitic stainless steels in synthetic river waters as function of chemical composition, temperature and stirring of corrosion media.

The obtained results have shown that the corrosion of carbon steel is controlled by the water oxygen content and that, in certain conditions, stainless steels are susceptible to pitting attack.

Even though the problem of ferrous alloys corrosion in waters has been extensively studied, the effects of several factors having a great influence on their corrosion behaviour, such as metallic composition and aggressive medium conditions, are not completely clarified today.

The object of this research was to determine the influence of a few factors on the corrosion rate of corrosive attack of carbon steel and some austenitic stainless steels.

PROCEDURE

Our observations have been made on a carbon steel and two stainless steels, having the compositions listed in table 1.

Table 1

The composition of the steels tested

Type of steel	Composition %								
	C	S	P	Mn	Si	Cr	Ni	Mo	Ti
N° 1	0.18	0.022	0.025	0.35	0.03	—	—	—	—
N° 2	$\leqslant$0.10	—	—	$\leqslant$2	$\leqslant$1	18	10	—	$\geqslant$5C
N° 3	$\leqslant$0.10	—	—	$\leqslant$2	$\leqslant$1	17.50	11.50	2.25	$\geqslant$5C

The tested steels were machined either in parallelepipedal samples (for gravimetric measurements) or in cylindric electrodes (for electrochemical measurements), having an average surface of 6 sq.cm. Before the exposure, the surfaces were mechanically polished on emery paper, then degreased in boiling benzene and chemically polished by pickling, using 5% HNO_3 for carbon steel and a mixture of HNO_3-HF-H_2O for stainless steels at 70°. After pickling, the surfaces were washed with tap water, distilled water and then acetone dried.

The synthetic river waters used in these experiments, were prepared from reagent grade chemicals and doubly distilled water. Their compositions are listed in table 2.

Table 2

The composition of synthetic river waters

Ionic content mg/l	Type of water				
	A	B	C	D	E
Ca^{2+}	52.1	89.4	89.4	89.4	89.4
Mg^{2+}	4.6	15.5	15.5	15.5	15.5
Na^{+}	20.94	68.4	79.67	228	420
K^{+}	3.58	5.43	5.43	5.43	5.43
SO_4^{2-}	49.27	67.30	67.30	67.30	67.30
Cl^{-}	31.51	163.79	250	500	800
HCO_3^{-}	134.54	159.21	159.21	159.21	159.21

The rate of corrosion of carbon steel was determined from the loss in weight of the samples exposed in stagnant conditions at room temperature, 50 and 80°, and in stirring conditions at room temperature, using a rotary stirrer of 40 r.p.m.

Independently of the exposure conditions, generally a ratio of 6 sq.cm/125 ml (exposed surface/quantity of electrolyte) was respected.

An X-ray analysis was made for the corrosion products formed by carbon steel exposure in doubly distilled water in stagnant conditions at room temperature and 80°.

For carbon steel, additional electrochemical measurements were also made.

The rates of corrosion of stainless steels were determined by electrochemical polarization.

The cylindric electrodes were assembled in a glass tub (being pressed on a Teflon gasket and threaded in a copper wire) and then placed in the centre of the electrochemical cell. A platinum gauze was used as counter electrode and an Ag/AgCl electrode, as reference.

The electrochemical measurements were made potentiostatically (step-by-step) applying 50 mV/5 min, from a Wenking potentiostate. The resulting currents were registred on a chart SEFRAM recorder.

RESULTS

CARBON STEEL

The variation in corrosion rates of carbon steel (mdd) exposed in A, B, C waters for 1–30 days, at room temperature, 50 and 80°, in stagnant conditions, is shown in figures 1, 2 and 3.

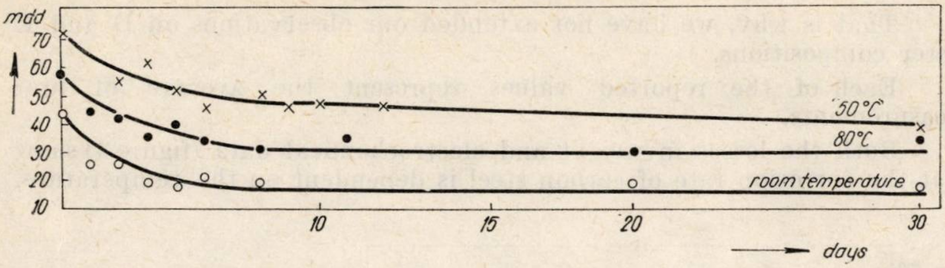

Fig. 1. — Time dependence of carbon steel corrosion rate, exposed in A composition water at different temperatures.

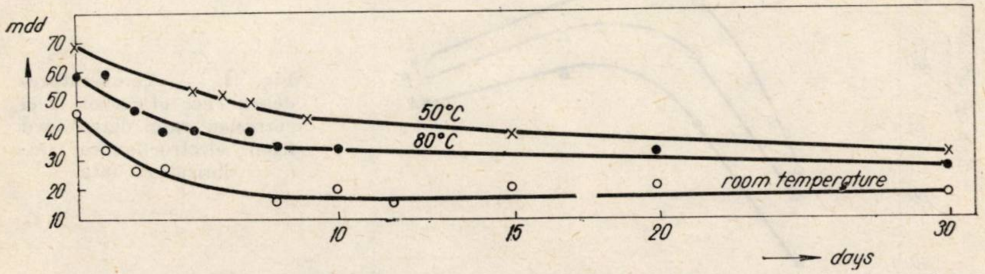

Fig. 2. — The dependence of carbon steel corrosion rate on temperature, for 1—30 days exposure in B synthetic river water and stagnant conditions.

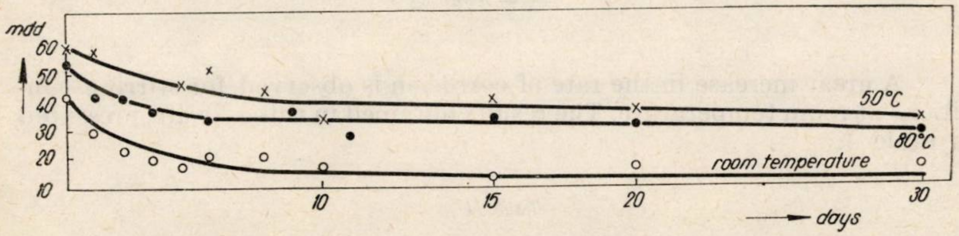

Fig. 3. — The variation in carbon steel corrosion rate as function of temperature for 1—30 days exposure in C water composition and stagnant conditions.

As can be seen from the above figures and from the amount of metal lost (mg/dm^2), only for a few exposure times (table 3), at the same temperature the rate of corrosion is nearly uninfluenced by water composition.

Table 3

The loss in weight of carbon steel (mg/dm^2), at room temperature, in stagnant conditions

Exposure time days	Type of water		
	A	B	C
1	44	46	42
3	83	86	70
6	130	130	130
8	150	140	168
15	408	300	350
30	532	560	528

That is why, we have not extended our observations on D and E water compositions.

Each of the reported values represent the average of four measurements.

Both the losses in weight and electrochemical data (figure 4) show that the corrosion rate of carbon steel is dependent on the temperature.

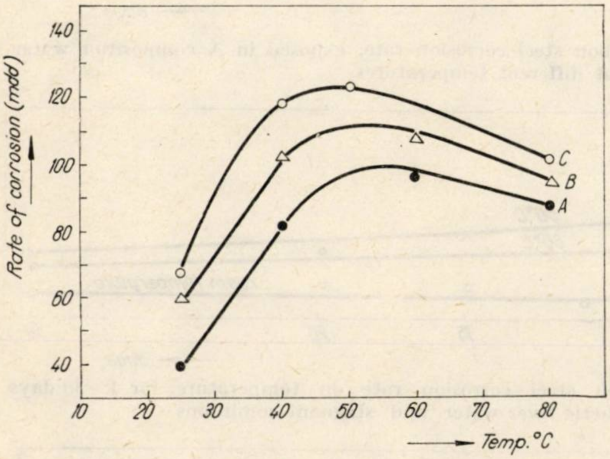

Fig. 4. — Temperature-dependence of carbon steel corrosion rate, determined from electrochemical polarization data.

A great increase in the rate of corrosion is observed for stirring conditions at room temperature. The results obtained in this case are presented in table 4.

Table 4

The loss in weight of carbon steel in stirring conditions at room temperature (mg/dm²)

Exposure time days	Type of water		
	A	B	C
1	160	200	175
3	380	350	360
6	690	630	610
10	860	870	830
30	1090	1100	1000

STAINLESS STEELS

Very well-known tendency of stainless steels to pitting in electrolytes containing halide ions, have determined us to prepare waters with high concentrations of chloride ions (D and E compositions).

In the case of stainless steel, the loss in weight technique seems inconvenient, because of the difficulty in passive film removing. Stainless steel samples, exposed for long time in synthetic water, have shown an increase in weight, proving the formation of oxide film on the surface.

Current-potential curves obtained potentiostatically (starting from −1000mV to noble potentials), were used to determine the rate of corrosion (in the absence of pitting), as well as to find out the conditions in which a localized attack occurs, as function of water composition and temperature. The results obtained are presented in tables 5 and 6.

Table 5

The corrosion rate of stainless steel No 2 and its pitting susceptibility as function of water composition and temperature (mdd)

Tempera-ture °C	Type of water				
	A	B	C	D	E
25	0.29	0.36	0.39	*	*
40	0.36	0.42	0.47	*	*
50	0.72	0.79	0.78	*	*
60	0.84	1.09	*	*	*
70	1.17	*	*	*	*

* – pitting

Table 6

The rate of corrosion of stainless steel No 3 and its pitting susceptibility as function of water composition and temperature (mdd)

Tempera-ture °C	Type of water				
	A	B	C	D	E
25	0.23	0.25	0.33	0.34	0.3
40	0.37	0.47	0.52	*	*
50	0.71	0.94	1.73	*	*
60	1.04	1.13	*	*	*
70	2.17	*	*	*	*

* – pitting

These results show the dependence of corrosion rate on both parameters.

The anodic control of the corrosion process is illustrated in figure 5.

Some differences seem to exist between the two stainless steels. For instance, in the same water and at the same temperature, stainless steel N° 3 shows a little better resistance to the pitting attack (figures 6*a* and *b*).

The increasing tendency to pitting, with an increasing content in chloride ions in waters, may be observed in figure 7.

The same effect results from the temperature increase.

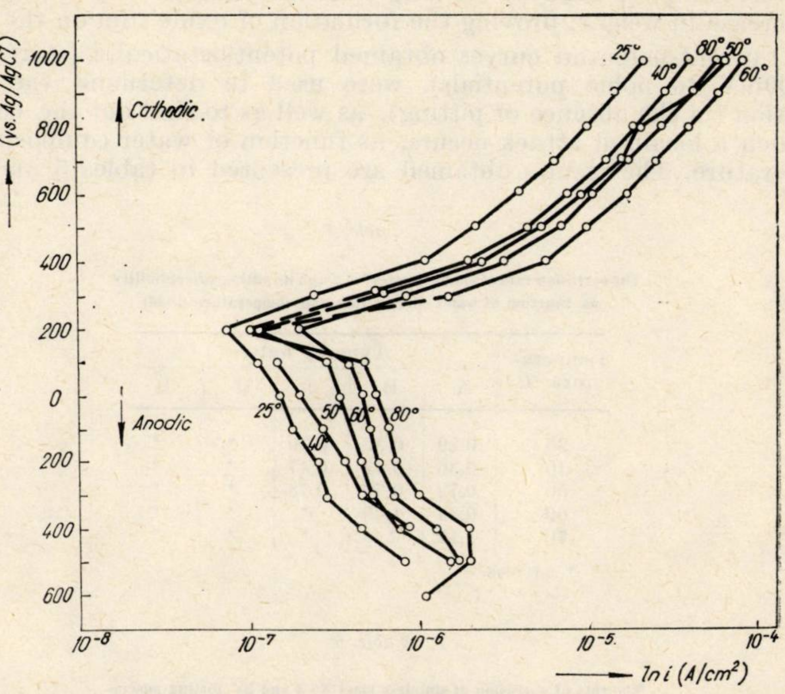

Fig. 5. — Cathodic-anodic polarisation curves of stainless steel N° 3 in B water, at different temperatures.

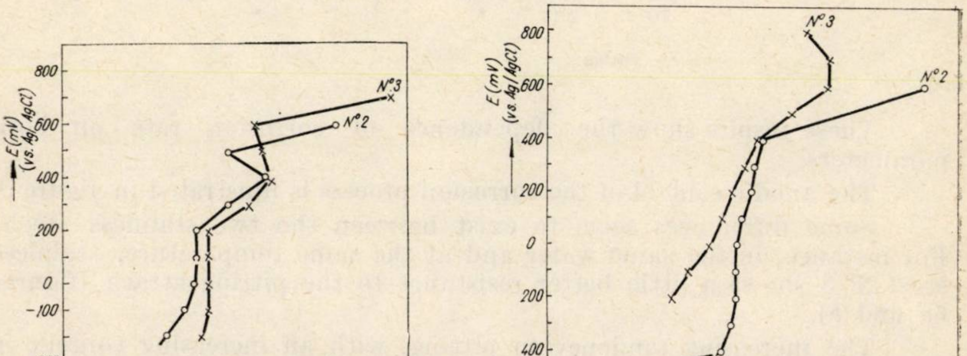

Fig. 6. — The effect of stainless steel composition on pitting susceptibility; *a*) at 80° in C water and *b*) at 25° in E water.

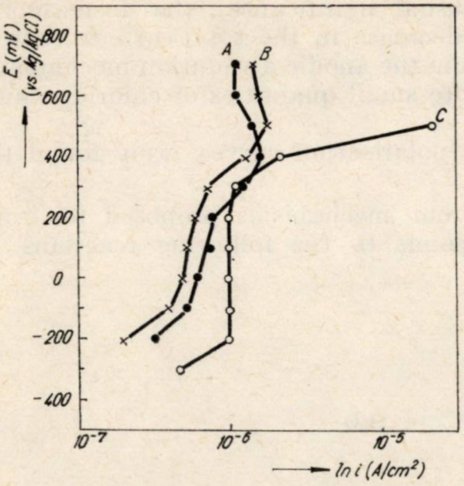

Fig. 7. — The effect of water composition on pitting susceptibility of stainless steel N° 3 at 60°.

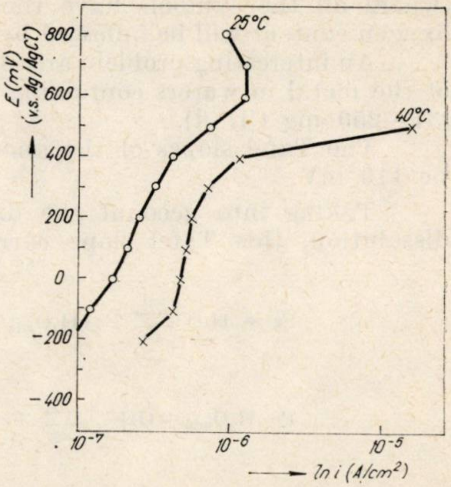

Fig. 8. — Temperature dependence of the pitting tendency of stainless steel N° 3 exposed in E water composition.

DISCUSSION

CARBON STEEL

From the results presented some conclusions may be drawn with regard to the corrosion mechanism of carbon steel in oxygen saturated water, containing small quantities of ions with high capacity of specific adsorption (chloride ions), as well as to the time evolution of the corrosion process.

The dissolution mechanism of carbon steel. As it is known, the corrosion process in neutral medium occurs under cathodic control of oxygen reduction.

Both gravimetric and electrochemical measurements show that the rate of corrosion in oxygen saturated water increases until a certain temperature is attained (~60°) and then decreases. This dependence of the corrosion rate on the temperature may be easily explained taking into account the activated character of the corrosion process, which supposes an increase in the corrosion rate as temperature increases. On the other hand, the corrosion rate is directly dependent on the content of oxygen dissolved, whose concentration decreases with temperature increase.

Thus, if the corrosion rate is determined by the cathodic current of oxygen reduction

$$i_L = zFDC_{O_2}\, 1/\delta \qquad (1)$$

(where all the symbols have their usual significance), the decrease in oxygen content will be followed by a decrease in the total corrosion rate.

An interesting problem arises from the anodic dissolution mechanism of the metal in waters containing quite small quantities of chloride ions ($31-250$ mg CL^-/l).

The Tafel slopes of the anodic polarisation curves were found to be 110 mV.

Taking into account the different mechanisms proposed for iron dissolution, this Tafel slope corresponds to the following reactions[1]:

$$Fe + H_2O \underset{-1}{\overset{-1}{\rightleftharpoons}} Fe \cdot H_2O_{ads}$$

$$Fe \cdot H_2O_{ads} + OH^- \underset{-2}{\overset{2}{\rightleftharpoons}} Fe\,OH^-_{ads} + H_2O$$

$$Fe\,OH^-_{ads} \underset{-3}{\overset{3}{\rightleftharpoons}} FeOH_{ads} + e^-$$

$$Fe\,OH_{ads} \xrightarrow{4} Fe\,OH^+ + e^- \text{ (the rate determining step)}$$

$$Fe\,OH^+ \underset{-5}{\overset{5}{\rightleftharpoons}} Fe^{2+} + OH^-$$

respecting the next kinetic equation

$$\frac{i_a}{F} = 2K_4\,\theta_{OH} - \left(\frac{K_1}{K_{-1}}\right)^{1/2} \exp\,(F\varphi/2RT) \qquad (2)$$

where : i_a is the anodic current density, θ_{OH} — is the surface coverage degree with OH^- ions, K_1, K_{-1}, K_4 are the equilibrium constants of the corresponding reactions, the other symbols having their usual meaning.

Such a mechanism supposes an absorbant-adsorbant interaction and not an adsorption-desorption one.

Thus, it may be concluded that in the dissolution process of carbon steel in electrolytes containing small concentrations of chloride ions there is no competition between chloride ions, water molecules and hydroxyl ions.

In other words, the anodic dissolution at these concentrations is controlled by H_2O and OH^- ions and not by Cl^- ions.

Time evolution of the corrosion process shows that the rate of corrosion decreases gradually in the first days and remains nearly constant after 10 days (figures 1, 2 and 3).

---

[1] MC. CAFFERTY and N. HACKERMAN, *J. Electrochem. Soc.*, **119**, 999 (1972).

This may be explained considering the possible secondary reactions due to the chemical transformation of hydrated iron oxides formed on the metallic surface under exposure conditions.

X-ray analysis of the corrosion products, covering the surface by exposure in distilled water, has shown that they are formed from quasi-amorphous hydrated oxides.

The protection conferred to the surface depends on their degree of adherence and compactness. The more adherent and compact the corrosion products layers are, the lower the corrosion rate is.

The inactivity showed by the hydrated oxides and hydroxides may be supported by the mechanism of oxolation and ollation processes. It might be appreciated that the decrease in corrosion rate of carbon steel depends on the rate of ollation and oxolation processes of the corrosion products covering the surface. These processes are accelerated by the temperature increase, in other words, the higher the temperature, the sooner the corrosion products become more compact. This fact is confirmed by our results. The great increase in the corrosion rate measured in stirring condition is due, on the one hand, to the smaller quantities of the corrosion products deposited on the surface allowing a permanent contact with the aggressive medium, and, on the other hand, to the convective transport of oxygen to the surface.[2,3]

STAINLESS STEELS

It was not our purpose to determine exactly the nucleating pitting potential values, but from the presented figures and listed data, some conclusions may be drawn about pitting susceptibility of the two stainless steels tested.

The higher the temperature and the bigger the chloride concentrations are, the stronger the tendency to pitting is. From these points of view, our results are in good agreement with some other published data.[4,5]

No conclusions in connection with the effect of metallic composition may be drawn, because the two stainless steels studied differ not only in molybdenum presence, but in nickel content, too. Both these constituents are able to give such an effect,[5,6] explaining the better resistance observed for stainless steel N° 3.

The existence, in all the cases studied, of at least 400 mV passive range, explains why no pits were formed on the metallic surface, after more than 1 year exposure, under stagnant conditions.

VISCOSITY OF BINARY MOLTEN ALKALI CHLORIDE SYSTEMS

ŞTEFANIA ZUCA and RODICA BORCAN

Institute of Physical Chemistry,

Str. Galaţi 31, Bucharest, Romania

Received August 3, 1973

Experimental data for the density and viscosity of (Li–K)Cl, (Li–Rb)Cl, (Li–Cs)Cl, (K–Rb)Cl, (K–Cs)Cl and (Rb–Cs)Cl systems are reported. The viscosity isotherms show the usual negative deviations from additivity. The observed $\Delta\eta$ increase with the difference between the cationic radii in the mixture and are found to obey the equation

$$\Delta\eta = a(r_1 - r_2)x_1x_2.$$

Carrying on our systematic study on the viscosity of binary mixtures of molten salts,[1–3] we presently report the results obtained in several alkali chloride mixtures: (Li–Rb)Cl; (Li–Cs)Cl; (K–Rb)Cl; (K–Cs)Cl and (Rb–Cs)Cl, for which no data are available in literature.

EXPERIMENTAL RESULTS

Both density and viscosity of pure salts and their mixtures (mole fraction $x = 0.25$; 0.50; 0.75) were determined over a temperature range of about 200°. All chemicals used in experiments were Merck or Analar (B.D.H.) *p. a.* reagent grade, twice recrystallized from water, dried for 24 h at 150° and melted while a dried HCl gas was bubbled through the melt, in order to remove any trace of humidity. LiCl melt was prepared by a special technique, successfully applied in our laboratory for very hygroscopic salts[4]. All salts were tested for neutrality with phenolphtalein, both before and after experiments.

A linear temperature dependence of density was observed over the whole temperature range covered in this work.

[4] S. Zuca and R. Costin, *ibid.*, **11**, 1831 (1970).

An Arrhenius plot expresses the temperature dependence of viscosity. Both density and viscosity data were fitted to the linear dependence by means of a least squares calculation. The equations for the linear fit are given in tables 1–4 along with the standard deviations and the applicable temperature range.

The present results on pure components, excepting CsCl, are in very good agreement with our earlier data.[5]

A comparison with the most recent literature data shows a satisfactory agreement for LiCl.[6,7] There is a close agreement with the literature[6,8] for KCl too, but considerably lower

(−11%) as well as higher values (+20%) are also reported by Dumas *et al.*[7] and Matsumura *et al.*[9], respectively. For RbCl, the agreement with [7] is very good but significantly higher values and a stronger temperature dependence is indicated by Janz and Reeves.[10]

A severe disagreement is found for viscosity of CsCl: the present results are by about 20% higher than our previous data[5]. With this in mind a special care was taken in purifying and melting the *p.a.* reagent grade CsCl. Samples of Merck suprapure reagent grade CsCl were also submitted to measurements. The equation for CsCl viscosity in table 2 was calculated from 56 experimental values, obtained on 1o different samples, both on heating and on cooling the melt. Only two investigations on the viscosity of CsCl have been reported in literature.[6,7] Very low values, in very good agreement with our former results [5] are reported by Smirnov and Hohlov [6]. The more recent data of Dumas *et al.*[7] are in a better agreement with our present results; the difference is of −5% at lower temperature but increases steadly with temperature to −10%.

As far as we know, a systematic investigation of viscosity in binary alkali chloride systems has not been published so far. The only data available refer to (Li−K)Cl[9] and (Li−Cs)Cl[6] systems. The results for (Li−K)Cl system were discussed elsewhere. Regarding (Li−Cs)Cl system, there is no agreement between our present data and the literature.[6] This is explained by the above mentioned discrepancies existing in the viscosity of pure CsCl melt. Moreover, even the dependence of viscosity on the composition of the mixture is different. The maximum in the CsCl rich region of viscosity isotherms reported by Smirnov and Hohlov [6] has never been observed by us.

DISCUSSION

For all presently studied systems, the plot of η *vs.* composition of the mixture, gives smooth curves which exhibit the usual negative deviations from linearity. Fig. 1 illustrates the results at 775°.

According to Rice-Alnatt theory,[11] the viscosity of an ideal binary mixture has to be additive. Since most of the ideal binary systems show systematic deviations of viscosity from linearity,[12] it was thought [7] necessary to resort to other semi-empirical theories. We believe that our previous investigations,[1−3] on the viscosity of binary molten salt systems, have proved the usefulness of additivity relationship in correlating the experimental data. Following out those results, we calculated the deviation from additivity, $\Delta\eta$, in the six presently studied alkali chloride mixtures and plotted the obtained values against mole fraction, as shown in fig. 2 for 775°. From the data in fig. 2 it is evident that the regularities established for molten binary nitrate systems [1,2] are found again:

— $\Delta\eta$ *vs.* composition curves are, within experimental errors, symmetrical, with the maximum at the value $x_1 = x_2 = 0.5$.

— $\Delta\eta$ are larger as the difference in size of the two cations in the mixture is larger.

[12] S. Bretsznajder, "Prediction of Transport and Other Physical Properties of Fluids", Pergamon Press, Oxford, 1971, p. 207.

As already stated,[1-3,13] due to the fact that transport properties depend on the energy of interaction between the ions, there is to expect that viscosity can be correlated with the length parameter. As seen in fig. 3, in all studied systems, the $\Delta\eta$ value for each composition varies linearly with the difference of the cationic radii. From fig. 3 it is obvious that, within experimental error, $\Delta\eta$ yields a straight line which passes through the origin, indicating that:

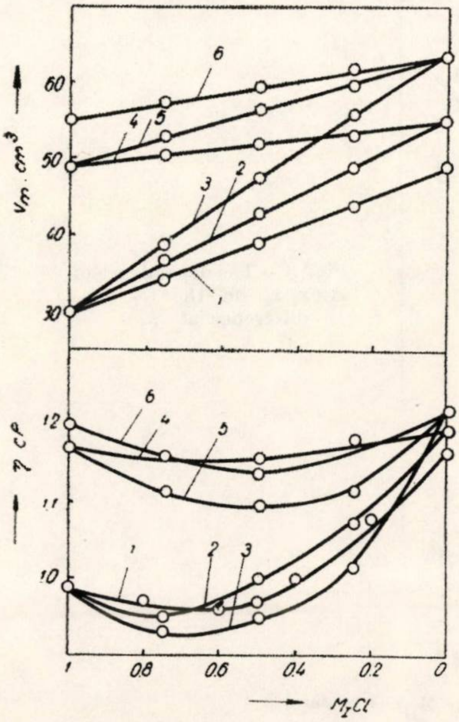

Fig. 1. — Isotherms of viscosity and molar volume at 775° in $M_I Cl - M_{II} Cl$ systems

1, (Li–K)Cl; 2, (Li–Rb)Cl; 3, (Li–Cs)Cl; 4, (K–Rb)Cl; 5, (K–Cs)Cl; 6, (Rb–Cs)Cl.

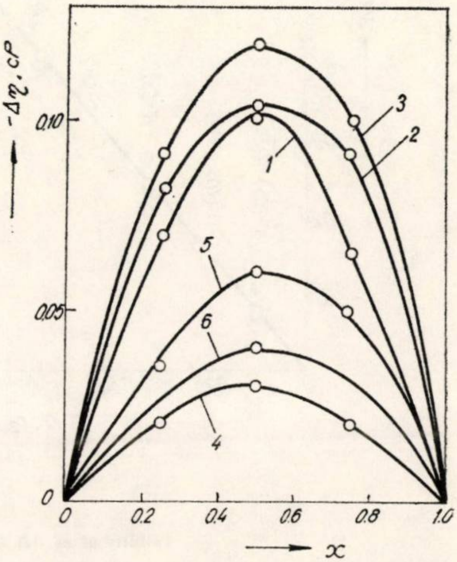

Fig. 2. — $\Delta\eta$ *vs.* molar fraction in $M_I Cl - M_{II} C$- systems at 775°.

1, (Li–K)Cl; 2, (Li–Rb)Cl; 3, (Li–Cs)Cl; 4, (K–Rb)Cl; 5, (K–Cs)Cl; 6, (Rb–Cs)Cl.

$$\Delta\eta = a(r_1 - r_2)x_1x_2 \qquad (1)$$

where *a* is a slightly temperature dependent parameter. Its kinetic molecular significance is given by Murgulescu[14] in terms of Eyring theory.

(Li−K)Cl	0.50	0.974	0.988	+1.4	0.923	0.935	+1.2
(Li−Rb)Cl	0.25	1.075	1.074	+0.1	1.004	1.011	+0.7
	0.50	1.001	0.990	−1.0	0.940	0.938	−0.2
	0.75	0.951	0.958	+0.7	0.907	0.917	+1.0
(Li−Cs)Cl	0.25	1.016	0.983	−3.2	0.950	0.928	−2.3
	0.50	0.950	0.910	−4.2	0.910	0.860	−5.4
	0.75	0.930	0.910	−2.1	0.880	0.868	−1.3
(K−Rb)Cl	0.25	1.185	1.189	+0.3	1.110	1.112	+0.1
	0.50	1.160	1.169	+0.8	1.090	1.096	+0.5
	0.75	1.160	1.159	−0.1	1.086	1.089	+0.3
(K−Cs)Cl	0.25	1.114	1.100	−1.2	1.043	1.028	−1.2
	0.50	1.097	1.090	−0.6	1.024	1.017	−0.7
	0.75	1.114	1.114	0.0	1.040	1.039	−0.1
(Rb−Cs)Cl	0.50	1.140	1.133	−0.6	1.060	1.060	0.0

table 5. The most notable exception in fig. 3 and table 5 is represented by (Li—Cs)Cl system whose $\Delta\eta$ are lower than those calculated by (1). The peculiarity of this system is also certified by its electrical conductance[13] as well as molar volume behaviour. As seen in fig. 1, the additivity of molar volume holds for the studied alkali chloride systems (ΔV are less than 0.5%), except for (Li—Cs)Cl system where ΔV values become appreciable going beyond 1%. An explanation for this behaviour may lie in the fact that the extremely large difference between the radii of the two cations (Li^+ and Cs^+) in the mixture enhances the ionic interaction to such an extent that complex ions are formed in these melts.

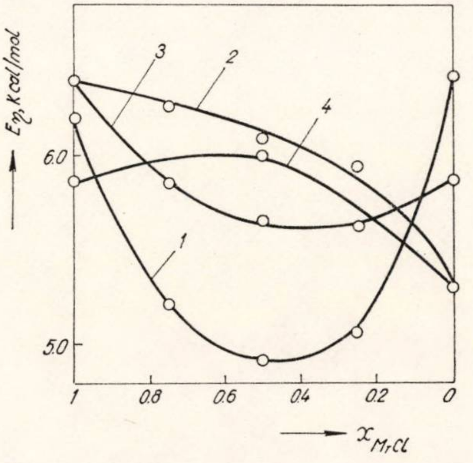

Fig. 4.—E_η *vs.* molar fraction in $(M_I - M_{II})$ Cl systems

1, (Li—K) Cl; *2*, (K—Rb) Cl; *3*, (K—Cs) Cl; *4*, (Rb—Cs)Cl.

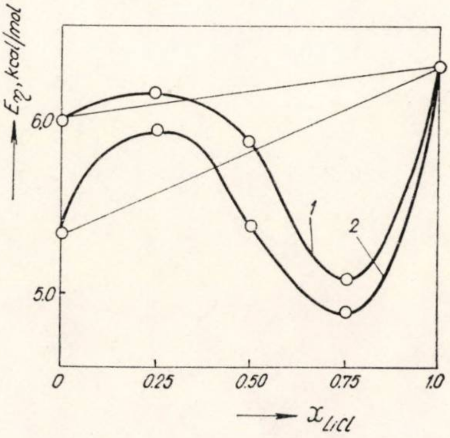

Fig. 5. — E_η *vs.* molar fraction for *1*, (Li — Rb)Cl and *2*, (Li—Cs)Cl.

As can be seen in figs. 4 and 5, for all six studied systems, the activation energy for viscous flow does not vary linearly with molar composition. These systematic deviations from additivity prove that changes in the cation-anion bonding energy take place by mixing. The larger the difference in cationic radii, the more complicated becomes the E_η *vs.* composition dependence and the larger is the deviation from additivity. The special place occupied by (Li—Cs)Cl system in the series is noticed again.

MECHANISM AND KINETICS OF THE DISSOLUTION IN WATER OF SOME HYDRATED BINDERS

I. TEOREANU, MARCELA MUNTEAN, N. CIOCEA,
and O. ŞANCU

Polytechnic Institute, Bucharest,
Str. Polizu n° 1, Romania

Received September 6, 1973

Using the "rotating disc" method, the kinetics and the mechanism of the dissolution in water of gypsum as well as of monocalcium and monobarium aluminates in hydrated state are studied.

1. INTRODUCTION

The dissolution process is considered as a result of the thermal vibrations of the particles forming the crystalline lattice and of a simultaneous action of the molecular forces exerted by the solvent. The material detached from the solid body surface passes in the solvent boundary layer and then it duffuses in the mass of the solvent. The dissolution can be congruent or incongruent; in the latter case the mechanism of the process is more intricate. When the rate of dissolution of the substance from the crystalline surface to the boundary layer is greater than the rate of diffusion into the mass of the solvent, the process is controlled by diffusion, contrarily the process is controlled by the chemical reaction.

If for the study of the mechanism and kinetics of the dissolution, the "rotating disc" method is used, according to the theory developed by Levich,[1] for the diffusion controlled domain, the following relation holds:

$$J \sim \sqrt{\omega} \tag{1}$$

where: J – is the diffusional mass flux;

ω – the disc angular velocity.

---

[1] V. G. Levicch, "Fizico-khimicheskaia ghidrodinamica", Izd. Fiz.-mat. lit., Moskva, 1959.

The J values are computed from the measurements of the quantities of material passed into solution after a period of time, by means of equation:

$$J = \frac{m}{St}, \tag{2}$$

where: m — the amount of substance passed into solution at moment t;
t — dissolution time;
S — the dissolution surface of the disc.

It results therefore that one can obtain, in a simple manner, information regarding both the mechanism of the process and its kinetics.

2. EXPERIMENTAL CONDITIONS

Gypsum ($CaSO_4 . 2H_2O$), monocalcium aluminate and monobarium aluminate hydrated for 28 days formed the hydrated binders whose behaviour was examined. The composition of monobarium and monocalcium aluminate samples has been checked before the experiment by roentgenographic analysis.

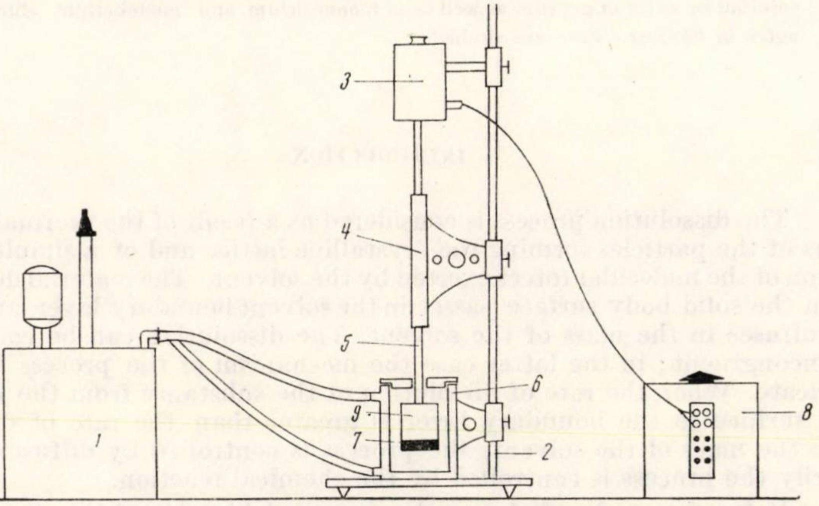

Fig. 1. — Sketch of "rotating disc" apparatus.

1, thermostat; *2*, stand; *3*, motor; *4*, guide; *5*, shaft; *6*, thermostat bath; *7*, sample (disc); *8*, autotransformer; *9*, holding head.

The experiments were carried out using the apparatus shown in fig. 1. It consists of a thermostated bath (6) filled with distilled water in which the binder disc (7), to be examined, is inserted; the binder disc is sticked to a rubber head (9) fixed on the shaft (5) driven by the variable speed motor (3). Three different speeds were used: 450 r.p.m., 850 r.p.m. and 1100 r.p.m. The dissolution time was 5, 10 and 15 minutes. At the end of the dissolution period the concentration of the solution in the bath was determined; for gypsum it was determined $CaSO_4$ concentration, for monocalcium aluminate the concentration of CaO and Al_2O_3 and for monobarium aluminate the concentration of BaO and Al_2O_3.

3. RESULTS AND DISCUSSION

The roentgenographic analysis of the hydration of the monocalcium and monobarium aluminates led to the conclusion that after 28 days of hardening both aluminates are quasitotally hydrated. Figs. 2 and 3 present the roentgenograms of the anhydrous aluminates and of the hardened samples of the same aluminates.

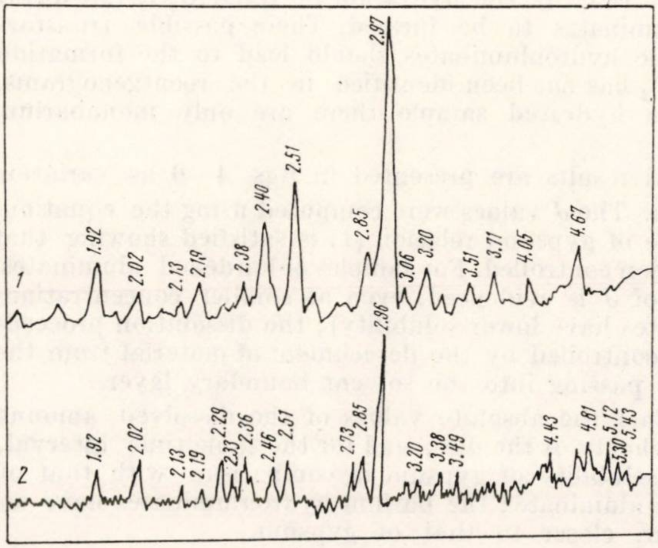

Fig. 2. — Roentgenograms for anhydrous (*a*) and hardened (28 days) (*b*) $CaO \cdot Al_2O_3$.

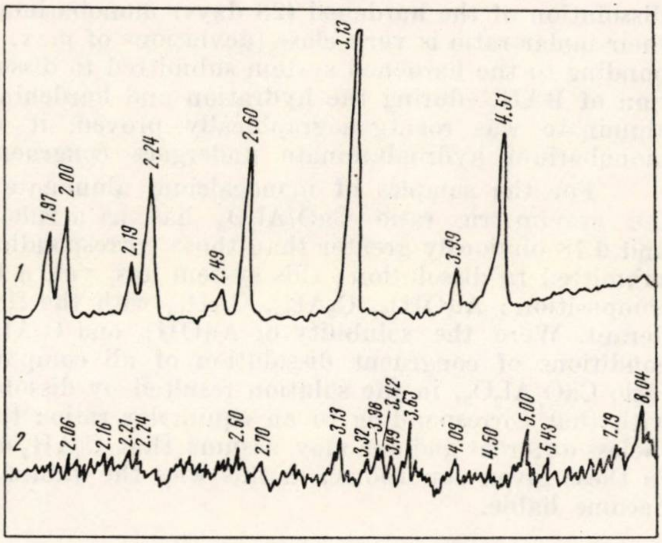

Fig. 3. — Roentgenograms for anhydrous (*a*) and hardened (28 days) (*b*) $BaO \cdot Al_2O_3$.

For the monocalcium aluminate samples hydrated and hardened for 28 days the preponderant presence of $3CaO.Al_2O_3.6H_2O$ (C_3AH_6) is ascertained; besides cubic C_3AH_6 there are smaller amounts of CAH_{10}*. Because the monocalcium decahydroaluminate formed during early hydration of $CaO.Al_2O_3$ is unstable, it passes into C_3AH_6, releasing $Al(OH)_3$; the aluminium hydroxide, initially a gel, crystallizes in time accounting for the presence of its characteristic lines in the roentgenograms of the hydrated monocalcium aluminate.

One could expect that by the hydration of $BaO.Al_2O_3$ (28 days) monobarium hydroaluminates to be formed. Their possible transformation into more basic hydroaluminates should lead to the formation of $Al(OH)_3$. As $Al(OH)_3$ has not been identified in the roentgenograms, it results that in the hydrated sample there are only monobarium hydroaluminates.

The experimental results are presented in figs. 4—6 as variation of J as function of $\sqrt{\omega}$. The J values were computed using the equations (1) and (2). In the case of gypsum, relation (1) is satisfied showing that the dissolution is diffusion controlled. For samples of hardened aluminates, the variation in time of J is evidenced, even at smaller concentrations (the hydrated aluminates have lower solubility); the dissolution proceeds in a domain which is controlled by the detachment of material from the binder surface and its passing into the solvent boundary layer.

As a matter of fact the absolute values of the dissolved amount for the same angular velocity of the disc, and for the same time interval, point out the greater solubility of gypsum in comparison with that of hardened monocalcium aluminate; the barium hydroaluminates have an intermediate behaviour, closer to that of gypsum.

The results regarding the BaO and Al_2O_3 concentration for the dissolution of the hardened (28 days) monobarium aluminate show that their molar ratio is very close (deviations of max. $+6\%$) to that corresponding to the hardened system submitted to dissolution; as the formation of BAH_x during the hydration and hardening of the monobarium aluminate was roentgenographically proved, it was assumed that the monobarium hydroaluminate undergoes congruent dissolution.

For the samples of monocalcium aluminate hardened (28 days), the gravimetric ratio CaO/Al_2O_3 has, as a rule, values between 0.6 and 0.78 obviously greater than those corresponding to the solid system submitted to dissolution; this system has, yet, a heterogeneous mineral composition: $Al(OH)_3$, C_3AH_6, CAH_{10} with the first two being preponderant. Were the solubility of $Al(OH)_3$ and C_3AH_6 comparable, in the conditions of congruent dissolution of all compounds, the gravimetric ratio CaO/Al_2O_3, in the solution resulted by dissolution, would be equal with that corresponding to an equimolar ratio; the solubility is nevertheless different and one may assume that C_3AH_6 dissolves incongruently in these given conditions; in this way the values found by experiment become liable.

---

*) Here $CaO = C$; $Al_2O_3 = A$; $BaO = B$; $H_2O = H$.

CONCLUSIONS

It results from the experimental data:

a. The solubility of hardened calcium aluminate is much lower than that of gypsum, while hydrated monobarium aluminate holds an

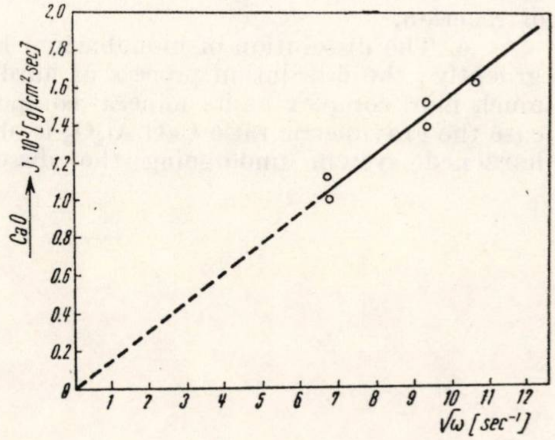

Fig. 4. — Plot of J *vs* $\sqrt{\omega}$ for gypsum.

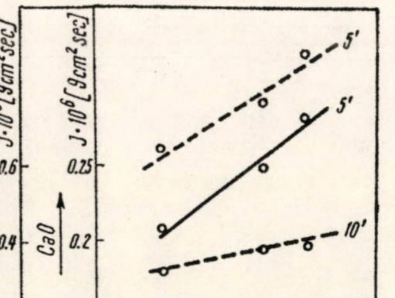

Fig. 5. — Plot of J *vs* $\sqrt{\omega}$ for hardened monocalcium aluminate; ——— Al_2O_3; --- CaO.

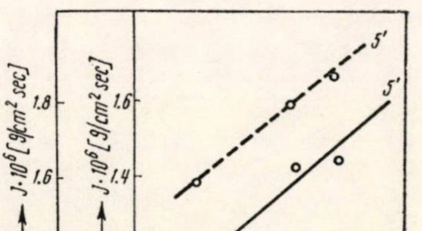

Fig. 6. — Plot of J *vs* $\sqrt{\omega}$ for hardened monobarium aluminate; ——— Al_2O_3; --- BaO.

intermediate position, closer to that of gypsum; barium-aluminous cements are, in these conditions, rather air binders.

b. The dissolution of gypsum in water, in the early stage, takes place in the diffusion domain; as the concentration of $CaSO_4$ in solution rises, the kinetics of the process becomes a mixed one, finally the dissolution becoming kinetically controlled; taking into account that the solubility in water of hardened calcium and barium aluminates is smaller, their dissolution is controlled from the very beginning by the kinetics of reaction.

c. The dissolution of monobarium hydroaluminate takes place congruently; the dissolution process of hardened monocalcium aluminate is much more complex as its mineral composition is heterogeneous; in this case the gravimetric ratio CaO/Al_2O_3 is obviously higher than that of the hardened system undergoing the dissolution.

MIXED LIGAND COMPOUNDS OF LANTHANIDES WITH NEUTRAL LIGANDS CONTAINING DONOR OXYGEN ATOMS. II

CHLOROSALICYLATES OF LANTHANIDES WITH TRIPHENYLARSINE OXIDE

SILVIA PLOŞTINARU and P. SPACU

Research Center of Physical Chemistry, Dumbrava Roşie, 23, Bucharest,
Romania

Received August 7, 1973

A new series of mixed ligand compounds of lanthanides with monodentate neutral ligands, Ln $(Ph_3AsO)_2$ $(ClSal)_3$, was synthetized. The obtained compounds have been chemically and physically characterized, by means of their UV and visible spectra which gave information concerning the nature of the chemical bonding in these complexes. The IR spectra have allowed us to establish the coordination of the ligands.

The ability of arsine and phosphine oxides to act as oxygen donors and to form complex compounds with different metal ions is well known. In this context, complex compounds of lanthanide nitrates, chlorides, thiocyanates with these ligands have been already reported.[1–3] In a previous paper,[4] the properties and the chemical behaviour of some mixed ligand compounds of lanthanides with chlorosalicylic acid and triphenylphosphine oxide were studied. The aim of the present note is to report the synthesis and the physico-chemical study of the complexes formed by lanthanide chlorosalicylates with triphenylarsine oxide (Ph_3AsO). The problem is very intricate due to the scarce coordinating ability of the lanthanide ions against monodentate ions (the entropic factor contributing to the complex stability is lower than that for bidentate ligands) and, finally, because the number of neutral ligands and their possibility to coordinate depends on the coordinating ability of the anions present in the coordination sphere. In our case, the hydroxycarboxylic acid is known as a characteristic chelating reagent for lanthanides.

EXPERIMENTAL

Reagents. The following reagents were used: oxides (Ln_2O_3) of spectral purity (Matthey and Johnson); 5-chlorosalicylic acid (Fluka AG-Switzerland); triphenylarsine oxide (Fluka AG-Switzerland).

Preparation of compounds. Essential for the obtention of these compounds is the reaction medium. The compounds were prepared using the liquid — liquid extraction method with benzene as organic phase. The mixed ligand compounds of Dy(III), Ho(III) and Er(III) are difficult to be prepared. In this case, an excess amount of ligand should be necessary in order to favour the extraction which at its turn involves repeated washing and recrystallizations of the obtained compounds. Irrespective of the ligand amount used, the following compounds were allways obtained:

$Ln(Ph_3AsO)_2\ (ClSal)_3$ where Ln = Pr, Nd, Sm, Eu, Tb, Dy, Ho, Er.
Ph_3AsO = triphenylarsine oxide
ClSal = 5-chlorosalicylic acid

The chemical formulas were determined on the elemental chemical analyses. (table 1).

Table 1

Analytical data

Formula of the compound	Ln		C		H	
	Calcd.	*Found*	*Calcd.*	*Found*	*Calcd.*	*Found*
$Pr(Ph_3AsO)_2\ (ClSal)_3$	10.84	10.98	52.66	52.41	3.33	3.49
$Nd(Ph_3AsO)_2\ (ClSal)_3$	11.07	11.32	52.53	52.23	3.22	3.58
$Sm(Ph_3AsO)_2\ (ClSal)_3$	11.48	11.70	52.29	52.02	3.20	3.52
$Eu(Ph_3AsO)_2\ (ClSal)_3$	11.59	11.45	52.22	52.38	3.20	3.47
$Dy(Ph_3AsO)_2\ (ClSal)_3$	12.29	12.11	51.80	51.58	3.17	3.43
$Ho(Ph_3AsO)_2\ (ClSal)_3$	12.46	12.63	51.70	51.37	3.17	3.50
$Er(Ph_3AsO)_2\ (ClSal)_3$	12.64	12.91	51.60	51.72	3.16	3.22

Analysis and measurements. The chemical analysis was performed through micromethods; C and H were determined by microcombustion. The metal was estimated gravimetrically by ignition to oxide.

The electric conductivity measurements were made by means of a conductometer Radelkis OK-102, in alcoholic solutions, acetone and DMF of 10^{-3}M concentration. Platinum electrodes were used and the constant of the cell was determined in aqueous solutions of the KCl of different concentrations.

IR spectra within 400—3600 cm^{-1} were recorded with a UR-10 spectrophotometer using KBr pellets.

Electronic spectra in UV and visible range were recorded with a VSU-2 Zeiss-Jena spectrophotometer on the ethanolic solutions for 220—360 nm and benzenic solutions for 360—900 nm range. The reflectance spectra were recorded with a VSU-1. Zeiss-Jena spectrophotometer using MgO as standard. Thermodifferential measurements were carried out with an OD-102 derivatograph, system F. Paulik, J. Paulik and L. Erdey, in air using platinum crucible and Al_2O_3 as reference.

RESULTS AND DISCUSSION

In order to characterize the complex compounds obtained, the melting points were determined as well as the solubility in the common organic solvents. The obtained melting points being compared with those of simple lanthanide chlorosalicylates. As results from this comparison, the mixed ligand compounds are characterized by lower melting points and by a higher solubility in benzene, chloroform, acetone and DMF, but they are less soluble in alcohols (ethanol and methanol). These facts prove the increase in the covalency of the chemical bonds as a consequence of the entrance of neutral ligands into the inner coordination sphere.

To prove the chemical formula ascribed to the complex compounds studied, the molar electrical conductivity measurements were performed. The results obtained were interpreted using the data reported in the related literature concerning the limits between the molar electrical conductivities for different types of electrolytes.[5] An examination of the data reported in table 2 has lead us to the conclusion that the new synthetized mixed ligand compounds of the lanthanides behave as nonelectrolytes, all carboxylic groups being coordinated.

Table 2

Some physical properties of the compounds Ln $(Ph_3AsO)_2$ $(ClSal)_3$

Compound	Colour	m.p. (°C)	$\wedge(\Omega^{-1}\ cm^2\ mol^{-1})$		
			C_2H_5OH	acetone	DMF
$La(Ph_3AsO)_2\ (ClSal)_3$	white	120	2.09	—	32.4
$Pr(Ph_3AsO)_2\ (ClSal)_3$	green-pale	121–23	2.08	9.3	32.4
$Nd(Ph_3AsO)_2\ (ClSal)_3$	pink	124–26	2.10	9.3	32.4
$Sm(Ph_3AsO)_2\ (ClSal)_3$	white-yellow	138–40	—	—	—
$Eu(Ph_3AsO)_2\ (ClSal)_3$	yellow	141–43	2.06	9.3	32.2
$Dy(Ph_3AsO)_2\ (ClSal)_3$	white-yellow	143–45	—	9.3	—
$Tb(Ph_3AsO)_2\ (ClSal)_3$	white	143–45	—	—	32.0
$Er(Ph_3AsO)_2\ (ClSal)_3$	pink	147–51	—	9.3	31.8

The absorption spectra in UV within 220–360 nm were also studied. Their interpretation has been made by comparing the spectra obtained with those of the free ligands. The chlorosalicylic acid has two absorption maxima at 233 nm and 316 nm, corresponding to the transition $\pi-\pi^*$ and $n-\pi^*$, respectively. The spectrum of triphenylarsine oxide has three absorption maxima at 258,263 and 270 nm. The band systems, observed with the electronic spectra of different substituted arsines, were interpreted in terms of charge transfer nature [6]. The same thing happens with the corresponding arsine oxides. The absorption bands around 270 nm, unaffected by the nature of the substituents and the medium polarity, are ascribed to $\pi-\pi^*$ transitions of the aromatic ring. The second group of the bands placed at 220–266 nm strongly dependent on the substituents was assigned to one electron transition from the lone pair of arsenic to a π antibonding orbital of the benzenic ring.

[6] W. R. Cullen and R. M. Hochstrasser, *J. Mol. Spectroscopy*, **5**, 118(1960).

The absorption spectra of the mixed ligand compounds contain the absorption maxima characteristic to the free ligands. These maxima occur practically with the same wavenumbers as in the free ligands, but with higher intensities, the last observation being a testimony of the chemical bond formation (fig. 1).

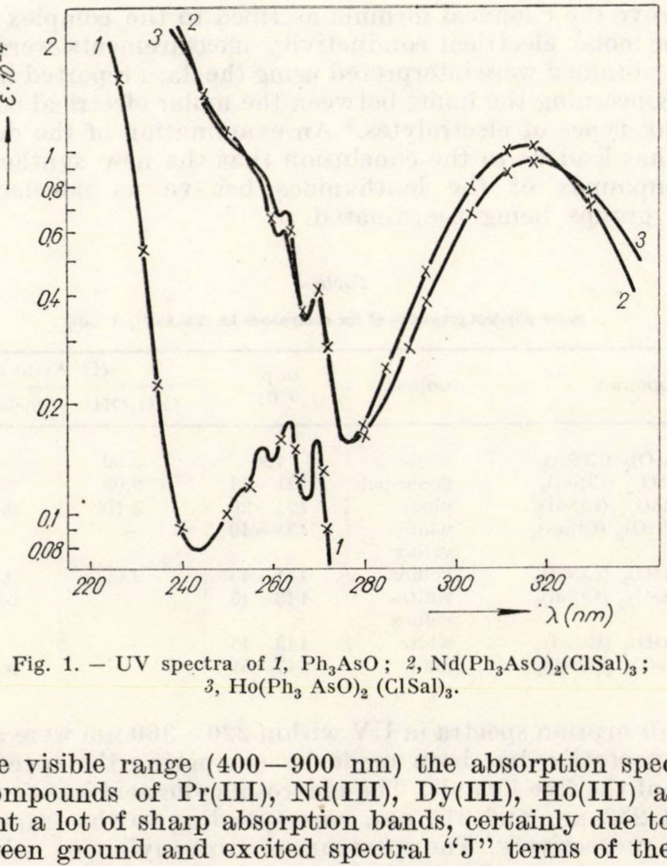

Fig. 1. – UV spectra of *1*, Ph_3AsO ; *2*, $Nd(Ph_3AsO)_2(ClSal)_3$; *3*, $Ho(Ph_3\ AsO)_2\ (ClSal)_3$.

In the visible range (400–900 nm) the absorption spectra of the complex compounds of Pr(III), Nd(III), Dy(III), Ho(III) and Er(III) ions, present a lot of sharp absorption bands, certainly due to the transition between ground and excited spectral "J" terms of the electronic configuration 4f. The spectral data obtained were used to estimate the chemical bonding in these mixed ligand complexes, and in what the lanthanide participation is concerned.

The coordination of different ligands to the central metal ion is reflected in a series of changes occurring in the absorption spectrum in the visible range of the complex, compared with the spectrum of the free metal ion. To emphasize these changes, the spectra of aquo ions were taken as reference. The spectra of Pr(f^2) and Nd(f^3) complexes show shifts of bands and an increase in their intensities. These bandshifts depend on the number of electrons in the *f*-shell, the shifts being smaller when the electron number increases. This fact should be explained by the lower ability of the "f" orbitals towards coordination, when they are filled with more electrons (table 3).

The nephelauxetic parameter taken as the covalency degree of the chemical metal-ligand bonds[7] has been calculated from the bandshifts observed with the absorption spectra of Pr(III) and Nd(III), taken the corresponding aquo ions as reference. In a previous paper,[8] it has been shown that the nephelauxetic ratio is due to the lowering in the interelectronic repulsion (Slater-Condon or Racah) parameters and spin-orbit constant values, caused by the increase in the radial extention of the AO's, as a consequence of MO formation. The lowering in the interelectronic repulsion energy values leads to a lowering in the transition frequencies and hence to a red shift. As it has been recently shown,[9] the covalency effects directly reflected on the lowering of the repulsion parameter and spin-orbit coupling constant values are too much small to account for the experimentally observed bandshifts at least in the case of $f-f$ transitions. The lowering of these parameters caused by central covalency suggested by Jørgensen[10] (reduction of the formal charge on the metal ion) is also too much small to explain the observed bandshifts. This is the reason why the parameter β ascribed by definition to the ratio between the interelectronic repulsion parameters or spin-orbit coupling constants may have another origins, as follows:

[10] C. K. Jørgensen, "Orbitals in Atoms and Molecules", Academic Press, London-New York, 1962.

$$\text{Let} \qquad E_f = E_f^0(F, \xi) + V_f$$

$$E = E_e^0(F, \xi) + V_e$$

the ground and excited state energies. $V_{f(e)}$ are the energetic contributions due to the chemical bonding or electrostatic perturbations caused by the chemical environment.

The transition between them will be:

$\nu = \nu_0 + \Delta V$ where ν_0 = transition in the free gaseous ion
$\Delta V = V_e - V_f$ the energetic contribution due to the chemical bond formation.

Taking the corresponding transition ν_a in aquo ion as reference, then

$$\frac{\nu_a - \nu_c}{\nu_a} = \frac{\Delta V_a - \Delta V_c}{\nu_0 + \Delta V_a}$$

Similarly to the formulas obtained in the nephelauxetic approximation one may formally obtain:

$$\frac{\Delta V_a - \Delta V_c}{\nu_0 + \Delta V_a} = 1 - \beta.$$

where $1-\beta$ also represents a measure of the covalency degree of the chemical bonds but with other signification, as mentioned above. The parameters $1-\beta$ and δ were calculated for Pr(III) and Nd(III) complexes (table 4). The positive value obtained shows that the chemical metal-ligand bonds in the studied compounds are more covalent that those in aquo ions.

Further information concerning the ligand coordination have been obtained using the IR data. For all the studied compounds, the spectra were recorded within 600–3600 cm^{-1} and for an exact assignment, the free ligand IR spectra were also recorded. The data are summarized in table 5. As may be seen from table 5, the chlorosalicylic acid has an intense band ascribed to the carbonyl group at 1670 cm^{-1}, occuring split and shifted in the complex compounds, as follows: $\nu_{as}COO^-$ (1580 cm^{-1}) and $\nu_s COO^-$(1370cm^{-1}) due to the asymmetric and symmetric vibration modes, respectively. It may be mentioned the presence in the mixed ligand compounds of absorption bands at 3050 cm^{-1} and 1620 cm^{-1} characteristic to the aromatic ring and another band at 650 cm^{-1} corresponding to the bending vibration of COO^-. In what the neutral ligand Ph_3AsO is concerned, it possesses a lot of vibrations active in IR. Some of them are perturbed by coordination, others, as an example the maxima appearing

at frequencies higher than 1400 cm^{-1} ascribed to C=C vibrations, are overlapped with the absorption bands due to the symmetric and asymmetric frequencies of the coordinated chlorosalicyclic acid. More important changes are especially produced in the position of the absorption band corresponding to the stretching frequency of As−O bond, due to the chemical bond formation. The very intense band occurring in the spectrum of the free Ph_3AsO at 885 cm^{-1}, assigned to the stretching vibration As–O, occurs in the mixed ligand complexes shifted towards higher wavenumbers (fig. 2).

This observation should be explained, in contrast with the similar compounds of Ph_3PO,[4] by the fact that during Ph_3AsO coordination to the lanthanide ion, the strengthening of τ_{As-O} bond together with the interaction π metal-oxygen have a predominant character, while the ${}_p\pi - {}_d\pi$ oxygen-arsenic bond is very weak, which leads practically to the increase of the stretching vibration ν_{As-O}. As may be observed in figure 3, the bandshift value depends linearly on the lanthanide ionic ray.

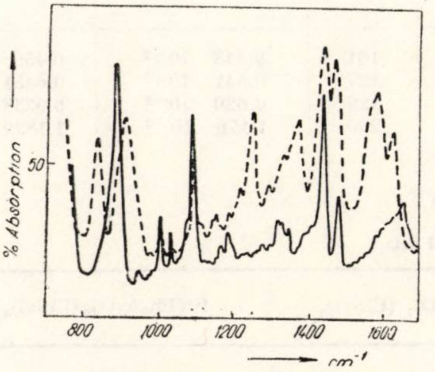

Fig. 2. – IR spectra of *1*, Ph_3AsO ; *2*, $Er(Ph_3AsO)_2$ $(ClSal)_3$.

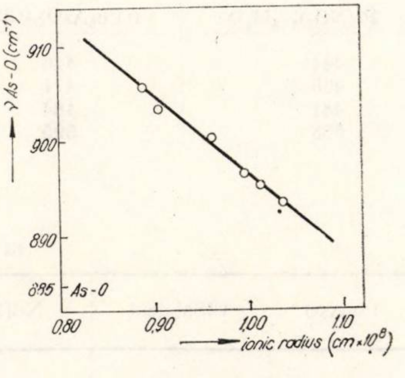

Fig. 3. – Linear dependence of ν_{As-O} on the ionic radius.

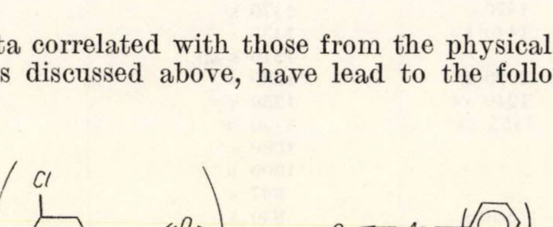
The IR data correlated with those from the physical and chemical measurements, as discussed above, have lead to the following chemical formulation :



The thermodifferential analysis performed on the mixed ligand compounds herein studied gave informations on their thermal stability and their chemical behaviour function of temperature. As an example the thermal analysis results are illustrated for the $Er(Ph_3AsO)_2(ClSal)_3$. The compounds are stable until 220–240° occuring on the TG curve as a level. Over this temperature, the elimination of the neutral ligand begins, followed by the partial decomposition of Erbium chlorosalicylate which continues up to 420°. If the TG data were correlated with the initial weight of the sample, the weight loss was estimated in this temperature point. According to the theoretical calculations, the weight loss corresponds to two molecules of neutral ligand and to a third part from the organic anion. Between 460—560° the oxidation of the volatile organic products takes place, the heat being emitted in the strong exothermal effect at 510°. The initial compound is transformed after oxidation into instable intermediate compounds, most likely oxycarbonates of the form $Ln_2O_3 . nCO_2$, as indicated in the related literature.[11] At temperatures higher than 600° the decomposition of the oxycarbonates takes place, the final level obtained corresponding to the Er_2O_3 formation.

PAPIERELEKTROPHORETISCHE UNTERSUCHUNG DER BILDUNG VON VERBINDUNGEN DES INDIUMS MIT R-WEINSÄURE

GH. MARCU, MARIA SUCIU und A. V. BOTAR

vom Institut für Chemie, Donath-Str. 65, Cluj

Eingegangen am 8. Mai 1973

Die Reaktion des Ions In^{3+} mit R-Weinsäure wurde papierelektrophoretisch untersucht. Die Bildung der Ionenarten des Typus $In(C_4O_6H_3)_2^{3-}$ und $In(C_4O_6H_3)_3^{6-}$ wurde festgestellt und ihre Stabilitätskonstanten bestimmt ($\beta_1 = 4{,}78 . 10^{10}$ bzw. $\beta_2 = 8{,}71 . 10^7$). Die Werte der papierelektrophoretisch gefundenen Stabilitätskonstanten stimmen mit denjenigen nach der Bjerrum-Methode ($\beta_1 = 6{,}33 . 10^{10}$ bzw. $\beta_2 = 1{,}40 . 10^7$) gut überein.

Als Fortsetzung der Untersuchungen der Reaktionen des In^{3+}-Ions mit organischen Hydroxysäuren,[1] wurde das Verhalten dieses Ions in weinsauerem Medium in Abhängigkeit vom pH elektrophoretisch untersucht.

Es ist bekannt, daß In^{3+} mit verschiedenen organischen Hydroxysäuren in wäßrigem Medium stabile Komplexe bildet. Die Stärke der Bindung zwischen dem Ion In^{3+} und diesen Liganden wird durch den Wert der Bildungskonstante des Komplexes ausgedrückt, welche durch eine Reihe von Faktoren bedingt wird, von welchen die elektronenspendenden Eigenschaften des Anions eine wichtige Rolle spielen. In der Fachliteratur werden eine Reihe von Komplexen des In^{3+} mit organischen Hydroxysäuren angeführt.[2-9] Spektrophotometrische, konduktometrische sowie potentiometrische Studien der Stabilität der Komplexe des In^{3+} in wäßriger Lösung von R-Weinsäure ergaben das Vorhandensein folgender Ionenarten: $In(C_4O_6H_3)^0$, $In(C_4O_6H_3)_2^{3-}$ und $In(C_4O_6H_3)_3^{6-}$. Zur stufenweisen Bildung der Komplexe tragen am wahrscheinlichsten folgende chemische Reaktionen bei :

$$In(C_4O_6H_3)_2^{3-} + C_4O_6H_4^{2-} + OH^- \rightleftharpoons In(C_4O_6H_3)_3^{6-} + H_2O$$

Die Methode der Papierelektrophorese wurde erfolgreich bei der Bestimmung der Bildungskonstanten verschiedener Komplexe angewendet.[10-12]

Da diese Methode beim Studium der Komplexverbindungen, der Radioisotopen gute Ergebnisse liefert, untersuchten wir das System In^{3+} — R-Weinsäure papierelektrophoretisch, um die Werte der Bildungskonstanten der Verbindungen des Indiums in R-Weinsäure zu bestimmen. Das Prinzip der Methode wurde in vorangegangenen Arbeiten[10-12] dargelegt.

EXPERIMENTELLER TEIL

Es wurde mit einem bereits beschriebenen[13] Papierelektrochromatographen gearbeitet. Die Versuche wurden in 0,5 m R-Weinsäure-Medium bei einem pH-Bereich von 1,08—7,92 durchgeführt. Das zu untersuchende Element wurde mittels einer Mikropipette zentral auf den chromatographischen Papierstreifen (Papier Whatman Nr. 1 der Dimensionen 32,5/1, 5 cm) aufgetragen, dessen Enden einer Potentieldifferenz von etwa 1100 V bei 15 mA ausgesetzt wurden. Die Zeit der elektrischen Wanderung war 12 Min. und die Arbeitstemperatur 15±2°.

Die Wandung der Verbindungen wurde durch Messen der Aktivität des Radioisotops ^{114}In verfolgt, und gegen die Stellung der Glukose, welche gleichzeitig auf den chromatographischen Papierstreifen aufgetragen wurde, korrigiert. Die elektrophoretischen Wanderungsgeschwindigkeiten der vorhandenen Ionenarten wurde anhand der Beziehung von Kunkel und Tiselius[14] berechnet. Die experimentell gefundenen Ergebnisse sind in Tabelle 1 angeführt unter Berücksichtigung der Absorbtion der Ionen am chromatographischen Papier ($R_f = 0{,}94$).

7,92	1180	+2,7	+1,90

AUSWERTUNG DER ERGEBNISSE

Die graphische Darstellung der Summe der elektrophoretischen Wanderungsgeschwindigkeiten der gebildeten Ionenarten in Abhängigkeit vom pH-Wert ergibt eine Doppelkurve in „S“-Form, welche für die Bildung von Komplexverbindungen charakteristisch ist. Es wird beobachtet, daß in stark saurem Medium der In^{3+}-Ion dem Katode zuwandert. Bei $pH > 2{,}5$ wandert der In^{3+}-Ion, welcher Ionenarten des Typs $In(C_4O_6H_3)_2^{3-}$und $In(C_4O_6H_3)_3^{6-}$ gebildet hat, dem Anode zu.

Zwecks Bestimmung der Bildungskonstanten der erhaltenen Ionenarten wurde die Summe der elektrophoretischen Wanderungsgeschwindigkeiten (u) gegen die pH-Werte aufgetragen und aus der Abhängigkeit des $\lg \frac{u + u_{In^{3+}}}{u - u_{In}^{(3-3x)-} - u}$ von pH wurde der dem Nullwert dieses Verhältnisses entsprechende pH-Wert berechnet.

Zum Schluß wurden die Bildungskonstanten jeder einzelnen Ionenart berechnet, die aus Tabelle 2 ersichtlich sind.

Die erhaltenen Werte für die Bildungskonstanten sind in guter Übereinstimmung mit denen nach der Bjerrum Methode bestimmten ($\beta_1 = 6{,}33.10^{10}$ bzw. $\beta_2 = 1{,}40.10^7$).

Tabelle 2

Werte der Stabilitäts- und Instabilitätskonstanten

Untersuchte Verbindung	Stabilitätskonstante	Instabilitätskonstante
$In(C_4O_6H_4)_2^{3-}$	$4{,}78.10^{10}$	$0{,}21.10^{10}$
$In(C_4O_6H_3)_3^{6-}$	$8{,}71.10^7$	$0{,}11.10^7$

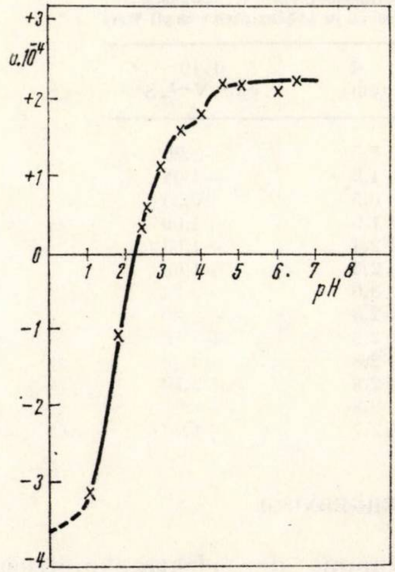

Abb. 1. — Abhängigkeit der Summe der elektrophoretischen Wanderungsgeschwindigkeit (u) von pH.

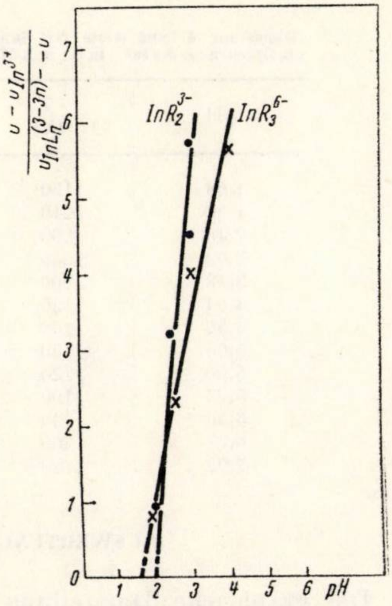

Abb. 2. — Abhängigkeit des $\dfrac{u - u_{\mathrm{In}^{3+}}}{u_{\mathrm{InL}_n}^{(3-3n)-} - u}$ von pH.

SCHLUSSFOLGERUNGEN

1. Die Bildung der Komplexe des In^{3+} mit R-Weinsäure wurde erstmals papierelektrophoretisch unter Anwendung des Radioisotops ^{114}In untersucht.

2. Es wurden die Werte der Stabilitätskonstanten der Ionenarten $In(C_4O_6H_3)_2^{3-}$ und $In\ (C_4O_6H_3)_3^{6-}$ bestimmt und gleich $\beta_1 = 4{,}78.10^{10}$ bzw. $\beta_2 = 8{,}71.10^7$ gefunden. Diese Werte sind in guter Übereinstimmung mit denen nach der Bjerrum Methode[1] bestimmten.

COMPUTER PROGRAM FOR DETERMINING ALL POSSIBLE E.S.R. SPECTRA WITH EQUIDISTANT LINES

A. T. BALABAN and C. POMPONIU

Institute of Atomic Physics, P. O. Box 35, Bucharest

Received September 28, 1973

A computer program was developed for displaying all possible theoretical ESR spectra of free radicals possessing nuclei with spins 1/2 and 1, and having equidistant lines (some of which may have zero intensity). A table of intensities of ESR spectra with M = 2–15 equidistant lines is presented.

INTRODUCTION

In a previous paper,[1] a method was devised for finding all possible electron spin resonance (ESR) spectra with M equidistant lines due to stable nitrogen free radicals, where the energy levels of the odd electron are split by interaction with atoms with nuclear spin 1/2 (e. g. protium) and/or 1 (e. g. nitrogen-14). This method is based on the partitions of the integer number of intervals between lines, M–1. The summands (partition numbers) in partitions must be assigned as coupling constants (in units equal to *d*, the smallest interval between lines) to ^{1}H and/or ^{14}N atoms, whereby one a_N coupling constant uses two equal summands from the partitions.[2] For instance, there are three partitions of the integer three : $3 = 2 + 1 = 1 + 1 + 1$. Therefore, there exist four and only four possible ESR spectra of free radicals with ^{1}H and /or ^{14}N atoms, with four equidistant lines, which correspond to the above three partitions namely :

Partition	$3 : 1a_H = 3d$;	intensities : 1 : 0 : 0 : 1
,,	$2 + 1 : 1a_H = 2d, \; 1a_H = 1d$;	,, 1 : 1 : 1 : 1
,,	$1 + 1 + 1 : 1a_H = 1d, \; 1a_N = 1d$;	,, 1 : 2 : 2 : 1
,,	$1 + 1 + 1 : 3a_H = 1d$;	,, 1 : 3 : 3 : 1

In the preceding paper,[1] a table was included showing all possible ESR spectra with 2–8 equidistant lines,* all having non-zero intensities (therefore, only the last three of the above ESR spectra with four lines were presented). Since inclusion of lines with zero intensity also allows the accomodation of ESR spectra with non-equidistant lines, this generalization to zero intensities will be used in the present paper.

---

[1] A. T. Balaban, *Rev. Roumaine Chim.*, **17**, 9 (1972).

[2] C. Pomponiu and A. T. Balaban, *Rev. Roumaine Chim.*, **18**, 1173 (1973).

* In the case of 8-line ESR spectra one spectrum was missing (with intensities 1 : 6 : 16 : 25 : . . .)

In practice, owing to the finite resolution of ESR spectrometers and to other factors, [3] most experimental ESR spectra can be approximated by this procedure. However, since coupling constants in fact are not multiples of a "quantum" d, this is only a first-order approximation which must be supplemented by a spectrum simulation in order to achieve an exact determination of coupling constants.[3]

For determining the complete table of all possible ESR spectra withm equidistant lines (including also lines of zero intensity*), hand calculations can be carried out up to a relatively small number of lines, around $M=10$. For interpreting ESR spectra with larger numbers of lines, two different approaches can be imagined : (i) to feed into a computer the approximate intensities of ESR lines determined from the experimental spectrum, the numbers and the types of atoms interacting with the odd electron in order to obtain the coupling constants compatible with the given ESR spectrum within adjustable error limits (this approach resulted in a computer program which can handle spectra with up to 800 equidistant lines[2]) ; (ii) to produce a table of all possible ESR spectra with the given number M of equidistant lines. This second approach is developed in the present paper.

It is, of course, tedious to handle output data with a very large number of entries. Since the number of possible ESR spectra with equidistant lines increases sharply with increasing M, as will be shown in table 1, this paper presents only the cases with $M \leqslant 15$ lines. However, the program can be used for higher M values whenever necessary. Even with this limitation, we hope that the present data will be useful because the more complex ESR spectra often contain subgroups of a relatively small number of lines, which can be deciphered by comparing them with the table of all theoretical possibilities (table 3).

ESR SPECTRA WITH EQUIDISTANT *versus* NON-EQUIDISTANT LINES

In practice, ESR spectra with more or less equidistant lines appear at low resolution of the ESR spectrometer : as the resolution of the spectrometer increases, ESR spectra with equidistant lines occur less frequently.

One can illustrate for systems with two or three spins in what cases spectra with equidistant lines appear, by planar or tridimensional diagrams, respectively. For systems with two spins we illustrate in figure 1 three cases : two hydrogens, two nitrogens, and one hydrogen plus one nitrogen. The diagram for the first case (fig. 1i) consists in a pair of points (A and B) at distance a_H ; each of these points is the apex of an isosceles triangle whose height and base are equal to a_H. The intersections of these four lines emerging from the points A and B, with a straight line parallel to line AB at distance a'_{H}, give four points which represent the ESR spectrum. In the second case (fig. 1ii), there are three collinear points A, B, and C : distances AB and BC are equal to a_{N} ; from each of these points, three lines emerge with angles of 45° between them. Again, the nine intersections of these lines with a straight line, parallel to ABC at distance a'_{N} from it, determine a model of the ESR spectrum. In the third case the diagram may start either with the hydrogen coupling constant a_{H} (fig. 1iii), or with the nitrogen coupling constant a_{N} (fig. 1iv).

---

[3] N. Negoiţă, R. Baican and A. T. Balaban, *Rev. Roumaine Chim.*, **18**, 995 (1973).

* We impose as the only condition that the first and last lines always have intensities equal to 1.

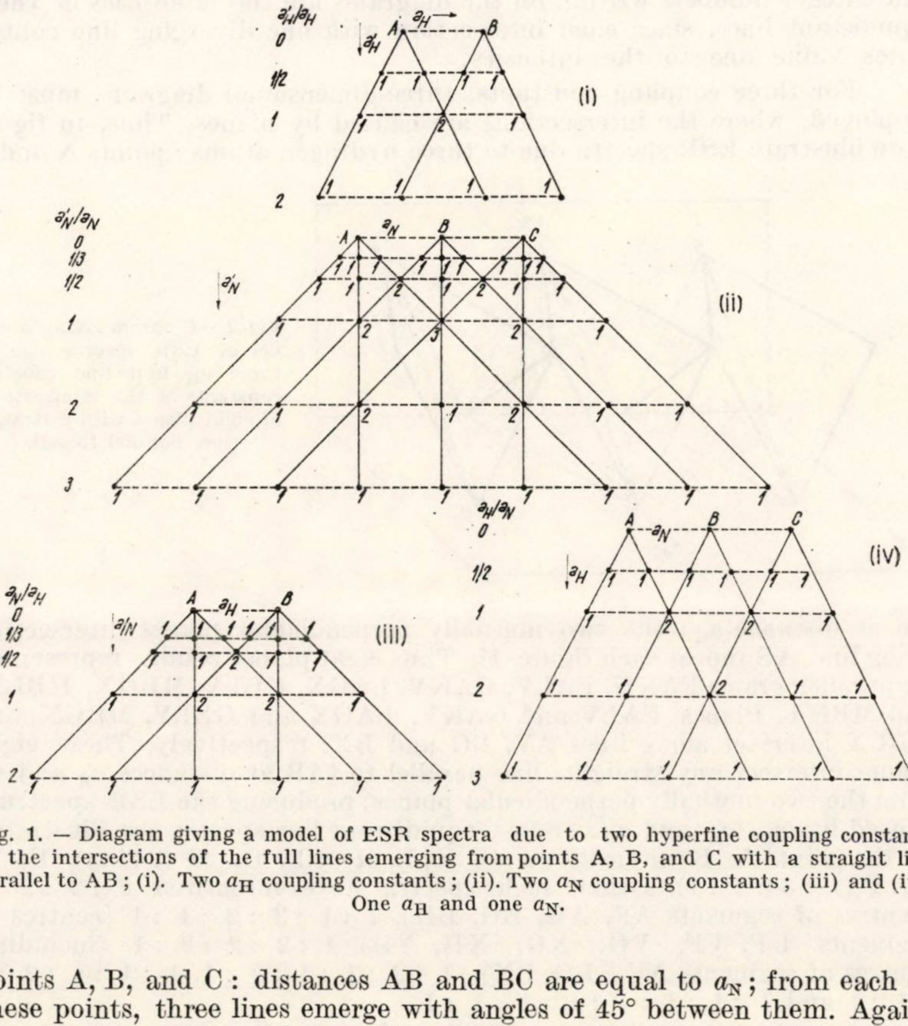

Fig. 1. — Diagram giving a model of ESR spectra due to two hyperfine coupling constants as the intersections of the full lines emerging from points A, B, and C with a straight line parallel to AB ; (i). Two a_{H} coupling constants ; (ii). Two a_{N} coupling constants ; (iii) and (iv). One a_{H} and one a_{N}.

To explore all possible ESR spectra with equidistant or non-equidistant lines due to two coupling constants for atoms with the same nuclear spin, it is sufficient in figures 1i and 1ii to sweep the ratio a/a' ranging only from zero to one. By translating the line parallel to AB through the prescribed range of a/a' values, one obtains an infinity of ESR spectra with non-equidistant lines, and a few spectra with equidistant lines corresponding to those a/a' ratios for which the divergent lines emerging from A, B(and C in appropriate cases) intersect among themselves. The integer numbers written on the diagrams are the intensities of these equidistant lines, since each intersection with one diverging line contributes value one to the intensity.

For three coupling constants, three-dimensional diagrams must be employed, where the intersections are caused by planes. Thus, in figure 2 we illustrate ESR spectra due to three hydrogen atoms : points A and B are at distance a_{H} ; the two mutually perpendicular planes intersecting along line AB repeat each figure 1i. Thus eight planes result, represented by parallelograms FAKU, FALV, GAKV, LAGX, GBLV, MBGX, HBLX, and MBHY. Planes FALV and GAKV, LAGX and GBLV, MBGX and HBLX intersect along lines AV, LG and BX, respectively. These eight planes intersect any straight line parallel to (AB at distances a'_{H} and a''_{H} from the two mutually perpendicular planes) producing the ESR spectrum caused by a_{H}, a'_{H} and a''_{H}. Some equidistant line spectra are illustrated by the points A, B (intensities 4 :4), K, L, M or F, G, H (2 :4 :2), U, V, X, Y (1 : 3 : 3 : 1). Other such spectra have intensities 2 : 2 : 2 : 2 (centres of segments AF, AG, BG, BH), 1 : 1 : 2 : 2 : 1 : 1 (centres of segments UF, VF, VG, XG, XH, YH), 1 : 2 : 2 : 2 : 1 (including centres of segments AV, LG, BX), 1 : 2 : 1 : 1 : 2 : 1, 1 : 1 : 1 : 2 : 1 : 1 : 1 and 1 : 1 : 1 : 1 : 1 : 1 : 1 : 1.

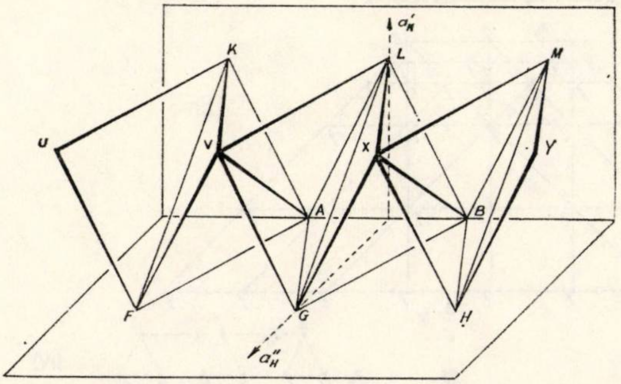

Fig. 2.—Diagram giving a model of ESR spectra due to three a_{H} hyperfine coupling constants as the intersections of eight planes with a straight line parallel to AB.

By this procedure one can easily survey the hyperfine couplings of ESR spectra due to two or three spins, but though it is possible to go beyond these numbers by a straightforward generalization to more than three dimensions, the visualization is lost.

One can see from the above diagrams that from the infinity of ESR spectra with non-equidistant lines, those spectra corresponding to certain ratios of hyperfine coupling constants approximate equidistant lines. The number of possible equidistant line spectra is quite small relatively to all possible (equidistant and non-equidistant) spectra. This serves to illustrate the usefulness of the present approach. By relating an experimental ESR spectrum to one or a few theoretical possibilities from a limited set, one can have a reasonable starting point for an exact determination of coupling constants by means of a spectrum simulator.[3]

DESCRIPTION OF THE PROGRAM

According to the performed jobs, the whole program can be split into three main parts:

I. *Generation of all spectra with a given number M of lines.* This task is accomplished by the modules:

subroutine DSPLY
subroutine MINIMA
subroutine PRDUCT
function INF
function C

As we suppose the reader to be familiar with the description of the last four modules,[2] we shall briefly comment on the first one, i. e. DSPLY. This module solves the diophantic system:

$$M-1=\sum_{i=1}^{M-1} i m_i + 2\sum_{j=1}^{M-1} j n_j$$

$$\chi_1=\sum_{i=1}^{M-1} m_i$$

$$\chi_2=\sum_{j=1}^{M-1} n_j$$

to find the values $m_1, m_2, \ldots$ for the partition numbers of atoms with spin $\frac{1}{2}$, and $n_1, n_2, \ldots$ for the partition numbers of atoms with spin 1. These partition numbers are then processed by MINIMA, PRDUCT, INF and C to yield the corresponding intensities of lines in the ESR spectrum.

II. *The arrangement of spectra in increasing order of magnitude of their intensities.* This is done by the MAINPGM itself together with the module:

subroutine COMP.

This module decides which one of the two given spectra has precedence, by successive comparison of their intensities starting from the leftmost margin. This comparison goes on as long as these intensities are equal. When a pair of unequal intensities is encountered, the spectrum with the smaller intensity is given priority. In this way the MAINPGM starts printing the smallest spectrum and proceeds along the well-known lines of sorting a set of objects (however, in this case the objects are arrays and one needs a generalized criterion for comparing them, which is just the job of COMP).

III. *Possible restrictions on the intensities of the spectra to be printed.* It may happen that one is not interested in the full output, i. e. all possible spectra with a given number of lines, M, arranged in increasing order of line intensity, but only in those spectra which exhibit a certain peculiarity. To allow for leaving out the rest of them, a module is included, called

subroutine COND

which causes the skipping of unwanted spectra.

We pass now to specific features of the above modules :

1. *Memory requirements*. To be able to perform the ordering, one must keep in the computer memory *all* spectra with a given number of lines. These are held in a matrix $V(i, j)$. Memory restriction led us to work up a table of spectra ranging from $M = 2$ to $M = 15$, because for $M \geqslant 16$, the spectra become too numerous for our computer memory. For the same reasons, we work with integers of reduced length (2 Bytes instead of 4) ; this is taken care of by appropriate INTEGER*2 statements. To further cut down the bulk of used storage, only half of a spectrum is retained and printed,* together with the corresponding values for partition numbers and coupling constants. All in all we gave a length of 28 locations (words) for every spectrum. This is quite enough for spectra with up to 20 lines. For spectra with more than 20 lines, provided one can accomodate them all at a time (as their number increases very fast, subroutine COND could be employed), one can design one's own format for printing the output. This would imply modification of the DIMENSION statements for the following arrays (see the MAINPGM) : V, PP, Q, LEAST, KMAX, LMAX, in that one assigns them the following amount of storage :

```
INTEGER*2 V, PP (MAXL), Q (MAXL), LEAST (MAXL),
KMAX, LMAX
COMMON V (MAXN, MAXL), KMAX (MAXN), LMAX (MAXN)
```

where MAXL = integer constant equal to the *estimated length* of the printing of one spectrum together with its partition numbers and coupling constants

MAXN = integer constant equal to the upper bound for the *number of spectra* with the given $M > 20$ number of lines.

2. *Arguments of the newly employed modules.*

a) subroutine DSPLY :

INTNUM = number of lines in the spectrum, i. e. M

HI1 = number of atoms with spin 1/2

HI2 = number of atoms with spin 1

ITAB = integer number used to print output in two different formats. To use the second format, set ITAB = −666666.

b) subroutine COMP :

FLAG = integer variable whose value can be +1 or −1. The value FLAG = +1 implies P bigger than Q, where

---

* Excepting the first spectrum in table 3, for M=2, which consists of only the two extreme lines.

P = integer*2 array that is to be compared
Q = integer*2 array that is to be compared
N = the largest value of index up to which comparison is made

c) subroutine COND.
I0 = integer constant equal to one, the first intensity of every spectrum
I = integer*2 array containing the next intensities of the spectrum
IT = integer constant whose value can be +1 or −1, according to whether the spectrum is to be printed or skipped.

In subroutine COND one can insert cards, specifying the particular features one is interested in. For instance, if one wishes to print only spectra whose second line has relative intensity 2, one has to insert the card :

IF (I(1). NE.2) IT = −1,
after the assignation card : IT = +1.

The listing of the new subroutines is presented in table 2 preceding the output (table 3).

DISCUSSION

Table 3 lists all possible ESR spectra with 2 through 15 equidistant lines (whose intensities may also be zero), presenting the number M of lines, the intensities of the first M/2 lines (for even M) or (M +1)/2 lines (for odd M), and the coupling constants (in *d* units, equal to the equidistance between lines). These coupling constants are formated in two groups, each one consisting of several diads : coupling constant*number of equal coupling constants/. E. g. 3*2/indicates that there are two equal coupling constants of magnitude 3*d* (three intervals). The first group includes couplings with nuclei of spin 1/2 (e. g. ^{1}H), while the second group includes couplings with nuclei of spin 1 (e. g. ^{14}N). For each spectrum the coupling constants are listed in decreasing order.

For a given number of lines the spectra are arranged in the order of increasing intensities of their lines. A special subroutine COMP was developed for ordering these spectra, considering the intensities of all their lines.

It may be seen that some ESR spectra are degenerate, i. e. the distribution of intensities can be assigned to two different sets of coupling constants.[1] Since intensities of ESR spectra due to interaction with χ_1 ^{1}H nuclei of coupling constant a_i are the binomial coefficients of $(x^{a_i} + 1)^{\chi_1}$, and those due to interaction with χ_2 ^{14}N nuclei of coupling constant a_j are [1] the trinominal coefficients of $(x^{2a_j} + x^{a_j} + 1)^{\chi_2}$, the intensities of an ESR spectrum of nitrogen free radicals (combining both types of nuclei) are the coefficients of the polynomial :

$$\prod_{i,j} (1 + x^{a_i})^{\chi_{1,i}} (1 + x^{a_j} + x^{2a_j})^{\chi_{2,j}}$$

Therefore, an ESR spectrum with six equal lines (intensities equal to 1) is degenerate, because from the equalities:

$$x^5+x^4+x^3+x^2+x+1=(x^3+1)(x^2+x+1)=(x+1)(x^4+x^2+1)$$

one sees that it can be ascribed either to a combination $a_{\mathrm{H}}=3$, $a_{\mathrm{N}}=1$, or to a combination $a_{\mathrm{H}}=1$, $a_{\mathrm{N}}=2$. These two combinations (or multiples thereof) appear in all degenerate ESR spectra. Thus, twelve equidistant lines of equal intensity (=1) constitute a triply degenerate ESR spectrum.

Table 1 was compiled on the basis of two runs of the program for up to 16 lines in the ESR spectrum: one in which the smallest number of atoms with nuclear spins 1/2 and 1 was at least one, and another in which it could be zero. The former run gave the numbers of possible ESR spectra with a_{H} *and* a_{N} presented in columns 2 and 4 of table 1, the latter run gave the remaining columns 1 and 3 with a_{H} *and/or* a_{N}. A semilogarithmic plot (fig. 3) of the data from table 1 indicates that the number of possible ESR spectra with M lines increases almost exponentially as a function of M. It can be observed that there is an alternation for even and odd N values in the number of possible ESR spectra with a_{H} and/or a_{N} (column 3) when some lines may have zero intensity and with a_{H} and a_{N} (column 2) when all lines have non-zero intensity. Maxima of column 3 occur for odd M, while maxima of column 2 occur for even M values. This alternation of column 3 values can be explained by the fact that for spectra with even N there exists the restriction that the number of hydrogen nuclei cannot be zero. When this restriction is applied to both ^{1}H

Table 1

Numbers of possibile ESR spectra of nitrogen free radicals with M equidistant lines in the spectrum (degenerate spectra are counted for each distinct set of coupling constants).

Number M of lines in the spectrum	Number of possible ESR spectra			
	All M lines have non-zero intensity		Some of the M lines may have zero intensity	
	With a_{H} and/or a_{N} (1)	With a_{H} and a_{N} (2)	With a_{H} and/or a_{N} (3)	With a_{H} and a_{N} (4)
2	1	0	1	0
3	2	0	3	0
4	3	1	4	1
5	5	2	9	2
6	9	5	12	5
7	14	7	23	9
8	21	13	31	16
9	35	22	54	27
10	53	37	73	43
11	77	52	118	69
12	118	88	159	103
13	171	128	246	158
14	244	192	329	228
15	355	276	489	339
16	495	399	649	472

and ^{14}N nuclei (number of ESR spectra with a_H and a_N, last column of table 1), the alternation disappears (fig. 3).

In conclusion, we have presented a program whose output is given in table 3 for M = 2—15 (but which table can be expanded for any desired number M of lines) giving an exhaustive list of all theoretical possible ESR spectra with M equidistant lines originating from the interaction of one odd electron with nuclei of spins 1/2 and 1. By comparing the intensities of any experimental ESR spectrum with those of the (expanded) table 3, one can pinpoint which set of coupling constants is compatible with the experimental spectrum, assisting in its interpretation. The philosophy of this approach for interpreting an ESR spectrum is best illustrated by the following quotation from A. Conan Doyle's "The Sign of the Four" and "The Beryl Coronet" : "When you have eliminated the impossible, wathever remains, however improbable, must be the truth".

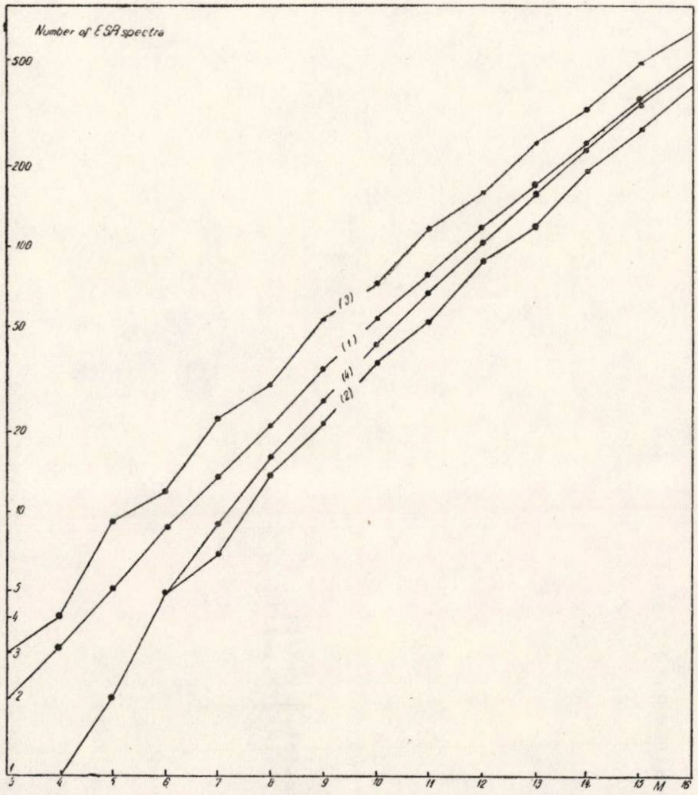

Fig. 3. — Semilogarithmic plot of the numbers of possible ESR spectra with M equidistant lines : the four curves correspond to the four columns (1)—(4) of table 1.

CHEMICAL GRAPHS. XX.[1]

GRAPHS OF PARALLEL AND/OR SUBSEQUENT SUBSTITUTION REACTIONS

A. T. BALABAN [a] and F. KEREK [b]

[a] Institute of Atomic Physics, P. O. Box 35, Bucharest
[b] Organic Chemical Laboratory, The Timişoara Polytechnic

Received September 28, 1973

A graph-theoretical model is given for parallel and/or successive substitution reactions of chemical species with *s* substitution sites, the total number of reagents which may become attached to one site being *r*. Three cases are discussed : the equivalent case giving rise to "involution graphs" $H(r^s)$, when all *s* sites are equivalent during all stages of the substitution ; the non-equivalent case, the only one which leads to regular graphs denoted by $G(r^s)$ and called "power graphs" ; and the mixed case, when no general treatment can be given because the graphs $L(r^s, M)$ depend also on the cycle index of the molecule M undergoing substitution. For the equivalent case, a computer program was devised to prepare the table giving the number of vertices with various degrees.

INTRODUCTION

Graph theory [2] was applied in chemistry in two major ways : either the points (vertices) of graphs symbolize atoms, and the lines (edges) symbolize covalent bonds in structural applications, or the points represent chemical species, and the lines represent interconversions of these species. Several recent reviews of both aspects are available.[3–8] Directed graphs (digraphs) found some applications in kinetics, [8] but most applications concern non-directed graphs. In the present paper, only non-directed graphs without loops or multiple edges will be considered; since reactions are assumed to be reversible, non-directed graphs must be employed. Among the second type of applications, the main emphasis so far was on stereoisomerizations of penta- and hexa-coordinated complexes. In the following, a different application of the second type will be developed.

Using the DARC topological system for codification of molecular structure[9] to describe chemical interconversions, Dubois and Panaye first mentioned the graph of reaction paths in the polyalkylation of aliphatic ketones.[10] We examine in the present paper the generalization of this idea for various substitution reactions.

NOTATIONS AND CLASSIFICATION

If in a molecule there are s reaction *sites* able to be substituted by $r-1$ types of *reagents*,* several chemical species will result in this substitution by parallel and/or subsequent processes. Each of these p species (including the initial, unsubstituted, one) will be represented by a vertex of the graph. The case when $r=1$ is to be excluded since it leads to the trivial graph consisting of only one point. Two points will be joined by an edge (line), i. e. will be adjacent, whenever they represent species resulting from one another by an elementary substitution (one displacement at one reaction site). The total number of elementary reactions will be denoted by q, i. e. the number of edges of the graph. The number of edges d_i incident with vertex i is called its *degree*. The total number of chemical species, p, i. e. of vertices of the graph, will be called the *order* of the graph.

Depending on the chemical structure of the initial species undergoing substitution, there are three cases to be discussed:

1. All s reaction sites are non-equivalent, e. g. in the halogenation of $R_2CH-CHR'-CHR_2''$ with $R \neq R' \neq R''$ assuming that the substitution involves only the displacement of the three hydrogens by halogens without affecting the other substituents (the non-equivalent case).

2. All reaction sites are equivalent at all stages of the substitution, e. g. in the deuteration or halogenation of methane, or in the hydrolysis of boron halides (the equivalent case). Enantiomerism will be ignored in this paper.

3. The mixed case, when either (i) the reaction sites become non-equivalent at some stage of the substitution though they are equivalent in the unsubstituted molecule, e. g. in the halogenation of benzene, ethane, or cycloalkanes, or in substitutions at square planar or octahedral complexes, or when (ii) the initial molecule has some equivalent and some non-equivalent sites as in the halogenation of alkylbenzenes or of alkanes higher than ethane, or in substitutions at trigonal-bipyramidal complexes.

1. THE NON-EQUIVALENT CASE

A previous paper [11] described combination graphs whose order (number of vertices) was expressible either as a combination: $\binom{a}{(a-1)/2}$ for regular halved combination graphs, or as a sum of combinations: $2\binom{a}{(a-1)/2}$ for regular combination graphs; $\binom{a}{b}+\binom{a}{b+1}$ for semiregular combination graphs; and $\sum_{i=0}^{(a-1)/2}\binom{a}{i} = 2^{a-1}$ for the halved hypercubes (regular chequered graphs); a and b were integers subject to the condition $1 \leqslant b \leqslant (a-1)/2$.

The present section describes a new class of graphs whose order p is expressible as a power r^s with both r and s being positive integers. Such graphs are therefore called "power graphs" and are denoted by $G(r^s)$.

Each vertex is labelled with s symbols from the set of the first r positive integers. The order of these symbols is important. No two vertices may have the same label. It results that the total number of vertices is[12a] the s-permutation with unrestricted repetition of r objects, i. e. $p = r^s$.

Two vertices are adjacent *iff* they differ by one and only one digit in the same position of the label. The resulting graph is therefore regular of degree $d = (r-1)s$. From the formula $2q = pd$ one obtains: $2q = s(r-1)r^s$.

According to this definition, all graphs $G(r^1)$ are the complete graphs K_r. They represent the set of chemical species which can be formed by substitution at one site with $r-1$ reagents, e. g. the interconversions of alkyl halides when there are r different halide anions present (including the one from the initial alkyl halide).

Whenever possible, graphs in the following enumerations will be presented so as to evidence Hamiltonian circuits.

1.1. Power graphs with $r=2$

These graphs with 2^s vertices, labelled with r symbols from a binary set (in our case, digits 1 and 2) are the well-known s-cubes.[2] Their degree is s. In combinatorics, such graphs are also encountered as the set of binary words of length s. Such graphs are presented in the first column of table 1, and in figure 1. They can be formed by a recurrence relationship: from a pair of graphs $G(2^{s-1})$ one obtains a graph $G(2^s)$ by linking pairwise corresponding vertices, i. e. each graph $G(2^s)$ has two identical vertex-disjoint subgraphs $G(2^{s-1})$.

Such graphs represent substitution at s non-equivalent sites by $r-1 = 1$ reagent, e. g. the chlorination of $R_2CH-CHR'-CHR''_2$ is represented by the 3-cube $G(2^3)$: there are $s=3$ reaction sites, and $r = 2$ reagents (H and Cl).

1.2. Power graphs with $r=3$

Such graphs have not been discussed previously. Their orders and degrees are presented in the second column of table 1. They have 3^s vertices and even degrees $d = 2s$. Also in this case a recurrent procedure for the construction of these graphs is apparent : each graph $G(3^s)$ consists of three $G(3^{s-1})$ subgraphs (figure 2).

Graph $G(3^2)$ is 1-unitransitive [2] and the order of its symmetry group is 72. Each of its nine vertices is common to two edge-disjoint three-circuits ; this property can be generalized to all $G(3^s)$ graphs by stating that each of their vertices is common to s edge-disjoint three-circuits. The topological representation of intramolecular rearrangements of octahedral complexes *via* digonal twists, disregarding enantiomerism,[13] con-

sisted in a graph $G(3^2) + K_{3,3}$. The same graph $G(3^2)$ describes conformational interconversions of the nine possible conformers of propane :[13a] the notation of vertices in this case results by assigning digits 1, 2, and 3 to the three torsion energy minima of the $C_1 - C_2$ and $C_2 - C_3$ bonds of propane. The obvious generalization is that graphs $G(3^{n-1})$ describe conformational interconversions of alkanes C_nH_{2n+2}.

An example of substitution belonging to this case is the alcoholysis of 1,2-dichloropropane in a mixture of ethanol and methanol, which is represented by $G(3^2)$: there are $s=2$ reaction sites and $r=3$ reagents (Cl, OMe, OEt).

1.3. Power graphs with $r=4$

Graphs $G(4^s)$ are presented in the third column of table 1, and in figure 3. Graph $G(4^2)$ is not isomorphic with $G(2^4)$, though both have 16 vertices, because their degrees are different. Since the system of equations

$$r_1^{s_1} = r_2^{s_2}$$

$$s_1(r_1 - 1) = s_2(r_2 - 1)$$

has no integer solutions greater than 1, no two power graphs with different r (hence s) are isomorphic.

Again, $G(4^s)$ has four subgraphs $G(4^{s-1})$. As a chemical example for $G(4^2)$ we could consider the reaction of 1,2-dichloropropane with a mixture of three different alcohols.

1.4. Power graphs with $r=5$

Figure 4 presents graphs $G(5^1)$, i.e. Kuratowski's K_5,[14] and $G(5^2)$ which contains five K_5 subgraphs.

1.5. Conclusions about power graphs

The following three conjectured theorems are presented without proof :

(i) Every power graph $G(r^s)$ consists of r vertex-disjoint subgraphs $G(r^{s-1})$.

(ii) Power graphs $G(r^s)$ are Hamiltonian. In all figures 1—4, Hamiltonian circuits were presented for power graphs.

(iii) The order of the symmetry group of power graphs $G(r^s)$ is $s!\,(r!)^s$.*

---

* This formula was found by Dr. R. W. Robinson from the Department of Mathematics of the University of Michigan, Ann Arbor, in April 1973.

2. THE EQUIVALENT CASE

When the structure of the species undergoing substitution is such that at all stages of the substitution, all sites are chemically equivalent, the order of the r symbols in the label of each vertex is no longer to be heeded. Examples of such reactions are substitutions of R_2CH_2, R_2CCl_2, BCl_3, cyanuryl chloride; when ignoring enantiomerism, one can add CH_4, CCl_4, RCH_3, PCl_3, $POCl_3$; when the substitution is accompanied by fast pseudorotations, one can add also PCl_5. It can be seen that the number of reaction sites is limited in this case by the necessary high symmetry. In the following, we shall consider 6 as the upper limit for both r and s.

Each of the p vertices of the graph is labelled with s symbols from the set of the r first positive integers (in practice, these digits are arranged in increasing numerical order, but the order is irrelevant); two vertices are adjacent *iff* they differ by one and only one digit of the label. The resulting graph will no longer be regular: its p vertices are partitioned into $p_{(d_i)}$ vertices of degree d_i. The following formulas can be deduced, expressing the total number of vertices, p, as combinations with repetition[12b]:

$$p = \binom{r+s-1}{s} = \frac{(r+s-1)!}{s!\,(r-1)!}$$

$d_i = (r-1)\,l_i$, l_i being the number of different symbols in the label of vertex i, with the limitations $1 \leqslant l_i \leqslant \min(r, s)$.

$$q = 1/2 \sum_i d_i \cdot p_{(d_i)}$$

The partition of the total number of vertices $p = \sum_i p_{(d_i)}$ into sets of vertices with the same degree follows the Vandermonde convolution formula[12c]:

$$\binom{r+s-1}{s} = \sum_{k=0}^{\min(r-1,\, s-1)} \binom{s-1}{s-k-1}\binom{r}{k+1}$$

Therefore these graphs will be called "convolution graphs" and will be denoted by $H(r^s)$. Graphs $H(r^s)$ can be considered as derived from power graphs $G(r^s)$ whose vertices possessing labels which differed only in the order of their digits collapsed into one vertex.

The numbers p of vertices, q of edges, and vertices $p_{(d_i)}$ of degree d_i as a function of r and s (with the limitations $1 \leqslant r \,\&\, s \leqslant 6$) are presented in table 2 which was computer-printed by a specially-devised computer program PASREG (PArallel Substitution REaction Graphs) written in COBOL.

It is easily seen that for $s = 1$, $G(r^1) = H(r^1) = K_r$, i. e. the complete graphs of order r, because there is no ordering when there is just one symbol.

2.1. Convolution graphs with $r=2$

These graphs $H(2^s)$ are simple paths with two end-points of degree one, and $s-1$ points of degree two. For instance, the graph describing the chlorination of methane has five points, with methane and carbon tetrachloride as the endpoints, and with methyl chloride, dichloromethane and chloroform as the points of degree two.

2.2. Convolution graphs with $r=3$ and 4

Figure 5 represents graphs $H(3^s)$ for $s = 2$, 3, and 4. As it may be seen, all these graphs are planar [2] triangulated graphs which possess Hamiltonian circuits. Graph $H(3^3)$ has ten vertices and can represent the reaction of boron trichloride with a mixture of ethanol and methanol, or the reaction of cyanuryl chloride with a mixture of two aromatics or primary amines.

Graphs $H(4^2)$ and $H(4^3)$ are presented in figure 6.

3. THE MIXED CASE

No general treatment of the mixed case can be indicated, therefore no general notation of the vertices is available : the notation must indicate both the number and the position of the substituents, therefore the usual chemical nomenclature will be applied. Most graphs corresponding to this case will be irregular.

Employing Pólya's theorem,[2] the numbers of isomers resulting from various substitution reactions can be calculated, e. g. those formed in the halogenation or hydrogen isotopic exchange of ethane, propane, benzene or toluene, resulting in a configuration-counting series.[15, 16] The cycle index of the molecule M determines these numbers of isomers.

To construct the graph of the substitution of such molecules, we shall join by edges those vertices which correspond to species derived from one another by an elementary substitution act (displacement by one reagent at one site). Such graphs will be denoted by $L(r^s, M)$, indicating by M which molecule (hence, cycle index) is involved.

3.1. Systems with initially equivalent sites

Thus, though in both ethane and benzene there are six hydrogens which can be gradually substituted by deuterium, the resulting graphs are different : $L(2^6, \text{benzene}) \neq L(2^6, \text{ethane})$. These two graphs are illustrated in figure 7, where the vertices without a label represent the hydrocarbons, and the other vertices in the usual chemical nomenclature the structure of the substitution (e. g. deuteration, chlorination) products.

Fig. 5. — Convolution graphs H(3^s) for s = 2, 3, and 4.

For $s = 3$, the numbers increase markedly, e. g. L(3^6, benzene) has 92 vertices, and L(3^6, ethane) has 55 vertices. These numbers of vertices result from the summation of appropriate terms in the coefficients of configuration counting series. Thus, the last figure for benzene results by summing all coefficients of $Z(D_{6h}, 1 + x_1 + x_2)$ exemplifying[16] the isomerism of benzene labelled with ^{13}C and ^{14}C.

Fig. 8. — Graphs for substitution with one added reagent of trigonal-bipyramidal and of octahedral complexes.

Figure 8 represents the graphs of substitution by one added reagent (i. e. $r = 2$) of trigonal-bipyramidal and octahedral complexes, ignoring enantiomerism: in both cases, stereochemical rigidity is, however, assumed by forbidding pseudorotations. Notations in the former case indicate how many axial (a) and equatorial (e) sites were substituted; in the latter case, figures indicate how many octahedral sites are substituted when only one isomer is possible; when two isomers are possible, they are indicated by letters E and Z relatively to a first substituent (the total number of substituents being greater by 1 than the number of letters E and/or Z).

L(3^4, hydrazine)

Fig. 9. — Graphs for substitution of hydrazine with one or two types of added reagents.

Figure 9 represents two graphs for hydrazine, namely L(2^4, hydrazine) with a self-explanatory notation indicating the number and location of the substituents of one type, and L(3^4, hydrazine) where two different types of substituents, x and y, are considered.

3.2. Systems with initially partly equivalent sites

As a last example we shall discuss systems whose initial molecules have some equivalent and some non-equivalent reaction sites. We shall confine ourselves to systems $H_mX - YH_n$ with $s = m + n$ sites. The m hydrogens are equivalent, and so are the n hydrogens, but X is different from Y, therefore substituents bonded to X are not equivalent to those bonded to Y.

Notations employed in figure 10 have digits 1, 2, ..., r for the reagents (including the substituent in the initial molecule). The s sites are partitioned by a fraction line into two groups, namely the m sites of atom X as the numerator, and the n sites of atom Y as the denominator of the fraction. Arbitrarily, whenever $m \neq n$, the larger number of sites was placed in the numerator. The notation for graphs $L(r^s, H_mX - YH_n)$ will be simplified for this case to $L(r^{m+n})$.

For substitution by one added reagent, e. g. deuteration of H_mX-YH_n, we obtain graphs $L(2^{m+n})$ which are "chequered $(m+1)(n+1)$ rectangles" identical to the Cartesian products [2] of two simple paths $H(2^m)$ and $H(2^n)$ with $m+1$ and $n+1$ vertices, respectively. Dubois and Panaye's graph [10] is $L(2^{3+2})$, presented in fig. 10A.

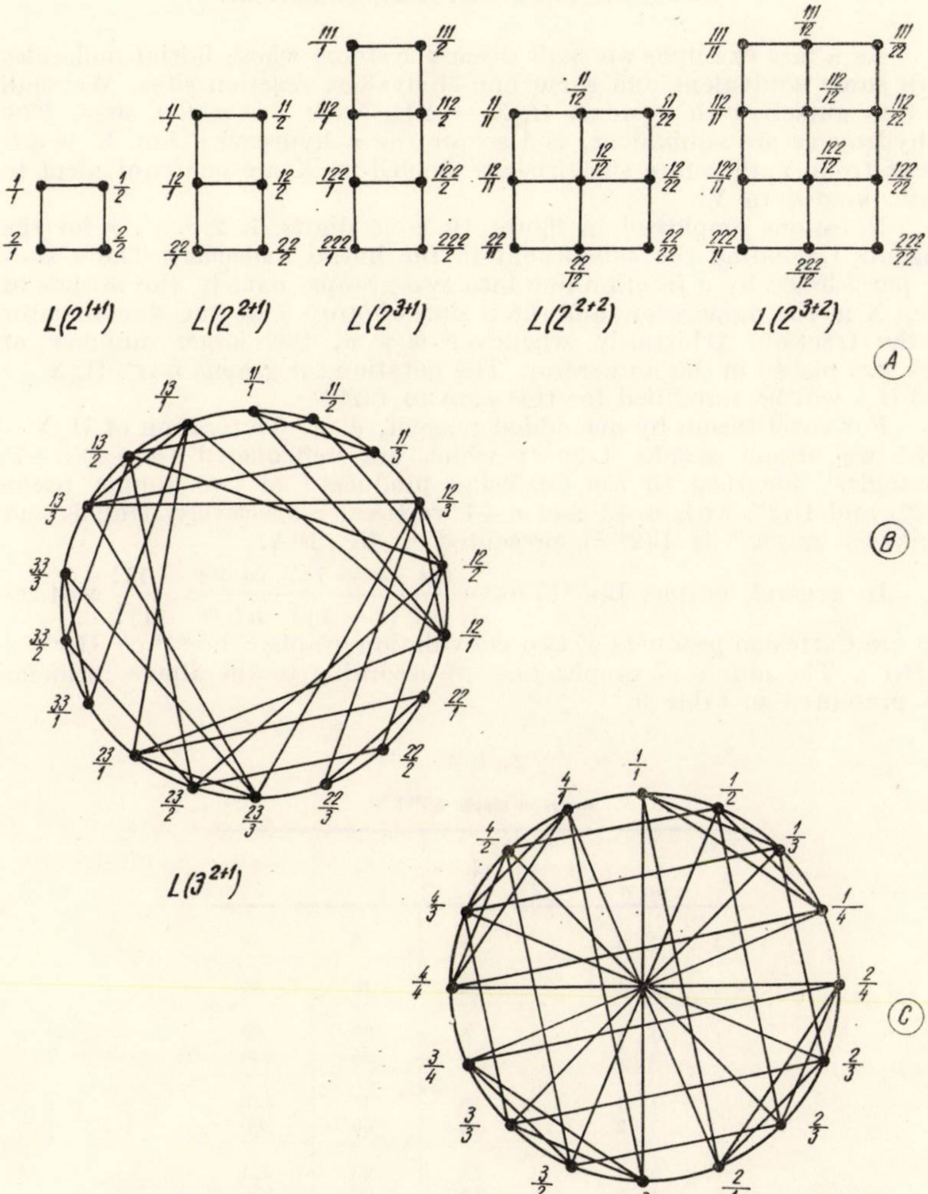
In general, graphs $L(r^{m+n})$ have $\dfrac{(m+r-1)!}{m!\,(r-1)!}\cdot\dfrac{(n+r-1)!}{n!\,(r-1)!}$ vertices and are Cartesian products of two convolution graphs : $L(r^{m+n}) = H(r^m) \times H(r^n)$. The orders of graphs $L(r^{m+n})$ according to the above formulas are presented in table 3.

Table 3

Orders of graphs $L(r^{m+n})$

s	r m n	2	3	4
2	1 1	4	9	16
3	2 1	6	18	40
4	3 1	8	30	80
	2 2	9	36	100
5	4 1	10	45	140
	3 2	12	60	200
6	5 1	12	63	224
	4 2	15	90	350
	3 3	16	100	400

For instance, $L(3^{1+1}) = H(3^1) \times H(3^1) = G(3^2)$; the isomorphism of $L(3^{1+1})$ and $G(3^2)$, or of $L(2^{1+1})$ and $G(2^2)$, originates in the non-equivalence of the two hydrogens in HX−YH with $m = n = 1$. This is general



$L(2^{1+1})$
$L(2^{2+1})$
$L(2^{3+1})$

A
B
$L(3^{2+1})$
C
$L(4^{1+1})$

Fig. 10. — Graphs $L(r^{m+n})$ for substitution of H_mX-YH_n with $r=2$, 3, or 4.

for all graphs $L(r^{1+1}) = G(r^2)$ and is illustrated by a presentation of $L(4^{1+1})$, isomorphic to $G(4^2)$ (notwithstanding the apparent difference between fig. 3 and fig. 10C).

The partition of degrees $p = \sum_i p_{(d_i)}$ for graphs $L(r^{m+n})$ is described by the product of two Vandermonde convolution formulas for the two graphs $H(r^m)$ and $H(r^n)$:

$$\frac{(m+r-1)!}{m!\,(r-1)!}\cdot\frac{(n+r-1)!}{n!\,(r-1)!} =$$

$$= \sum_{j=0}^{r-1}\binom{m-1}{m-j-1}\binom{r}{j+1}\cdot\sum_{k=0}^{r-1}\binom{n-1}{n-k-1}\binom{r}{k+1}$$

Thus, in general the properties of graphs representing substitutions depend on r, s, and on the cycle index of the molecule undergoing substitution : with particular forms of the cycle index we discussed separately the totally equivalent and non-equivalent cases.

BENZIMIDAZOLIUM-YLURES. I

L'ACTION DES ACÉTYLÈNES ACTIVÉS SUR QUELQUES BENZIMIDAZOLIUM-YLURES

ION ZUGRĂVESCU, JEAN HERDAN et ION DRUȚĂ

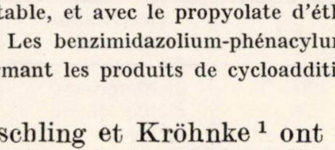
Laboratoire de Chimie organique,
Université «Al. I. Cuza», Jassy, 11, str. 23 August

Reçu le 31 juillet 1973

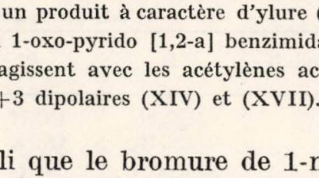
On a étudié les réactions des benzimidazolium-ylures obtenus « in situ » par élimination d'acide bromhydrique, à partir des sels respectifs, avec des philodiènes acétyléniques. La réaction des benzimidazolium-carbétoxyméthylures avec le diméthylacétylènedicarboxylate conduit à un produit à caractère d'ylure (IX), très stable, et avec le propyolate d'éthyle à 1-oxo-pyrido [1,2-a] benzimidazole (XV). Les benzimidazolium-phénacylures réagissent avec les acétylènes activés en formant les produits de cycloaddition 2+3 dipolaires (XIV) et (XVII).

Reuschling et Kröhnke[1] ont établi que le bromure de 1-méthyl-3-(4-bromophénacyl) benzimidazolium réagit avec le chlorure de pycrile, en milieu alcalin, pour conduire à 1,3-dinitro-3-méthyl-11-(4-bromobenzoyl)-5H-benzimidazo[2,1-a]isoindole, par l'intermédiaire du 1-méthylbenzimidazolium-*p*. broophénacylure.

Des benzimidazolium-ylures ont été récemment mis en évidence par Ogura et Kikuchi,[2] en traitant les bromures correspondants par le carbonate de potassium en diméthylformamide. Les ylures obtenus « in situ » réagissent avec le propyolate d'éthyle conduisant au pyrrolo [1,2-a] benzimidazole. La réaction du 1-méthylbenzimidazolium-carbéthoxyméthylure avec le diméthylacéthylènedicarboxylate (DMAD) conduit[2] à un mélange de deux produits : le cycloadduct normal (I) et le 1-oxo-pyrido[1,2-a]benzimidazole (II)



I



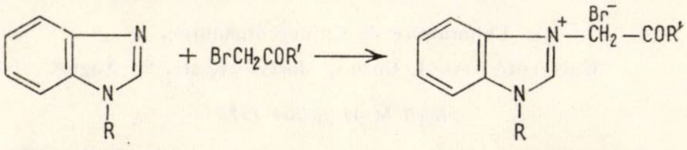
II

D. B. Reuschling et F. Kröhnke, *Chem. Ber.*, **104**, 2103 (1971).
[2] H. Ogura et K. Kikuchi, *J. Org. Chem.*, **37**, 2679 (1972).

Pour expliquer la formation du produit (II) les auteurs proposent un mécanisme réactionnel, qui admet l'apparition d'un intermédiaire non isolable, qui par décyclisation et élimination d'alcool conduit à (II).

Ces résultats nous ont déterminé à étudier le comportement d'autres benzimidazolium-ylures vis-à-vis des acétylènes activés.

Les benzimidazolium-ylures, que nous avons étudiés ont été préparés par la méthode « du sel ». Les benzimidazoles 1-alcoyl substitués réagissent avec les esters de l'acide bromoacétique et avec le bromure de phénacyle, en solution benzénique et il en résulte les bromures correspondants (IV) (tableau 1)



III a ; $R=CH_2C_6H_5$

c ; $R=CH_2C_6H_5$; $R'=C_6H_5$
d ; $R=CH_3$; $R'=OC_2H_5$

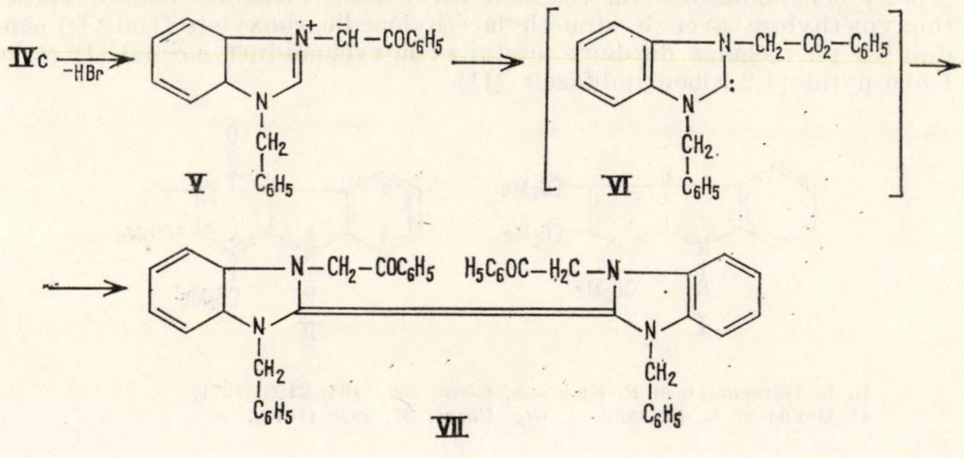
Tableau 1

Sels quaternaires de benzimidazolium (IV)

Produit	*R*	*R'*	P.f.	Recristallisé dans du :	Rend.
IVa	$CH_2C_6H_5$	OC_2H_5	170–2°	dichloréthane	77 %
IVb	$CH_2C_6H_5$	OCH_3	152–4°	dichloréthane	86 %
IVc	$CH_2C_6H_5$	C_6H_5	211–2°	méthanol	80 %
IVd	CH_3	OC_2H_5	85–7°	dichloréthane	83 %

Leur structure a été confirmée par les analyses chimiques et par les spectres IR et RMN (tableau 2).

Le spectre RMN du produit (IVc) révèle, à part l'existence du bromure, celle de l'ylure correspondant et d'un dimère à double liaison éthylénique. L'ylure (V) se formerait par élimination spontanée d'acide bromhydrique, tandis que le dimère (VII) prendrait naissance à partir du carbène (VI), formé de l'ylure par suite de transfert de proton



Cette supposition est suggérée par la présence des 3 singulets dans la région de résonance du groupement méthylène benzylique, qui pourraient être attribués aux 3 produits existants dans le mélange.

En comparaison d'autres carbalcoxy-méthylures,[3-5] les benzimidazolium-carbalcoxyméthylures (VIII) sont beaucoup moins stables, ce qui nous a déterminé à effectuer les réactions de cycloaddition « in situ ».

Tableau 2

Analyses chimiques et spectres IR et RMN des produits (IV)

Produit	Analyses chimiques		$\nu_{C=O}$ cm^{-1}	RMN
	Calculé	Trouvé		
IVa	C 57,55 % H 5,07 % N 7,46 %	57,64 4,92 7,81	1760	($CDCl_3$) : triplet $\delta = 1,31$ (3H) CH_3 du groupement éthyle estérique ; quartet $\delta = 5,82$ (2H) CH_2 du groupement éthyle estérique ; singulet $\delta = 5,91$ (2H) CH_2 benzylique ; multiplet $\delta = 7,30-7,92$ (9H) protons aromatiques ; singulet $\delta = 11,71$ (1H) H de la position 2
IVb	C 56,50 % H 4,71 % N 7,55 %	56,82 4,57 8,21	1760	
IVc	C 64,90 % H 4,67 % N 6,89 %	65,61 5,03 7,26	1680	(DMSO) : singulet $\delta = 5,18$ (2H) CH_2 lié de N^+ ; singulet $\delta = 5,82$; 5,94 ; 6,05 (2H) CH_2 benzylique ; multiplet $\delta = 7,22 - 8,45$ (14H) protons aromatiques ; singulet $\delta = 10,27$ (1H) H de la position 2
IVd	C 48,20 % H 5,01 % N 9,36 %	48,36 5,16 9,50	1755	($CDCl_3$) : singulet $\delta = 4,36$ (3H) CH_3 de la position 1 ; triplet $\delta = 1,34$ (3H) CH_3 du groupement éthyle estérique ; quartet $\delta = 4,15-4,53$ (2H) CH_2 du groupement éthyle estérique ; singulet $\delta = 5,82$ (2H) CH_2 lié de N^+ ; multiplet $\delta = 7,50-8,20$ (4H) protons aromatiques ; singulet $\delta = 11,24$ (1H) H de la position 2

Ainsi, les bromures de méthylcarbalcoxy-benzimidazolium (IVa, b, d), dans du benzène ou de l'acétonitrile anhydre, en présence de triéthylamine, réagissent avec le DMAD en formant un seul produit de réaction.

Dans le spectre RMN du composé résulté (IX) on observe l'absence des signaux correspondant aux groupements éthyle et respectivement méthyle estériques. Ces données, et aussi le fait que, indifféremment de l'ylure intermédiaire (VIIIa) ou (VIIIb), on obtient le même produit, montrent que pendant la réaction a lieu l'élimination d'une molécule d'alcool éthylique, respectivement méthylique. On peut supposer pour

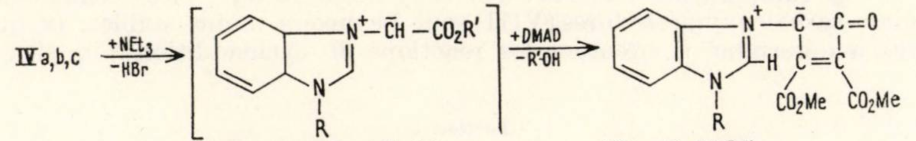
[5] I. Zugrăvescu, M. Petrovanu, M. Caproşu et I. Druţă, *Rev. Roumaine. Chim.*, **17**, 397 (1972).

les produits de réaction deux structures : une structure similaire à (II) ou une structure à caractère d'ylure (IX)

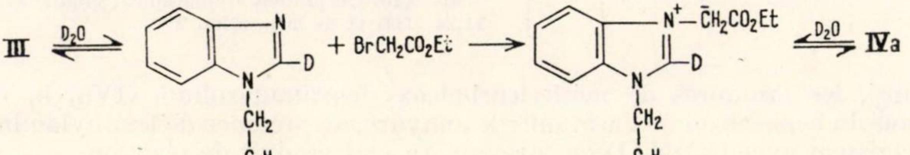


VIII a; $R=CH_2C_6H_5$; $R'=C_2H_5$
b; $R=CH_2C_6H_5$; $R'=CH_3$ c; $R=CH_3$; $R'=C_2H_5$

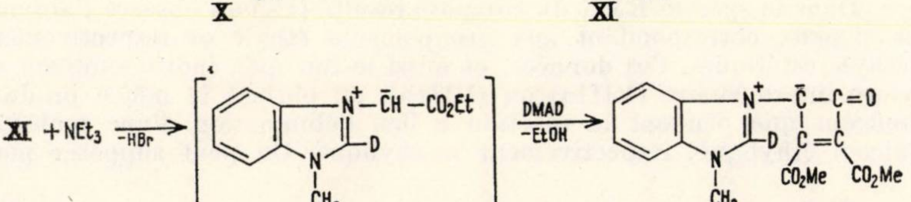
IX a; $R=CH_2C_6H_5$
b; $R=CH_3$

Le composé (II), obtenu par Ogura et Kikuchi [2] a le même point de fusion et le même spectre IR que le composé (IXb) isolé par nous. Dans le spectre RMN à $\delta = 8{,}21$ ppm les auteurs cités [2] trouvent un doublet, pendant que nous avons trouvé un singulet. Ce doublet est attribué par eux au proton aromatique de la position 6 dans la structure (II). En tenant compte que les autres protons aromatiques apparaissent à $\delta = 7{,}50$ ppm, la structure (II) ne peut pas expliquer un déplacement de 0,71 ppm du signal de ce proton. Il est toujours difficile à expliquer la différence de 30 cm^{-1} entre les deux maxima IR correspondant aux vibrations des groupements carbonyles estériques. Le singulet trouvé par nous à $\delta = 8{,}21$ a été attribué au proton de la position 2 du cycle benzimidazolique.

Pour prouver que le produit de réaction entre l'ylure (VIIIa) et le DMAD correspond à la structure (IX), proposée par nous, on a substitué l'hydrogène de la position 2 du cycle benzimidazolique par le deutérium. Le 1-benzyl-2D-benzimidazole (X) traité par le bromoacétate d'éthyle conduit au sel de benzimidazolium deutéré (XI). Le même produit (XI) peut être obtenu par deutération directe du sel (IVa)



X XI

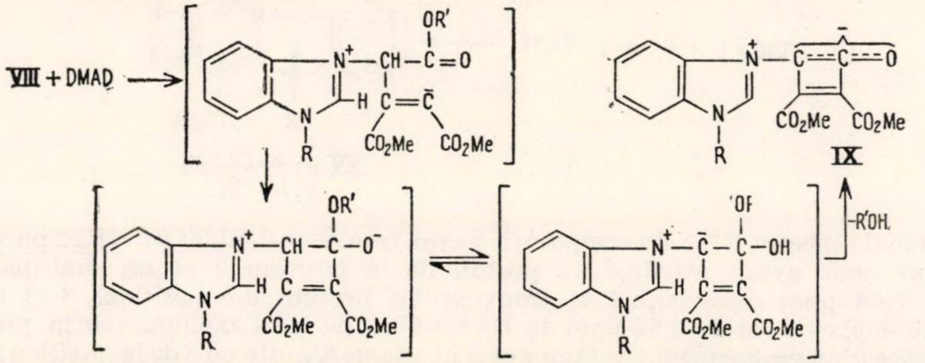


XII

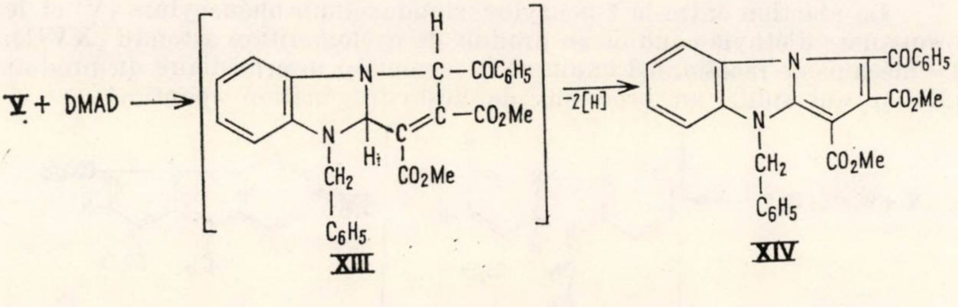
Les spectres RMN du benzimidazole (X) et du bromure (XI) présentent un amoindrissement d'environ 50% des signaux correspondant aux protons de la position 2, pendant que tous les autres signaux restent non modifiés. Ces faits nous indiquent que, dans les conditions expérimentales utilisées par nous, seulement le proton de la position 2 subit l'échange partiel avec le deutérium.

Le bromure de benzimidazolium (XI), dans de l'acétonitrile, en présence de triéthylamine, réagit avec le DMAD conduisant au composé (XII). Dans le spectra RMN de ce produit (XII) le singulet de 8,21 ppm, que nous avons attribué, par différence des auteurs cités, [2] au proton de la position 2 du cycle benzimidazolique présente, conformément à l'intégrale, un amoindrissement de 50%. Cela prouve que ce proton ne s'élimine pas, comme on le prétend dans le travail cité. [2] En conséquence l'élimination d'alcool implique un autre proton, fait qui infirme la structure proposée (II). En outre, la bande de 1200 cm^{-1}, qui appartient à la vibration de déformation C—H et qu'on trouve dans les spectres IR des benzimidazoles (III) et aussi dans le spectre IR du composé (IX) est déplacée dans le spectre IR du produit (XII) à 875 cm^{-1}. Le rapport 1200/875 correspond à la valeur 1,35 trouvée dans d'autres cas [6] pour le rapport ν_{C-H}/ν_{C-D}.

En tenant compte des faits expérimentaux mentionnés plus haut on peut supposer pour la formation du produit de structure (IX) le mécanisme réactionnel suivant:



Par différence de (VIIIa, b, c) le 1-benzylbenzimidazolium-phénacylure (V) réagit avec le DMAD d'après le schéma d'une cycloaddition 2+3 dipolaire, conduisant au pyrrolo[1, 2-a]benzimidazole (XIV)



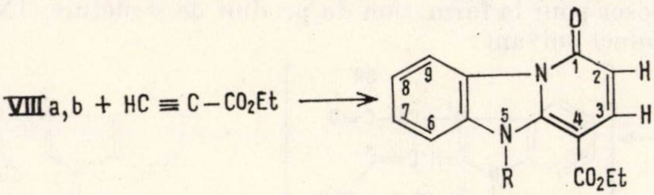
---

[6] L. A. Kazitzyna et N. B. Koupletskaya, «Primenenie UF—, IK— i YaMR spektroskopij v organicheskoj khimij», Vyschaya Shchola, Moskwa, 1971, p. 214—234.

Dans une première phase se forme le composé non isolable (XIII), qui subit un processus de déshydrogénation sous l'influence de l'oxygène atmosphérique ou d'une partie de DMAD. Dans le spectre RMN apparaissent seulement les deux signaux des groupements CH_3 estériques à 3,30 et à 3,72 ppm, le groupement méthylène benzylique à 5,72 ppm et les signaux des protons aromatiques.

La différence de comportement de ces deux ylures (V) et (VIII) dans la réaction avec le DMAD s'explique par la difficulté d'élimination d'une molécule de benzène dans le cas de l'ylure (V), qui réagit donc d'après le schéma habituel.

La réaction entre le 1-benzylbenzimidazolium-carbéthoxy-méthylure (VIIIa) et le propyolate d'éthyle prend un cours différent de celui indiqué dans la littérature. [2] Ainsi, on obtient le même produit (XV) dans la réaction du propyolate d'éthyle, soit avec du 1-benzylbenzimidazolium-carbéthoxyméthylure (VIIIa), soit avec du 1-benzylbenzimidazolium-carbométhoxyméthylure (VIIIb). L'analyse des spectres IR et RMN indique pour (XV) une structure de 1-oxo-pyrido[1, 2-a]benzimidazole

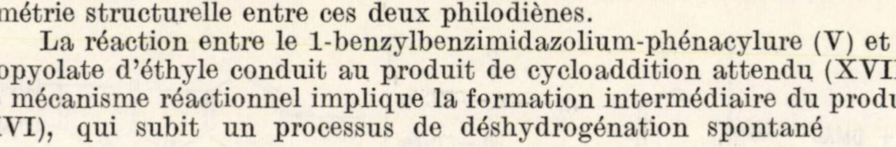


XV a; $R=CH_2C_6H_5$
b; $R=CH_3$

Dans le spectre RMN du composé (XVa) on trouve un doublet à $\delta=8,22$ ppm, que nous avons attribué au proton de la position 2 et un multiplet à 7,68 ppm dans lequel se trouvent les protons des positions 3 et 6. Le déplacement de 0,54 ppm du H^2 vis-à-vis de H^3 s'explique par la présence d'un groupement C=O en α et d'un atome d'azote en β de la position 2.

Comme dans d'autres cas, [7] on observe aussi pour les benzimidazolium-ylures une différence de comportement entre le propyolate d'éthyle et le DMAD, qui peut être attribuée à la différence de réactivité et de symétrie structurelle entre ces deux philodiènes.

La réaction entre le 1-benzylbenzimidazolium-phénacylure (V) et le propyolate d'éthyle conduit au produit de cycloaddition attendu (XVII). Le mécanisme réactionnel implique la formation intermédiaire du produit (XVI), qui subit un processus de déshydrogénation spontané



XVI XVII

---

[7] C. Leonte, *Thèse de doctorat*, Univ. «Al. I. Cuza », Iaşi, 1972.

La structure (XVII) est soutenue par les spectres IR et RMN. Le proton de la position 2 apparaît à 8,95 ppm et dans le spectre IR on trouve le groupement carbonyle estérique à 1702 cm^{-1} et le groupement carbonyle cétonique à 1630 cm^{-1}.

PARTIE EXPÉRIMENTALE

Le 1-benzylbenzimidazole a été préparé par l'alcoylation du benzimidazole avec du chlorure de benzyle selon la méthode de Reddy et Rao [8] et le 1-méthylbenzimidazole selon la méthode de Pojarskii et Simonov. [9]

Modé opératoire général de la préparation des sels quaternaires de benzimidazolium (IV)

On dissout 0,05 moles de benzimidazole dans 100 cm^3 de benzène anhydre et on ajoute 0,05 moles de dérivé halogéné. Le mélange est maintenu pendant 5 jours à la température ambiante. On filtre le sel formé, on lave sur le filtre avec un peu de benzène et on le recristallise dans un solvant approprié (tableau 1). Les analyses chimiques et les spectres IR et RMN des produits se trouvent dans le tableau 2.

Réaction du DMAD avec le 1-benzylbenzimidazolium-carbéthoxy-méthylure et avec le 1-benzylbenzimidazolium--carbométhoxyméthylure (IXa)

a) 0,005 moles de bromure de 1-benzyl-3-méthylcarbéthoxy-benzimidazolium (IVa) ou de bromure de 1-benzyl-3-méthylcarbométhoxy-benzimidazolium (IVb) suspendus dans 30 cm^3 de benzène anhydre sont traités par 1,4 cm^3 de triéthylamine et 0,615 cm^3 (0,005 moles) de DMAD. Le mélange est maintenu pendant la nuit à la température ambiante et après on porte à reflux pendant 5 heures. On filtre la solution benzénique, le benzène est distillé sous pression réduite et le résidu est recristallisé dans n-héxane et dans du dichloréthane. Cristaux blancs fusibles à 258–9°. Rend. 12%.

b) On dissout 1,9 g (0,005 moles) du produit (IVa) ou (IVb) dans 20 cm^3 d'acétonitrile anhydre et on ajoute 1,4 cm^3 de triéthylamine et 0,615 cm^3 de DMAD. On porte la solution à reflux pendant 3 heures. Après le refroidissement de la solution, le produit insoluble dans l'acétonitrile est recristallisé dans du dichloréthane. On obtient (IXa) en rendement de 14%.

Analyses $C_{22}H_{18}N_2O_5$:

Calculé : C 67,60 ; H 4,61 ; N 7,18%

Trouvé : C 67,81 ; H 4,58 ; N 7,47%

Spectre IR : 1720 cm^{-1}, 1760 cm^{-1} $\nu_{C=O}$ estérique ; 1670 cm^{-1} $\nu_{C=O}$ cétonique.

Spectre RMN ($CDCl_3$) : singulet $\delta = 3{,}82$ (3H) CH_3 estérique ; singulet $\delta = 3{,}97$ (3H) CH_3 estérique ; singulet $\delta = 5{,}39$ (2H) CH_2 benzylique ; multiplet central $\delta = 7{,}29$ (8H) protons aromatiques ; multiplet $\delta = 7{,}50-7{,}75$ (1H) H de la position 7 ; singulet $\delta = 8{,}175$ (1H) H de la position 2.

Réaction du DMAD avec le 1-méthylbenzimidazolium-carbéthoxyméthylure (IXb).

On suspend 1,09 g (0,005 moles) de bromure de 1-méthyl-3-méthylcarbéthoxy-benzimidazolium (IVd) dans 30 cm^3 de benzène anhydre et on ajoute 1,4 cm^3 de triéthylamine et

0,615 cm^3 de DMAD. Du mélange réactionnel on obtient le produit (IXb) de la manière décrite plus haut. P. f. 255—7°. Rend. 10%.

Analyses $C_{16}H_{14}N_2O_5$:

Calculé: C 61,10 ; H 4,46 ; N 8,92%

Trouvé: C 61,24 ; H 4,28 ; N 9,15%

Spectre IR : 1725 cm^{-1}, 1752 cm^{-1} $\nu_{C=O}$ estérique ; 1658 cm^{-1} $\nu_{C=O}$ cétonique.

Spectre RMN ($CDCl_3$) : singulet $\delta = 3,68$ (3H) CH_3 de la position 1 ; singulet $\delta = 3,96$ (3H) CH_3 estérique ; singulet $\delta = 4,12$ (3H) CH_3 estérique ; multiplet $\delta = 7,30-8,02$ (4H) protons aromatiques ; singulet $\delta = 8,21$ (1H) H de la position 2.

1-Benzyl-2D-benzimidazole (X)

On dissout 5,02 g (0,025 moles) de 1-benzylbenzimidazole dans 40 cm^3 de dioxanne. On ajoute 3 cm^3 (0,15 moles) d'eau deutérée et on chauffe le mélange à 80°, pendant 12 heures. Après le refroidissement de la solution on distille sous vide le solvant et l'excès d'eau deutéré. Le produit obtenu est deutéré en proportion d'environ 50%.

Spectre RMN ($CDCl_3$) : singulet $\delta = 5,34$ (2H) CH_2 benzylique ; multiplet $\delta = 7,34-7,42$ (8H) protons aromatiques ; multiplet $\delta = 7,86-8,04$ (1,5H) H^6 et H^2.

Bromure de 1-benzyl-2D-3-méthylcarbéthoxy-benzimidazolium (XI)

a) Le produit (XI) résulte de la réaction entre le 1-benzyl-2D-benzimidazole et le bromoacétate d'éthyle d'après le mode opératoire général de la préparation des sels quaternaires de benzimidazolium décrit plus haut.

b) 1,9 g (0,005 moles) de bromure de 1-benzyl-3-méthylcarbéthoxy-benzimidazolium sont dissous dans 100 cm^3 de dioxanne et on ajoute 1 cm^3 (0,05 moles) d'eau deutérée. La solution est chauffée à 80° pendant 12 heures. On distille sous vide le solvant et l'excès d'eau deutéré.

Spectre RMN ($CDCl_3$) : singulet $\delta = 11,71$ (0,5H) H de la position 2 ; le reste du spectre est identique à celui du composé (IVa).

Réaction du DMAD avec le bromure de 1-benzyl-2D-méthylcarbéthoxy-benzimidazolium (XII)

On dissout 1,9g (0,005 moles) de bromure de benzimidazolium (XI) dans 20 cm^3 d'acétonitrile. On ajoute 1,4 cm^3 de triéthylamine et 0,615 cm^3 de DMAD. On procède comme pour la préparation du produit (IXa).

Spectre IR : 1760 cm^{-1}, 1719 cm^{-1} $\nu_{C=O}$ estérique ; 1667 cm^{-1} $\nu_{C=O}$ cétonique ; 875 $cm^{-1}\nu_{C=D}$.

Spectre RMN ($CDCl_3$) : singulet $\delta = 8,21$ (0,5H) H de la position 2 ; le reste du spectre est identique à celui du composé (IXa).

Réaction du DMAD avec le 1-benzylbenzimidazolium-phénacylure (XIV)

2,035 g (0,005 moles) de bromure de 1-benzyl-3-phénacyl-benzimidazolium (IVc) dans 30 cm^3 de benzène anhydre sont traités par 1,4 cm^3 de triéthylamine et 0,615 cm^3 de DMAD. Après 24 heures de repos à la température ambiante le mélange est porté à reflux pendant 3—4 heures. Après le refroidissement on filtre la solution benzénique et on chasse le solvant sous pression réduite. Le résidu est recristallisé dans du dichloréthane (XIV). Cristaux blancs, fusibles à 212–3°. Rend. 8%.

Analyses $C_{28}H_{22}N_2O_5$:

Calculé: C 72,05 ; H 4,72 ; N 6,01%

Trouvé: C 71,84 ; H 4,96 ; N 6,63%

Spectre IR : 1722 cm^{-1}, 1695 cm^{-1} $\nu_{C=O}$ estérique ; 1618 cm^{-1} $\nu_{C=O}$ cétonique.

Spectre RMN ($CDCl_3$) : singulet $\delta = 3,30$ (3H) CH_3 estérique ; singulet $\delta = 3,72$ (3H) CH_3 estérique ; singulet $\delta = 5,72$ (2H) CH_2 benzylique ; multiplet $\delta = 6,86-7,63$ (13H) protons aromatiques ; multiplet $\delta = 8,08-8,36$ (1H) H de la position 5.

Réaction du propyolate d'ethyle avec le 1-benzylbenzimidazolium-carbéthoxyméthylure ou avec le 1-benzylbenzimidazolium-carbométhoxyméthylure (XVa)

On introduit 0,005 moles de sels (IVa) ou (IVb) dans 30 cm^3 de benzène anhydre. On ajoute 1,4 cm^3 de triéthylamine et 0,49 g (0,005 moles) de propyolate d'éthyle. Le mélange est maintenu 24 heures à la température ambiante et après on porte à reflux pendant 3 heures. On filtre la solution benzénique, on distille le benzène sous pression réduite et on recristallise le résidu dans du méthanol. On obtient (XVa). Produit blanc fusible à 178–9°. Rend. 10,3%.

Analyses : $C_{21}H_{18}N_2O_3$:

Calculé: C 72,80 ; H 5,20 ; N 8,09%

Trouvé: C 73,24 ; H 4,95 ; N 8,60%

Spectre IR : 1721 cm^{-1} $\nu_{C=O}$ estérique ; 1622 cm^{-1} $\nu_{C=O}$ cétonique.

Spectre RMN ($CDCl_3$) : triplet central $\delta = 1,43$ (3H) CH_3 du groupement éthyle estérique : quartet $\delta = 4,23-4,58$ (2H) CH_2 du groupement éthyle estérique ; singulet $\delta = 5,52$ (2H) CH_2 benzylique ; multiplet central $\delta = 7,29$ (8H) protons aromatiques ; multiplet central $\delta = 7,68$ (2H) H^3 et H^6 ; doublet $\delta = 8,22$ (1H) H^2.

Réaction du propyolate d'éthyle avec le 1-méthylbenzimidazolium-carbéthoxyméthylure (XVb)

1,09 g (0,005 moles) du produit (IVd) dans 30 cm^3 de benzène anhydre sont traités par 1,4 cm^3 de triéthylamine et 0,49 g de propyolate d'éthyle. Le mélange est chauffé à reflux pendant 4–5 heures. Après le refroidissement on filtre la solution benzénique, on chasse le solvant sous vide et on recristallise le résidu dans du méthanol. On obtient des cristaux aciculaires, blancs, fusibles à 196–7° (XVb). Rend. 9%.

Analyses $C_{15}H_{14}N_2O_3$:

Calculé: C 66,66 ; H 5,19 ; N 10,04%

Trouvé: C 66,84 ; H 5,07 ; N 10,42%

Spectre IR : 1720 cm^{-1} $\nu_{C=O}$ estérique ; 1668 cm^{-1} $\nu_{C=O}$ cétonique.

Spectre RMN ($CDCl_3$) : triplet central $\delta = 1,41$ (3H) CH_3 du groupement éthyle estérique ; singulet $\delta = 3,56$ (3H) CH_3 de la position 5 ; quartet $\delta = 4,11-4,48$(2H) CH_2 du groupement éthyle estérique ; multiplet central $\delta = 7,52$ (3H) protons aromatiques ; multiplet $\delta = 7,47-7,73$ (2H) H^3 et H^6 ; doublet $\delta = 8,07$ (1H) H^2.

Réaction du propyolate d'éthyle avec le 1-benzylbenzimidazolium-phénacylure (XVII)

Un mélange formé de 2,035 g de bromure de 1-benzyl-3-phénacyl-benzimidazolium (IVc), 1,4 cm^3 de triéthylamine et 0,49 g de propyolate d'éthyle dans 30 cm^3 de benzène anhydre est porté à reflux pendant 3 heures. On filtre la solution benzénique et le résidu, obtenu après la distillation du benzène sous vide, est recristallisé dans du méthanol. Cristaux blancs, aciculaires, fusibles à 175–8° (XVII). Rend. 17%.

Analyses $C_{27}H_{22}N_2O_3$:

Calculé: C 76,75 ; H 5,21 ; N 6,64%

Trouvé: C 76,54 ; H 5,09 ; N 6,98%

Spectre IR : 1702 cm^{-1} $\nu_{C=O}$ estérique ; 1630 cm^{-1} $\nu_{C=O}$ cétonique.

Spectre RMN ($CDCl_3$) : triplet central $\delta = 1,27$ (3H) CH_3 du groupement éthyle estérique ; quartet $\delta = 4,09-4,45$ (2H) CH_2 du groupement éthyle estérique ; singulet $\delta = 6,10$ (2H) CH_2 benzylique ; multiplet $\delta = 7,22-8,00$ (14H) protons aromatiques ; multiplet $\delta = 8,95$ (1H) H de la position 2.

Les spectres RMN ont été enregistrés avec des appareils Jeol 60 Mhz et Varian 60 Mhz et les spectres obtenus ont été identiques.

BENZIMIDAZOLIUM-YLURES. II[1]

SUR LES RÉACTIONS DE QUELQUES BENZIMIDAZOLIUM-YLURES AVEC DES PHILODIÈNES

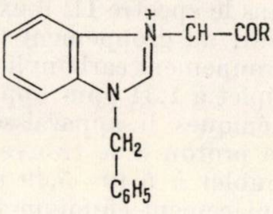
ION ZUGRĂVESCU, JEAN HERDAN et ION DRUȚĂ

Laboratoire de Chimie organique
Université « Al. I. Cuza », Jassy, 11, str. 23 August

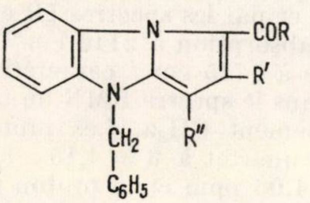
Reçu le 13 octobre 1973

Le 1-benzylbenzimidazolium-carbéthoxyméthylure (Ib) réagit avec l'acrylonitrile en formant le produit (V) de cycloaddition 2+3 dipolaire. Avec l'isocyanate de phényle les ylures (Ia) et (Ib) conduisent aux ylures carbanion-disubstitués (VIa) et respectivement (VIb), très stables. La réaction entre le 1-benzyl-2-méthylbenzimidazolium-carbéthoxyméthylure (IX) et l'isocyanate de phényle conduit au produit (XI), par suite d'un transfert 1,6 de proton.

Dans un travail précédent [1] on a présenté les réactions de cycloaddition du 1-benzylbenzimidazolium-phénacylure (Ia) et du 1-benzylbenzimidazolium-carbéthoxyméthylure (Ib) sur des acétylènes activés. L'ylure (Ia) réagit avec le propyolate d'éthyle et avec le diméthylacétylènedicarboxylate (DMAD) donnant naissance aux produits attendus (II)



I a ; $R=C_6H_5$
b ; $R=OC_2H_5$



II a ; $R=C_6H_5$, $R'=R''=CO_2Me$.
b ; $R=C_6H_5$, $R'=H$, $R''=CO_2Et$

Le 1-benzylbenzimidazolium-carbéthoxyméthylure (Ib) réagit d'une autre manière conduisant à des produits différents de ceux connus dans la littérature [2]. Dans la réaction de l'ylure (Ib) avec le DMAD on obtient un nouvel ylure stable (III) et avec le propyolate d'éthyle on obtient le 1-oxo-pyrido [1, 2-a] benzimidazole (IV)

---

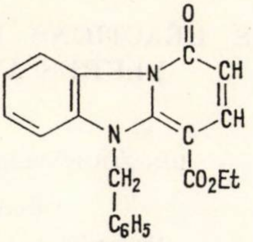
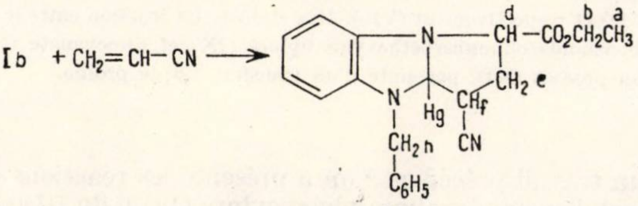
III



IV

Continuant ces recherches nous avons étudié les réactions des benzimidazolium-ylures (I) avec des philodiènes à doubles liaisons. L'ylure (Ib), obtenu « in situ » par le traitement du bromure correspondant avec de la triéthylamine, réagit en milieu de benzène anhydre avec de l'acrylonitrile, conduisant au tétrahydropyrrolo[1, 2-a]benzimidazole (V)



V

Une structure similaire a été obtenue par Froelich et Kröhnke [3] dans la série des pyridinium-ylures. La structure (V) est confirmée par l'analyse chimique et par les spectres IR et RMN. Dans le spectre IR il existe une bande d'absorption à 2140 cm^{-1} correspondant au groupement C≡N, et une autre à 1745 cm^{-1} caractéristique du groupement carbonylique estérique. Dans le spectre RMN on trouve un triplet à 1,34 ppm appartenant au groupement CH_3a. Les protons méthyléniques b apparaissent sous forme de quartet à $\delta = 4{,}15-4{,}45$ ppm. Le proton d se trouve comme triplet à 4,06 ppm et le proton f comme doublet à 5,40–5,49 ppm. Le groupement méthylène benzylique h a un déplacement chimique différent des autres cas ($\delta = 4{,}61$ ppm), fait qui indique une interaction stérique entre le groupement C≡N et le noyau benzénique qui affecte l'anisotropie de la molécule.

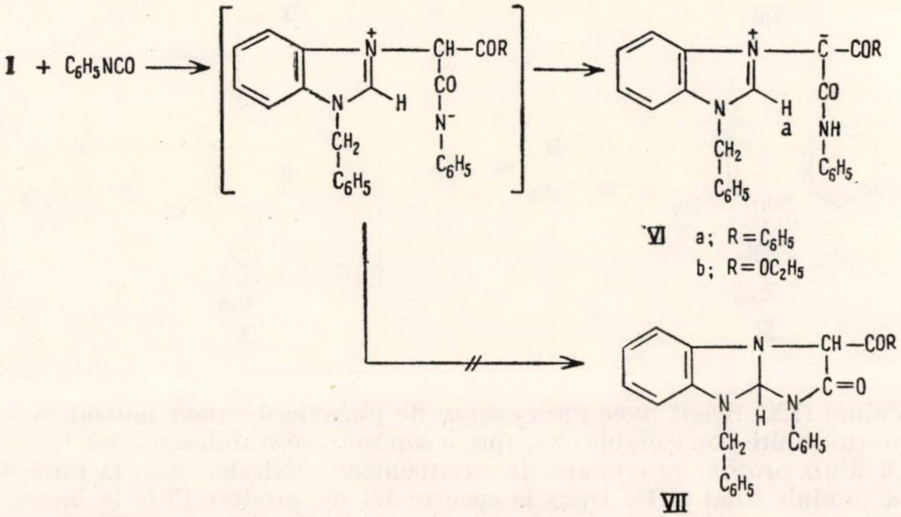
L'ylure (Ia) avec le même réactant conduit à un produit huileux à structure indéfinie.

[2] H. Ogura et K. Kikuchi, *J. Org. Chem.*, **37**, 2679 (1972).

[3] J. Froelich et F. Kröhnke, *Chem. Ber.*, **104**, 1621 (1971).

On a étudié aussi les réactions des ylures (I) avec une philodiène à double liaison carbone-azote. L'isocyanate de phényle donne avec les ylures deux types de produits de réaction. Dans certains cas [4] on a isolé les produits de cycloaddition de l'isocyanate de phényle sur l'ylure et dans d'autres cas on a obtenu un nouvel ylure carbanion-disubstitué [5].

Les 1-benzylbenzimidazolium-ylures (Ia) et (Ib) réagissent avec l'isocyanate de phényle, en milieu de benzène ou d'acétonitrile anhydre, conduisant, par transfert 1,3 de proton aux ylures (VI), très stables. On n'observe pas, dans ce cas, la réaction de cycloaddition 2+3 dipolaire et on ne peut pas isoler un produit de structure (VII)



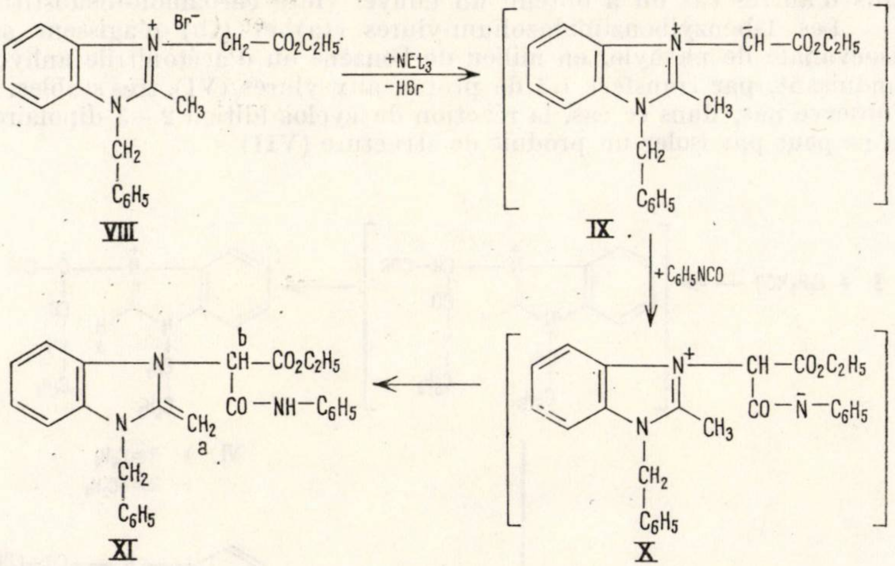
Dans le spectre IR du produit (VIa) on trouve une bande à 2950 cm^{-1} correspondant au groupement NH amidique et deux bandes à 1625 et à 1690 cm^{-1}, correspondant aux vibrations des groupements C=O cétoniques et respectivement amidiques. L'une des bandes amidiques est superposée à la bande du groupement cétonique. Le déplacement de ces bandes vers des longueurs d'onde plus élevées que leur valeur normale nous indique un amoindrissement de la constante de force de la liaison, due au voisinage de la charge anionique. Le spectre de RMN a deux signaux à $\delta = 9{,}98$ et 12,82 ppm qui disparaissent après la deutération. Ces signaux ont été attribués au NH et respectivement au proton de la position du cycle benzimidazolique. Les spectres IR et RMN du composé (VIb) sont tout à fait semblables.

---

[4] R. Huisgen, M. Morikawa, K. Herbig et E. Brunn, *Chem. Ber.*, **100**, 1094 (1967).

[5] I. Zugrăvescu, E. Rucinschi et G. Surpăţeanu, *Tetrahedron Lett.*, **12**, 941(1970).

Si dans la position 2 du cycle benzimidazolique on substitue un groupement méthyle, la réaction des ylures avec l'isocyanate de phényle prend un cours différent et il se forme le produit (XI)



L'ylure (IX) réagit avec l'isocyanate de phényle donnant naissance à un intermédiaire non isolable (X), qui, à son tour, se stabilise par un transfert 1,6 d'un proton, provenant du groupement méthyle, avec la formation du produit final (XI). Dans le spectre IR du produit (XI) la bande de 1735 cm^{-1} a été attribuée au groupement carbonylique estérique et les bandes de 1630 cm^{-1}et 1590 cm^{-1} aux deux vibrations amidiques. Les valeurs normales trouvées pour ces vibrations prouvent l'absence de la charge anionique sur l'atome de carbone. Les deplacements chimiques observés dans le spectre RMN correspondent à la structure (XI), formulée plus haut.

PARTIE EXPÉRIMENTALE

Les ylures ont été préparés « in situ », en traitant les bromures correspondant par la triéthylamine.

Réaction du 1-benzylbenzimidazolium-carbéthoxyméthylure avec l'acrylonitrile (V)

On suspend 1,9 g (0,005 moles) de bromure de 1-benzyl-3-méthylcarbéthoxybenzimidazolium dans 30 cm^3 de benzène anhydre et on ajoute 1,4 cm^3 (0,01 moles) de triéthylamine et 0,106 cm^3 d'acrylonitrile (0,005 moles). On maintient le mélange 24 heures à la température ambiante et ensuite on porte à reflux pendant 3 heures. On filtre la solution benzénique et on chasse le solvant sous pression réduite. Le résidu est recristallisé dans du *n*-hexane et puis dans de l'alcool éthylique. Le produit obtenu (V) est fusible à 108°. Rend. 18%.

Analyses $C_{21}H_{21}N_3O_2$:

Calculé : C 72,60 ; H 6,05 ; N 12,10%

Trouvé : C 72,71 ; H 6,09 ; N 12,36%

Spectre IR : 2140 cm^{-1} $\nu_{C\equiv N}$; 1745 cm^{-1} $\nu_{C=O}$.

Spectre RMN ($CDCl_3$) : triplet central $\delta = 1,34$ (3H) CH_3 a ; multiplet $\delta = 2,20-2,42$ (2H) CH_2 e ; quartet $\delta = 2,91-3,20$ (1H) CH f ; triplet central $\delta = 4,30$ (2H) CH_2 b ; singulet $\delta = 4,61$ (2H) CH_2 h ; doublet $\delta = 5,40-5,49$ (1H) H g ; multiplet central $\delta = 6,86$ (4H) protons aromatiques multiplet central $\delta = 7,52$ (5H) protons aromatiques.

Réaction du 1-benzylbenzimidazolium-phénacylure avec l'isocyanate de phényle (VIa)

2,035 g (0,005 moles) de bromure de 1-benzyl-3-phénacylbenzimidazolium dans 30 cm^3 de benzène anhydre sont traités par 1,4 cm^3 de triéthylamine et 0,6 cm^3 (0,005 moles) d'isocyanate de phényle. Le mélange est chauffé à reflux pendant 5 heures, après quoi on filtre la solution benzénique. Par évaporation partielle du benzène on obtient un produit blanc, qui recristallisé dans du méthanol est fusible à 235–8°. Les analyses chimiques et le point de fusion nous ont indiqué qu'il s'agit du N, N'-diphénylurée. Le mélange avec un échantillon original de N, N'-diphénylurée présente le même point de fusion.

On recristallise le produit insoluble dans du benzène dans du méthanol, en obtenant le produit (VIa). Cristaux blancs, fusibles à 218–9°. Rend. 12%.

Analyses $C_{29}H_{23}N_3O_2$:

Calculé : C 78,21 ; H 5,17 ; N 9,44%

Trouvé : C 78,84 ; H 5,36 ; N 9,22%

Spectre IR : 2950 cm^{-1} ν_{N-H} amidique ; 1625 cm^{-1} $\nu_{C=O}$; 1590 cm^{-1} $\nu_{C=O}$.

Spectre RMN (DMSO-D_6) : singulet $\delta = 5,67$ (2H) CH_2 benzylique ; multiplet $\delta = 6,58-8,18$ (19H) protons aromatiques ; singulet $\delta = 9,98$ (1H) deutérable NH ; singulet $\delta = 12,8$ (1H) deutérable CHa.

Réaction du 1-benzylbenzimidazolium-carbéthoxyméthylure avec l'isocyanate de phényle (VIb)

On dissout 1,9 g de bromure de 1-benzyl-3-méthylcarbéthoxybenzimidazolium dans 20 cm^3 d'acétonitrile. On ajoute 1,4 cm^3 de triéthylamine et 0,6 cm^3 d'isocyanate de phényle. On porte à reflux pendant 5 heures. On chasse sous pression réduite la moitié du solvant et on recristallise le produit obtenu dans du dichloréthane. Cristaux blancs fusibles à 210–1° (VIb). Rend. 16%.

Analyses $C_{25}H_{23}N_3O_3$:

Calculé : C 72,25 ; H 6,02 ; N 10,12%

Trouvé : C 71,54 ; H 6,21 ; N 10,50%

Spectre IR : 2980 cm^{-1} ν_{N-H} amidique ; 1625 cm^{-1} $\nu_{C=O}$ estérique ; 1600 et 1580 cm^{-1} $\nu_{C=O}$ amidique.

Spectre RMN (DMSO-D_6) ; triplet central $\delta = 0,92$ (3H) CH_3 du groupement éthyle estérique ; quartet $\delta = 3,79-4,15$ (2H) CH_2 du groupement éthyle estérique ; singulet $\delta = 5,8$ (2H) CH_2 benzylique ; multiplet $\delta = 6,84-8,04$ (14H) protons aromatiques ; singulet $\delta = 9,93$ (1H) deutérable NH ; singulet $\delta = 10,96$ (1H) deutérable CH *a*.

Bromure de 1-benzyl-2-méthyl-3-méthylcarbéthoxy-benzimidazolium (VIII)

Le produit (VIII) est obtenu à partir du 1-benzyl-2-méthyl-benzimidazole et le bromoacétate d'éthyle, d'après le mode opératoire général pour la préparation des sels quaternaires de benzimidazolium.[1] Recristallisé dans du méthanol ; P. f. 245—8°. Rend. 68 %.

Analyses $C_{19}H_{21}BrN_2O_2$:

Calculé : C 57,12 ; H 5,26 ; N 7,02 %

Trouvé : C 56,78 ; H 5,31 ; N 7,25 %

Spectre IR : 1760 cm^{-1} $\nu_{C=O}$ estérique.

Spectre RMN (DMSO-D_6) : triplet central $\delta = 1,22$ (3H) CH_3 du groupement éthyle estérique ; singulet $\delta = 2,93$ (3H) CH_3 de la position 2 ; quartet $\delta = 4,01-4,37$ (2H) CH_2 du groupement éthyle estérique ; singulet $\delta = 5,60$ (2H) CH_2 lié de N^+ ; singulet $\delta = 5,82$ (2H) CH_2 benzylique ; multiplet $\delta = 7,27-8,05$ (9H) protons aromatiques.

Réaction du 1-benzyl-2-méthylbenzimidazolium-carbéthoxyméthylure avec l'isocyanate de phényle (XI)

On introduit 1,9 g (0,005 moles) de bromure de 1-benzyl-2-méthyl-3-méthylcarbéthoxy-benzimidazolium dans 30 cm^3 de benzène anhydre. On ajoute 1,4 cm^3 de triéthylamine et 0,6 cm^3 d'isocyanate de phényle. Le mélange est maintenu pendant 5 jours à la température ambiante. On filtre la solution benzénique et on chasse le solvant sous vide. Le produit huileux obtenu est maintenu pendant 2 jours à +4° et il devient cristallin. On recristallise ce produit dans de l'éthanol (XI). Produit blanc, fusible à 181—4°. Rend. 21 %.

Analyses $C_{26}H_{25}N_3O_3$:

Calculé : C 73,37 ; H 5,85 ; N 9,83 %

Trouvé : C 73,12 ; H 6,04 ; N 10,21 %

Spectre IR : 3000 cm^{-1} ν_{N-H} ; 1735 cm^{-1} $\nu_{C=O}$ estérique ; 1630 et 1590 cm^{-1} $\nu_{C=O}$ amidiques.

THE ELECTRONIC SPECTRUM OF 1, 2, 3-TRIMETHOXYACRIDINE-N-OXIDE

M. VLASSA, MARIA IONESCU and J. FABIAN *

Institute of Chemistry, Cluj, Str. Donath 65–103, Romania
*Department of Chemistry, Technical University of Dresden,
The Democratic Republic of Germany

Received May 8, 1973

The π-electronic transitions of 1,2,3-trimethoxyacridine-N-oxide and those of the 9-chloro-substituted derivative were computed by the SCF-MO-CI (PPP) method. The calculated electronic transitions are in satisfactory agreement with the experimental data. The influence on the π-electronic transitions of acridine of three methoxy groups in vicinal position 1, 2 and 3 is compared with that of the N–O group.

1. INTRODUCTION

In connection with our current investigations on chemical and physico-chemical properties of 1,2,3-trimethoxyacridine derivatives[1,2,3] we have calculated the π-electronic transitions of 1,2,3-trimethoxyacridine N-oxide (**1**). The success of the PPP method, in spite of the rather drastic approximations involved, in computing the π-electronic structure and transitions of 1,2,3-trimethoxyacridine and acridine [3] encouraged us to extend the calculations to the N-oxide derivative.

2. METHOD AND PARAMETERS EVALUATION

The SCF-MO-CI variant of the PPP method was utilized. The SCF calculations were performed by using the Mataga-Nishimoto procedure,[4] for the two center repulsion integrals.

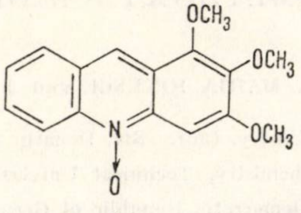
[4] K. Nishimoto and L. Forster, *Theor. Chim. Acta*, **4**, 155 (1966).

The π-electronic system of the 1,2,3-trimethoxyacridine-N-oxide (**1**) molecule consists of a number of 22 π-electrons delocalized over 17 centers. The molecule is assumed to be planar (C_s symmetry group) with an idealized overall bond distance $r_{\mu\nu}$ of 1.40 Å.



1

The parameters used are listed in table 1 and the determination of these parameters is described below.

Table 1

Parameter summary

Resonance integrals eV	One-center repulsion integrals eV	Ionization potential eV	$a_{\mu\nu}$
$\beta_{CC} = -2.38$	$\gamma_{\dot{C}\dot{C}} = 8.25$	$I_{\dot{C}} = 8.72$	1.745
$\beta_{CN} = -2.636$	$\gamma_{\dot{O}\dot{O}} = 10.60$	$I_{\dot{O}} = 13.72$	1.358
$\beta_{NO} = -2.241$	$\gamma_{\dot{N}\dot{N}} = 12.00$	$I_{\ddot{N}} = 19.22$	1.999
$\beta_{CCl} = -1.534$	$\gamma_{\ddot{O}\ddot{O}} = \gamma_{\ddot{N}\ddot{N}} = \gamma_{\ddot{Cl}\ddot{Cl}}$	$I_{\ddot{O}} = 20.72$	1.999
$\beta_{CO} = \beta_{CC}$		$I_{\ddot{Cl}} = 21.50$	1.999

For the two center repulsion integrals $\gamma_{\mu\nu}$, the Nishimoto and Mataga procedure [4] was used, as in our previous work [3] ($\gamma_{\mu\nu} = 14.397\text{eV}/a_{\mu\nu} + r_{\mu\nu}$).

The one-center repulsion integrals $\gamma_{\mu\nu}$ and ionization potentials I_μ were taken identical with those used in the calculation of the π-electronic structure of unsubstituted acridine-N-oxide. [5]

The resonance integrals $\beta_{\mu\nu}$, were derived from the π-bond order of acridine-N-oxide given by Mantsch and co-workers [5] using the following β/p relations [4]:

$$\beta_{CC} = -0.51p - 2.04 \text{ eV}$$

$$\beta_{CN} = -0.53p - 2.34 \text{ eV}$$

$$\beta_{NO} = -0.56p - 2.00 \text{ eV}$$

---

[5] H. H. Mantsch, W. Seiffert and V. Zanker, *Rev. Roumaine Chim.*, **14**, 125 (1969).

The calculations were carried out on a Elliot 503 b computer using an autocode program.

3. RESULTS AND DISCUSSION

Table 2 shows the results of our calculations in comparison to 1,2,3-trimethoxyacridine, reported in a previous paper.[3] The electronic transitions calculated for 1,2,3-trimethoxyacridine-N-oxide (**1**) are in satisfactory agreement with the experimental data.

The ultraviolet spectra of azanaphtalene N-oxides and their benzenoid homologs can be interpreted by considering the N-oxide group as a simple substituent because the larger the conjugated system in the parent heterocycles, the smaller the charge transfer character pertinent to the N-oxide group.

* Only (0 – 0′) transmisions are considered.

N-oxidation stabilizes considerably the transitions along the short axis of the parent heterocycle and the red shift of the ^1L_a band is larger than the one of the ^1L_b band.[7]

This bathochromic shift becomes evident also by comparing the experimental and calculated data of acridine and 1,2,3-trimethoxyacridine with those of acridine-N-oxide and **1** (see tables 2 and 3).

It is interesting to note (see table 4) that the bathochromic shift, of all three bands, due to the presence of vicinal methoxy groups in the acridine molecule is smaller than that produced by the N-oxide group. In a nonpolar solvent (e. g. heptane) the smaller the polarity of the molecule, the higher the degree of solvation. The polarity of these molecules increases in the following order: acridine $<$ 1,2,3-trimethoxyacridine $<$ acridine-N-oxides.[3] The excited states of acridine-N-oxides are less polar than the ground states. Consequently, there is a higher bathochromic shift in nonpolar solvents due to the N-oxide group as compared to three vicinal methoxy groups. This interpretation is also supported by the bathochromic shift of acridine derivatives compared to the hypsochromic shift of acridine-N-oxide derivatives with increasing solvent polarity.[7]

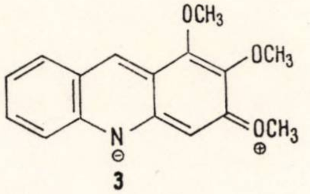
2



3

In contrast to N-oxidation, which stabilizes the transitions along the short axis of the parent heterocycle, the introduction of 3 vicinal methoxy groups stabilizes the transitions along both axes, since the structures **2** and **3** are energetically equivalent.

EXPERIMENTAL

The U.V. spectra were recorded in heptane, on a Carl Zeiss Specord spectrometer.

The 1,2,3-trimethoxyacridine, 1,2,3-trimethoxyacridine-N-oxide and 1,2,3-trimethoxy-9-chloroacridine were obtained by the methods previously reported.[1 2]

ELECTRONIC SPECTRA AND ACID-BASE EQUILIBRIUM OF SOME α-ACYLAMINO-N-HETEROCYCLES

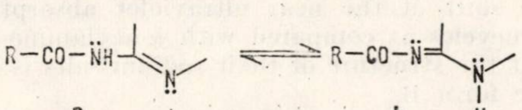
D. SUCIU and Z. GYÖRFI

Oncological Institute, Cluj, Str. Republicii 34–36, Romania

Received April 24, 1973

The formation of the sodium salts derived from α-acylamino-N-heterocycles is associated with a strong bathochromic shift of the near ultraviolet absorption band. The ionization constants indicate that the stability of the sodium salts is determined by both the electron attracting properties of the acyl group and the resonance stabilization of the exocyclic N=C bond. The later effect increases in the series: pyridines < pyrimidines < thiazoles < thiadiazoles.

α-Acylamino-N-heterocycles are capable of a vinylogous amidine type of tautomerism. On the basis of the ultraviolet spectra recorded in neutral solvents of different polarities as well as of the infrared spectra, Sheinker *et al.*[1] have shown that the imido form is stable only from the derivatives which contain acyl groups with strong electron attracting properties ($CO-CCl_3$, $CO-CF_3$ etc.). The ultraviolet absorptions of the imido tautomeric form are generally shifted to longer wavelengths as compared with those of the amido form.



In the present work we report some ultraviolet data on the formation of the sodium salts and the protonation of α-acylamino-N-heterocycles. The spectra of 2-acylamino-thiazoles, 2-acylamino-1,3,4-thiadiazoles and 2-acylamino-pyrimidines in alkaline solution show bathochromic shifts of the near ultraviolet absorption bands as compared with the spectra recorded in neutral medium (tables 1–3). This effect could be explained if we assume the formation of the corresponding sodium salts of α-acylamino-N-heterocycles. As it was elsewhere described by Brzozowski[2] such a sodium salt derived from 2-acetylamino-thiazole has been isolated from a concentrated sodium hydroxide solution. Taking into account

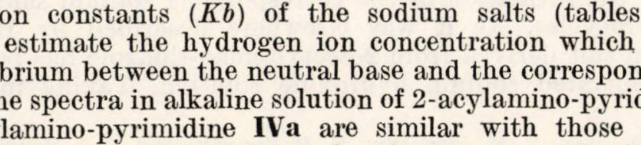
the bathochromic shift of the near ultraviolet absorption band of α-acylimino-N-heterocycles as compared with α-acylamino-N-heterocycles,[1] it is probably that the structure of their sodium salts is better described by the mesomeric form B.



The spectral properties of α-acylamino-N-heterocycles in alkaline solutions permit us the determination by spectrophotometric titration of the ionization constants (*Kb*) of the sodium salts (tables 1—3). The *pKb* values estimate the hydrogen ion concentration which corresponds to the equilibrium between the neutral base and the corresponding sodium salt. Since the spectra in alkaline solution of 2-acylamino-pyridines (**IIIa-e**) and 2-acetylamino-pyrimidine **IVa** are similar with those recorded in neutral medium, it is probably that for these compounds the formation of the corresponding sodium salts is prevented.

a) The compound is hydrolyzed during the recording of the spectrum

The results (tables 1 and 2) indicate that the stability of the sodium salts of α-acylamino-N-heterocycles is determined not only by the presence of an acyl group with strong electron attracting properties, but also by the nature of the heterocycle. From this point of view, the stability of the mesomeric form B decreases in the order thiadiazoles, thiazoles and pyrimidines. It appears that, the shift from the neutral base to the corresponding sodium salt should be the result of both the electron withdrawing effect of the acyl group which decreases the strength of the amidic N−H bond and the $p-\pi$ conjugation effect which allows the resonance stabilization of the exocyclic N=C bond. As the charge density of the ring decreases by the presence of the second nitrogen atom for thiadiazoles and pyrimidines as compared with thiazoles and pyridines, the $p-\pi$ conjugation effect is increased and allows the stabilization of the exocyclic N=C bond. The results also indicate that the mesomeric form B is more stable for the five-membered heterocycles containing the sulphur bridge, which probably enhances the resonance stabilization of the exocyclic N=C bond.

With the purpose to establish a correlation between the basicity of α-acylamino-N-heterocycles and their ability to form the corresponding sodium salts an attempt was made to determine the *pKa* values. It can be seen from table 2 that the *pKa* values of 2-acylamino-pyrimidines decrease with the increasing of electron attracting properties of the acyl group, and the ability of these compounds to form the corresponding sodium salts (*pKb*) increases in the same order. On the other hand, the protonation of 2-acyl-amino-pyridines takes place at lower hydrogen ion concentrations than the protonation of the corresponding 2-acylamino-pyrimidines. Since 2-acylamino-thiazoles and 2-acylamino-thiadiazoles present similar ultraviolet spectra in neutral and acid media, the spectrophotometric determination of their *pKa* values failed (table 1). As it appears from the above mentioned data the stability of sodium salts of α-acylamino-N-heterocycles increases as the charge deficit of the heteroaromatic ring is increased. Therefore, it was regarded as a matter of interest to test the influence of some ring substituents on the formation of the sodium salts. It can be seen from tables 1 and 3 that 2-acylamino-5-acetylthiazoles (**Va**—**h**) have lower pKb values than the corresponding 2-acylamino-5-(α-hydroxy)ethylthiazoles (**VIa**—**e**) and 2-acylamino-thiazoles (**Ia**—**e**). Therefore, the sodium salts of the derivatives which contain a ring substituent with strong electron attracting properties are more stable. By plotting on logarithmic co-ordinates the *Kb* values of 2-acylamino-thiazoles or 2-acylamino-5-(α-hydroxy)-ethylthiazoles *versus* the corresponding values of 2-acylamino-5-acetylthiazoles, parallel straight lines were obtained (fig. 1).

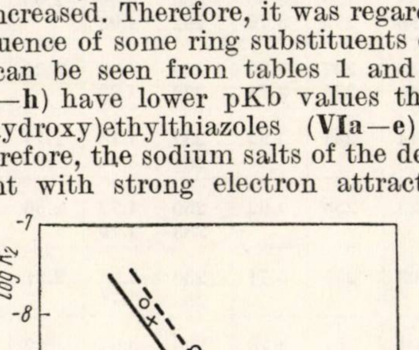

Fig. 1. — Logarithmic plot of the basic dissociation constants of 2-acylamino-thiazoles (table 1) and 2-acylamino-5-(α-hydroxy)ethylthiazoles (broken line) *versus* the corresponding values of 2-acylamino-5-acetylthiazoles (table 3).

If the free-energy change of the 2-acylamino-thiazole system is calculated for the derivatives containing an additional 5-acetyl group, the $|\Delta F|$ values (table 3) decrease in accordance with the strength of

the electron attracting effect exercised by the 2-acylamino group. That means that the contribution of the electron withdrawing effect of the 5-acetyl group to the

$$\Delta F = - RT \ln \frac{K_1}{K_2}$$

K_1 — ionization constants (Kb) of 2-acylamino-5-acetyl-thiazoles (**Va—c, e**)

K_2 — ionization constants of 2-acylamino-thiazoles (**Ia—d**)

stabilization of the mesomeric form B decreases as the electron attracting properties of the 2-acylamino group are increased.

In conclusion, the position of the tautomeric equilibrium of 2-acylamino-thiazoles, 2-acylamino-thiadiazoles and 2-acylamino-pyrimidines is largely dependent on the hydrogen ion concentration. Generally, in neutral and acid media the amido form a dominates. On the contrary, in alkaline medium, as a result of the formation of the sodium salts, the resonance stabilization of the imido mesomeric form B is preferred. However, the ultraviolet spectra indicate that 2-acylamino-pyridines did not form the corresponding sodium salts. The results support the assumption that the stability of the sodium salts of α-acylamino-N-heterocycles is determined not only by the presence of an acyl group with strong electron attracting properties, which enhances the elimination of the amidic proton, but also by a reasonable resonance stabilization of the exocyclic N=C bond. The intensity of the later effect increases in the order pyridines, pyrimidines, thiazoles and thiadiazoles. On the other hand, for the same heterocycle the resonance stabilization of the exocyclic N=C bond is enhanced for the derivatives which contain ring substituents with strong electron attracting properties.

Compounds **IIb,c** and **Vd** were prepared by the treatment of the corresponding amines (0.01 mole) with the appropriate acylchloride (0.01 mole) in benzene (20 ml). The mixture was refluxed for 5–7 hours, then evaporated to dryness and the residue was triturated with a $NaHCO_3$ solution. The suspended material was filtered, dried and recrystallized from the suitable solvent. The analytical data of compounds **IIb,c** and **Vd** are found in table 4.

Table 4

Physical and analytical data of compounds IIb, c, IVc-e and Vd

Compound	Molecular formula	m.p°. (solvent)	Yield %	Nitrogen %	
				Calcd.	*Found*
IIb	$C_9H_7N_3OS$	208–209 Ethanol	65	20.46	20.32
IIc	$C_4H_4ClN_3OS$	178–180 Ethanol	47	28.18	27.95
IVc	$C_8H_{10}ClN_3O$	106 Ethanol	74	21.05	20.80
IVd	$C_8H_9Cl_2N_3O$	130 Acetone	81	17.94	18.11
IVe	$C_8H_8Cl_3N_3O$	86 Acetone	67	15.63	15.52
Vd	$C_8H_7Cl_3N_2O_2S$	179–181 Ethanol	83	9.29	9.44

The preparation of compounds **IVc–e** was achieved by the treatment of 2-amino-4,6-dimethylpyrimidine (0.01 mole) with the appropriate acylchloride (0.01 mole) and pyridine (0.01 mole) in chloroform (20 ml). The reaction mixture was heated for 5–10 min, then cooled and extracted 3 times with water. The chloroform layer was dried over Na_2SO_4, then evaporated to dryness and the residue was recrystallized from the suitable solvent. Table 4 includes the physical and analytical data of compounds **IVc–e**.

The ultraviolet spectra were recorded with a VSU-2P (Carl Zeiss-Jena) spectrophotometer.

The *pKa* values were determined with standard spectrophotometric technique in glycine–HCl and Na citrate-HCl buffer solutions and the ionization constants of the sodium salts of α-acylamino-N-heterocycles in glycine–NaOH, Na borate–HCl and phosphate buffer solutions. The *pKa* and *pKb* data represent mean values of 4 determinations carried out near the pH of equivalence (25°).

2-THIO-5-NITROBARBITURIC ACID

R. NUŢIU, I. SEBE and MARIA NUŢIU *

University of Timişoara, Department of Chemistry, Bd. V. Pîrvan 4, Romania

* The "Traian Vuia" Polytechnic Institute, Department of Organic Chemistry, Timişoara, Romania

Received March 20, 1973

The synthesis of a new compound, 2-thio-5-nitrobarbituric acid, and its characterization by infrared and ultraviolet spectroscopy as well as by thermogravimetric analysis are presented. The structure of the anhydrous acid is established as corresponding to 2-thio-6-keto-4-hydroxy-5-nitro-1,2,3,6-tetrahydropirimidine, while the trihydrate is 2-mercapto-4,6-diketo-hexahydropyrimidine-5-nitronic acid. The second ionization constant as determined by spectrophotometry is $pK_2 = 8.95$. The molecular formulae, thermal behaviour and solubility in water at 25° were established for the compounds of this acid, obtained by precipitation with the ions of alkaline and alkaline-earth metals. A method for potassium determination is given, consisting in the spectrophotometry of the solution obtained by dissolution of the potassium salt of this acid in alkaline medium.

In a previous work [1] we reported the synthesis of 2-thio-5-nitrobarbituric acid (ATNB) by condensation of diethylnitromalonate with thiourea, ATNB gives scarcely soluble compounds with the ions of alkaline and alkaline-earth metals, similarly to dilituric acid [2] (5-nitrobarbituric acid). ATNB, as well as its compounds with alkaline and alkaline earth metals, give an intense yellow colour in alkaline medium, enabling the spectrophotometric determination of these ions.

The aim of this note is to characterize ATNB and its compounds with the alkaline and alkaline-earth metal ions, as well as to elaborate a spectrophotometric method for the determination of potassium, as its ATNB compound has the lowest solubility among those of ATNB with alkaline metal ions.

EXPERIMENTAL

SYNTHESIS OF ATNB

In 100 ml flask with round bottom, provided with an ascending condenser, to which a tube containing calcium chloride is attached at the top, sodium ethoxide is prepared by gradually introducing 1.84 g (0.08 moles) metallic sodium through the condenser into 40–50 ml absolute ethyl alcohol. After the reaction of the metallic sodium is completed and the solution cooled to room temperature, 6.8 ml (0.04 moles) diethyl-nitromalonate and afterwards 3–3.2 g (0.05 moles) anhydrous thiourea are introduced with precaution, in small portions and under cooling. The mixture is then vigorously stirred and refluxed for 3.5–4 hours at 105–110°. After cooling, a gelatinous dirty-brown product results, to which drops of (1 :1) hydrochloric acid are added until a pH 6–6.5 is attained. The monosodium salt of ATNB precipitates at intense cooling (on ice) and is filtered in vacuum. ATNB sodium salt falls out as intensely yellow crystals from a water-alcohol (50 % vol) solution, after recrystallization and decolouration with charcoal.

The elementary analysis of the anhydrous sodium salt gave the following results :

Found : C, 22.88 ; H, 1.06 ; N, 20.22%

Calcd. : C, 22.75 ; H, 0.95 ; N, 19.90 %

Determination of crystallization water was performed by thermogravimetry. The thermogram (compound II) is given in figure 3.

The free acid, crystallized with three molecules of water, is obtained through the passing of an aqueous solution of the sodium salt, of about 1 %, over an ion exchanger (Amberlite IR–120) and concentration in vacuum of the solution obtained. The ATNB ($C_4H_3O_4N_3S.3H_2O$) thus obtained has the colour of sulphur, is soluble in water and alcohol and insoluble in the usual organic solvents. The anhydrous product ($C_4H_3O_4N_3S$) is obtained by dehydration of the crystalline acid in an Abderhalden apparatus, at 100° and is lemon-yellow with the same transformation (189–190°) and decomposition (193°) temperatures as the trihydrate.

While ATNB trihydrate undergoes a slow decomposition – it smells like hydrogen sulphyde – anhydrous ATNB is stable and can be stored for a long time.

The following results were obtained by the elementary analysis of anhydrous ATNB :

Found : S, 16.79 ; C, 25.70 ; H, 1.84 ; N, 22.26%

Calcd. : S, 16.93 ; C, 25.40 ; H, 1.60 ; N, 22.21 %

Determination of crystallization water was performed by thermogravimetric analysis ; the derivatogram of this compound, recorded on a "OD 102 – Paulik-Paulik-Erdely" type derivatograph, is given in fig. 1.

SPECTROPHOTOMETRIC DETERMINATIONS

Infrared spectrophotometry was performed on a Perkin-Elmer, type 457 Spectrophotometer. The samples were studied [3] as tablets in KBr (concentration 1–5 mg per 100 mg KBr) and in a nujol suspension, because anhydrous ATNB reacts with KBr during pastillation.

Ultraviolet spectrophotometric determinations [4] were performed on a Unicam SP-8000 Spectrophotometer, with a 5 mm quartz vat. The concentrations used were always 10^{-4} M in the solvents listed in table 2. The buffers used to determine the ionization constant were aqueous borax solutions the pH being also checked with an LPY-ol, USSR, model 1968, type pH-meter.

[4] C. N. R. Rao, "Ultraviolet and Visible Spectroscopy", London, Butterwoths, 1961.

Preparation and characterization of the alkaline and alkaline earth salts. For the precipitation of the alkaline and alkaline-earth salts, aqueous-alcoholic (50% vol) solutions of 2% ATNB were used, obtained by dissolution in warm water and dilution with alcohol. Chlorides or sulphates of the respective metals were employed. The molar precipitation ratio was 1.2 moles ATNB for one metal equivalent. After cooling the solution with the sediment to about 10°, the precipitate is filtered, washed with a 5–6 times diluted ATNB solution and then with alcohol and ether. The products are dried by prolonged aspiration at a water-jet pump.

The solubilities of the studied compounds were determined at 25°±0.1° by the method used of Berlin and Robinson,[5] which we also used in previous works.[6]

The thermograms were performed by means of a manufactured thermobalance with reading on a calibrated milivoltmeter, at a temperature increase rate of 5° per minute.

GRAVIMETRIC AND SPECTROPHOTOMETRIC DETERMINATION OF THE POTASSIUM ION

Gravimetric determination of the potassium ion by precipitation with ATNB was performed under the precipitation conditions described above. The spectrophotometric determinations were performed with a Spekol ZV type Cakl Zeiss Jena spectrophotometer, of the solutions obtained as described below:

In 5 centrifuge test tubes of about 10 ml, 0.5; 1.0; 2.0; 3.0 and 4.0 ml aqueous n/100 KCl solution were pipetted and 4 ml alcoholic-aqueous (about 75% vol) 0.5% ATNB solution were added to each test tube.

In another test tube the sample to be analysed is introduced with about the same molar potassium ion concentration and 4 ml ATNB solution are added. The walls of the test tube are rubbed with a suitable glass rod.

The test tubes are kept for 5–6 hours, or better overnight, in order to assure the completion of the precipitation. A temperature difference of ±3° does not influence the result. The test tubes are centrifugated at 5–6000 rotations per minute. The supernatant is decanted, the precipitate is washed two or three times with alcohol, stirred with the rod, and the interior walls of the test, on which crystal rests are observed, are washed.

After a last washing, centrifugation and separation of the alcohol used for washing, 5 ml KOH 10% is added to each test tube and the dissolution of the precipitate is ascertained by vigorous stirring with the rod. The solutions thus obtained, of intense yellow colour, are passed quantitatively, by washing with distilled water, into 100 ml marked flasks.

In another marked flask, 5 ml KOH 10% are added and completed with water up to the sign; this solution is used for comparison, respectively compensation.

The solutions thus obtained are spectrophotometrated by reading the extinctions at 410 or 420 nm, using 5 mm vats. The results are recorded as a plot of extinction (E) or extinction module (E_d) *vs.* the potassium ion concentration. The spectrophotometration of the solutions can be performed within two hours, during which the extinction remains constant.

EXPERIMENTAL RESULTS AND DISCUSSIONS

STRUCTURE AND PROPERTIES OF ATNB

The derivatogram of ATNB (figure 1), indicates that the three water molecules are eliminated in two steps ; the first two molecules in the 25°—70° interval and the third in the 75°—98° interval. We conclude from these facts that the first two water molecules are network water, while the third seems to be included in the structure of the ATNB, the activation energy for the second step being of 23 kcal/mol (as determined according to the mehod of Freeman and Caroll [7]). Following the derivatogram at higher temperatures, it results that ATNB is stable until 150°, when decomposition begins, and becomes explosive at 175° ; the exothermicity of this process is apparent also on the DTA curve. The decomposition is completed at about 500°.

788–90 i	790 m	
720 m	740 w	740 w

i = intense; m = medium; w = weak; b = broad; s = shoulder; sh = sharp.

Comparing the absorption maxima given in table 1 with the infrared spectrum and its interpretation for dilituric acid, [8] we conclude that anhydrous ATNB exists as 2-thio-6-keto-4-hydroxy-5-nitro-1,2,3,6-tetrahydropyrimidine. This conclusion is based on the absorption at 1600 cm^{-1}, characteristic for the double carbon-carbon bond [9] and at 1345 cm^{-1} and respectively 1560–85 cm^{-1}, characteristic for the symmetric and respectively asymmetric valence vibration of the nitro group. [10] The strong absorption at 1670–80 cm^{-1} which does not appear in the IR-spectrum of 5-nitro-5-ethyl-barbituric acid is attributed to the thio group, respectively to the α,β-unsaturated carbonyl.[11] The thioamidic group may be responsible [12, 13] also for the absorption at 1295 cm^{-1}. The absorption for the hydroxylic group appears at very low values, as for the dilituric acid, because of the probably intramolecular association of the hydroxyl group, with the nitro group. The intense band at 1292–98 cm^{-1}, accompanied by a medium band at 1260 cm^{-1}, which appears for hydrate ATNB, suggests that this compound is in the aci-nitro form, as these bands are characteristic for the aci-nitro ion [14] ($=NOO^-$).

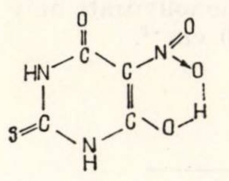
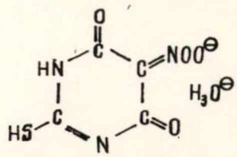
b) L. N. SHORT and H. W. THOMPSON, *J. Chem. Soc.*, **1952**, 168.



Absorption recorded at 1560 cm^{-1} is attributed to vibrations of the pyrimidinic cycle,[8] as well as the one at 1378 cm^{-1}; both are found also for other pyrimidines (for ethylbarbituric acid, as an example). A weak and narrow band is recorded at 2595 cm^{-1} for the hydrated compound which can be attributed only to the mercapto group (–SH).[13] The broad absorption at 1645–80 cm^{-1} may include the carbonyl valencevibration and also the one for the carbon-nitrogen double bond ($C=N$)[15] of the aci-nitro form. We conclude, thus, that the hydrated ATNB exists as 2-mercapto-4,6-diketo-1,4,5,6-tetrahydropyrimidine-5-nitronic acid, probably the anion associated with a hydroxonium cation. The high activation energy (23 kcal/mol) for the elimination of the last water molecule also favours this interpretation.



The sodium compound of ATNB has a similar spectrum with that of ATNB trihydrate and might thus be a salt of this nitronic acid.

The ultraviolet spectra of ATNB are given in table 2. They contain bands characteristic for π-π* transitions. The K bands at 208 and 217 nm may be attributed to the NO_2 chromophor in the monoanion and the B bands at 337 and 357 nm to the dianion corresponding, assumedly, to the dissociation of the mercapto group (–SH). The isosbestic point at 348.5 nm ($\varepsilon = 14000$) is recorded in this region and used for the determination of the second ionization constant. The value of this constant, $K_2 = 1.12 \times 10^{-9}$, established from spectrophotometric titration, is much higher than that for dilituric acid [16] ($K_2 = 5.6 \times 10^{-11}$).

According to our potentiometric and colorimetric evaluations, the first ionization constant is similar to that of hydrochloric acid.

Table 2

Absorption maxima recorded in ultraviolet spectra

Solvent	Absorption					
	λ_{max}	ε_{max}	λ_{max}	ε_{max}	λ_{max}	ε_{max}
H_2O	208	19200	271	7600	337	16800
HCl N/10	208	19000	271	7500	337	16750
NaOH N/10	217	19900	243– 248 288	8100– 8000 5440	354	14200

These spectra demonstrate also a bathochromic effect, when ATNB is solved in alkaline solutions, a fact which we used for quantitative spectrophotometric evaluations.

SALTS WITH ALKALINE AND ALKALINE-EARTH IONS

Table 3 gives the combinations of ATNB with the ions of the alkaline and alkaline-earth ions, while figures 2 and 3 the thermograms of these ions. The solubilities of these compounds decrease from lithium to potassium and from magnesium to barium. The thermal stabilities of these salts are higher than that of ATNB, except for the calcium salt. A gravimetric determination of potassium, rubidium and cesium with ATNB is possible (in the conditions described in a previous paragraph) with errors below ± 2.5%.

Table 3

Results of nitrogen elementary analysis, water solubility at 25° and decomposition temperatures for the salts of ATNB with alkaline and alkaline-earth ions

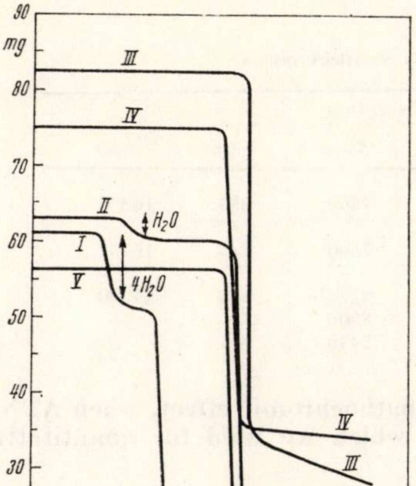

Fig. 2. — Thermogravimetric curves of compounds (I)–(V).

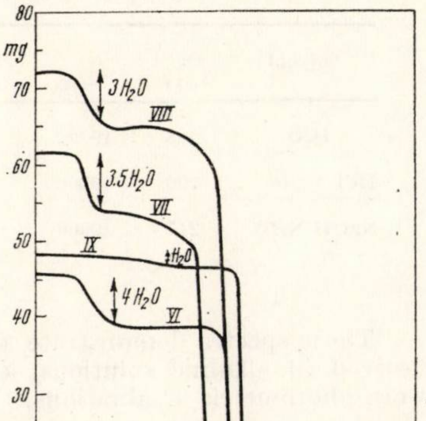

Fig. 3. — Thermogravimetric curves of compounds (VI)–(IX).

ATNB and its metal salts studied are solved in strongly basic solutions, with an intense yellow colour which respects the Lambert-Beer law up to a concentration of $4 \cdot 10^{-5}$ M. A spectrophotometric dosage of these ions is thus possible.

SPECTROPHOTOMETRIC DETERMINATION OF THE POTASSIUM ION

The determination of potassium with ATNB, under the conditions described in this paper, has the advantage of a spectrophotometry in the visible range of a solution obtained by solving the precipitated potassium salt of ATNB in basic solutions which have an intense yellow colour. The determination of potassium with ATNB is disturbed by the other ions of alkaline metals, within the solubility limits given in table 3.

Figure 4 gives the calibration curve at 410 and 420 nm for our method. The errors for the determinations performed by us were below ±0.8%.

We would like to specify that all compounds of ATNB with a solubility below 10 mmol/l can be determined by this spectrophotometric method.

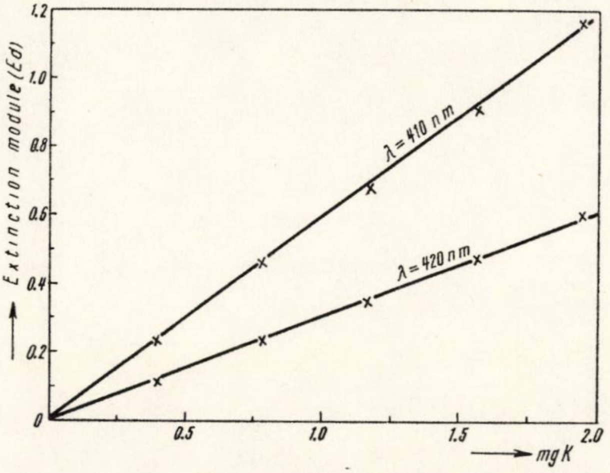

Fig. 4. – Calibration spectrophotometric curves for the determination of potassium ion with ATNB.

PEPTIDES. XV [1]

THE USE OF β-DICARBONYL N-PROTECTED ASPARAGINE AND GLUTAMINE IN PEPTIDE SYNTHESIS

A. BALOG*, E. VARGHA**, D. BREAZU*, F. GÖNCZY*, and LUCIA BEU*

* Institute for Chemical and Pharmaceutical Research, str. Fabricii 126, Cluj, Romania

** The Department of Organic Chemistry, Babeş-Bolyai University, Str. Arany J. 11, Cluj, Romania

Received May 8, 1973

The potassium and dicyclohexylammonium salts I—VIII of asparagine and glutamine were prepared using for α-amino protection the AE, CP, AC and BA*** groups. These salts were converted readily into the corresponding phenacyl and *p*-nitrobenzyl esters (IX—XIX). After removal of the amino protecting groups in acidic medium, the asparagine and glutamine ester hydrochlorides or hydrobromides (XX—XXIII) were obtained in good yields. The dipeptide esters involving N-terminal or C-terminal asparagine and glutamine respectively (XXIV—XXX), were synthesized *via* the mixed anhydride method.

The investigations which have been developed in peptide synthesis, involving asparagine or glutamine, showed that the peptide-bond formation is accompanied by several side reactions.[2] Thus, dehydration or hydrolysis of the ω-amidic group, appearance of isoasparagine and isoglutamine derivatives [2] as well as formation of N-substituted α-glutarimides [3,4] and pyroglutamic acid derivatives, [5] respectively, were observed.

*** The abbreviations used in this paper are the followings : AE = 1-ethoxycarbonyl propen-2-yl ; CP = 2-ethoxycarbonyl-cyclopenten-1-yl ; AC = 1-acetyl-propen-2-yl ; BA = = 1-benzoyl-propen-2-yl ; DCHA = dicyclohexylamine ; THF = tetrahydrofuran ; AcOEt = = ethyl acetate ; DMF = dimethylformamide ; EtOH = ethanol ; MeOH = methanol ; TEA = = triethylamine.

The symbols used for amino acid derivatives correspond to the recommendations of IUPAC-IUB Commission on Biochemical Nomenclature (1971), *J. Biol. Chem.*, **247**, 977 (1972).

To avoid these undesired reactions new N-protecting groups were introduced in the ω-amide residue.[6] Of course this procedure increased the steps of synthesis and at the same time decreased the solubility of N-substituted derivatives of the amides in the usually employed solvents for peptide synthesis.

Owing to the promising results obtained by us in the peptide synthesis involving bifunctional amino acids [7,8] as well as several trifunctional amino acids,[9,10] using for the protection of the α-amino group β-dicarbonyl compounds, we have also extended this method to the asparagine and glutamine series.

A. *The protection of α-amino group*. Among the β-dicarbonyl compounds the benzoylacetone was used at first for the α-N-protection of asparagine and glutamine (Southard and co-workers, 1971).[11] The N-protected derivatives IVb and VIII, respectively, were isolated as dicyclohexylammonium salts only without using them for peptide synthesis. Before the publication of Southard's paper, we embarked our investigation on the α-amino protection of asparagine and glutamine, using for this purpose ethyl acetoacetate, 2-ethoxycarbonyl cyclopentanone, acetylacetone and benzoylacetone.

According to the earlier elaborated method,[7] about 8–10% excess of the amino acid and about 30% excess of the β-dicarbonyl compound were added to a solution of methanolic potassium hydroxide or dicyclohexylamine, respectively. The mixture is then refluxed until the most part of the amino acid is dissolved. Working up as usual, the potassium and dicyclohexylammonium salts were obtained with over 70% yields. The scheme below shows, that only one potassium salt was isolated in the glutamine series (Va). It is to be remarked that, by treating the potassium salt Va with dicyclohexylammonium bromide, the corresponding dicyclohexylammonium salt Vb was obtained in a higher purity than by direct synthesis.

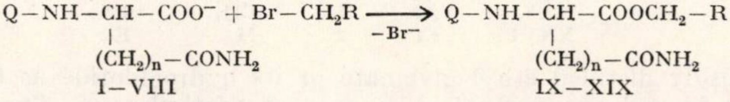
[11] G. L. Southard, G S. Brooke and J. M. Pettee, *Tetrahedron*, **27**, 1359 (1971).

Our attempts to obtain from asparagine the potassium salt, using 2-ethoxycarbonyl cyclopentanone for N-protection, or dicyclohexylammonium salt by protecting with ethyl acetoacetate, failed.

The dicyclohexylammonium salt of the β-dicarbonyl N-protected asparagine and glutamine are in general fairly soluble in organic solvents used for peptide syntheses (THF, AcOEt, DMF, dioxan). These salts (I—VIII) are suitable starting materials both for the protection as well as for the activation of the α-carboxyl group.

B. *Preparation of phenacyl and p-nitro-benzyl esters.* The phenacyl and *p*-nitrobenzyl group, frequently used for the protection of amino acid carboxyl, can be easily introduced into N-protected asparagine and glutamine. Thus, the potassium or dicyclohexylammonium salts I—VIII were treated in acetone and dimethylformamide solution with phenacyl bromide or *p*-nitrobenzyl bromide. The reaction takes place according to equation (1), either at room temperature, or at the boiling point of the solvent mixture (about 80°).



$$\underset{\text{I}-\text{VIII}}{Q-NH-\underset{\underset{\displaystyle (CH_2)_n-CONH_2}{|}}{CH}-COO^-} + Br-CH_2R \xrightarrow[-Br^-]{} \underset{\text{IX}-\text{XIX}}{Q-NH-\underset{\underset{\displaystyle (CH_2)_n-CONH_2}{|}}{CH}-COOCH_2-R} \qquad (1)$$

	Q	R	n		Q	R	n

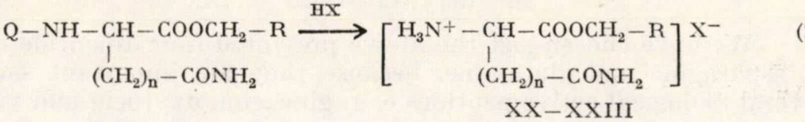
XII	AE	,,	2	XVII	BA		1
XIII	CP	,,	2	XVIII	AE	,,	2
				XIX	CP	,,	2

The removal of the N-protecting groups was carried out conveniently in an adequate solvent at room temperature, by acidification to pH 2.5—2 with hydrogen chloride in ethanol, or hydrogen bromide in water or anhydrous acetic acid :



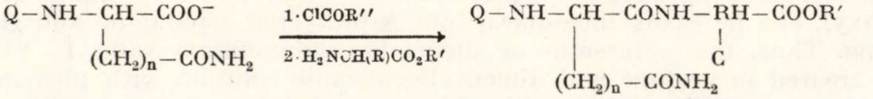
$$Q-NH-\underset{\underset{\displaystyle (CH_2)_n-CONH_2}{|}}{CH}-COOCH_2-R \xrightarrow{HX} \underset{\text{XX}-\text{XXIII}}{\left[H_3N^+-\underset{\underset{\displaystyle (CH_2)_n-CONH_2}{|}}{CH}-COOCH_2-R\right]X^-} \qquad (2)$$

	X	R	n		X	R	n
XXa	Cl	COC_6H_5	1	XXIIa	Cl	$C_6H_4NO_2(p)$	1
XXb	Br	,,	1	XXIIb	Br	,,	1
XXI	Br	,,	2	XXIII	Br	,,	2

The phenacyl esters XX—XXI and *p*-nitrobenzyl esters XXII—XXIII were isolated as hydrochlorides (a) or hydrobromides (b) and, as usual, crystallized relatively easily from anhydrous ethanol-ether.

C. *Peptide bond formation.* For the preparation of asparaginyl and glutaminyl peptides only those methods are promising, which avoid the undesired side reactions due to the ω-carbonyl group. Thus, satisfactory results were obtained by applying the mixed anhydride [2] and *p*-nitrophenyl ester method,[2] or more recently the N-carboxy anhydride one.[12]

We have found, that the potassium and dicyclohexylammonium salts I–VIII are adequate starting materials for the synthesis of both asparaginyl and glutaminyl peptides by using for mixed anhydride formation ethyl chloroformate, pivaloyl or benzoyl chloride and a catalytical amount of N-methyl morpholine. Starting from the dicyclohexylammonium salts, the mixed anhydride solution was filtered to eliminate the insoluble dicyclohexylammonium chloride. The coupling was carried out



$$\underset{\substack{|\\(CH_2)_n-CONH_2}}{Q-NH-CH-COO^-}\xrightarrow[2\cdot H_2NCH(R)CO_2R']{1\cdot ClCOR''}Q-NH-\underset{\substack{|\\(CH_2)_n-CONH_2}}{CH}-CONH-\underset{\substack{|\\C}}{RH}-COOR' \quad (3)$$

XXIV–XXVI

XXIV	CP	1	H	Et
XXV	AE	1	CH_3	PAc
XXVI	CP	2	H	Et

with freshly distilled ethyl glycinate or its hydrochloride as C-terminal amino acid and one equivalent amount of triethylamine. The dipeptide esters were isolated according to the general method proposed by us,[7, 8, 10] treating the reaction mixture with saturated sodium hydrogen carbonate solution and evaporating the organic solvents under reduced pressure.

For the synthesis of peptides with C-terminal asparagine and glutamine, their phenacyl or *p*-nitrobenzyl esters were used. Thus, the N-protected dipeptide esters XXVII–XXX were obtained in good yields (over 80%) by means of the mixed anhydride method :

AE–ALa–Asn–ONBzl	(XXVII)
AE–Ala–Gln–ONBzl	(XXVIII)
CP–Gln–Asn–OPAc	(XXIX)
CP–Gln–Asn–ONBzl	(XXX)

We have chosen just the above presented four dipeptide derivatives of asparagine and glutamine, because they are important sequences in several biological active peptides e. g. glucagon, oxytocin and vasopressin.

EXPERIMENTAL

Melting points were taken in capillary tubes and are uncorrected. The analyticasamples were dried *in vacuo* over P_2O_5 for 3–4 hours at 64° and 16–30 torr. Optical rotations were measured with a Metra 400/a Prague polarimeter. Infrared spectra were determined on a Carl Zeiss UR–10 spectrophotometer and the UV-spectra on a Zeiss VSU–1 model in methanol. Yields were calculated on the weight of vacuum dried (over P_2O_5 and KOH) substances.

A. SALT FORMATION *

N-(1-Ethoxycarbonyl-propen-2-yl)-L-asparagine potassium salt (*AE-Asn-O$^-$K$^+$, I*). 15 g (0.1 mol) L-asparagine monohydrate in 68 ml of methanolic potassium hydroxide of 7.84 g/100 ml concentration (0.095 mol) was treated with a solution of 14 ml ethyl acetoacetate in 30 ml methanol. The reaction mixture was heated on the steam bath for 1 hr and filtered off (0.9 g unreacted amino acid). The clear solution was concentrated *in vacuo* and dried by addition of benzene (4 × 50 ml) and distilled azeotropically. The remaining solid was treated with petroleum ether, filtered and washed with light petroleum, dried in desiccator. Yield 25 g (94%); mp. 175–176° (decomp.); $[\alpha]_D^{21}$: +45.2° (c = 0.97, methanol).

Found: N, 9.72; K, 13.70

Calcd. for $C_{10}H_{15}KN_2O_5$: N, 9.92; K, 13.85

N-(2-Ethoxycarbonyl-cyclopenten-1-yl)-L-asparagine dicyclohexylammonium salt (*CP-Asn-O$^-$DCHA.H$^+$, II*). A mixture of 3 g (20 mmoles) L-asparagine, 4 ml (25 mmoles) of 2-ethoxycarbonyl-cyclopentanone in 50 ml methanol was treated with freshly distilled dicyclohexylamine (4.4 ml, 22 mmoles) on a steam bath for 5 hr and filtered while hot, to remove any unreacted amino acid (0.8 g). The filtrate was concentrated *in vacuo* and the residue evaporated three times to dryness *in vacuo* by adding three portions of benzene (50 ml). The remaining yellow oil was treated with 100 ml anhydrous ether. After standing for 24 hours the crystals were collected. Yield 6.4 g (71%); mp. 148–150°; $[\alpha]_D^{22}$: +11.2° (c = 1.02, methanol).

N-(1-Acetylpropen-2-yl)-L-asparagine potassium salt (*AC-Asn-O$^-$K$^+$, IIIa*). 10.4 ml (0.1 mol) acetylacetone and 78 ml methanolic potassium hydroxide of 7.2 g/100 ml concentration (0.1 mol) was added to 16.5 g (0.11 mol) of asparagine suspended in 10 ml methanol and refluxed for one hour, filtered while hot (0.8 g unreacted asparagine) and the filtrate was concentrated *in vacuo*. The solid residue was dried by the addition of benzene (3×50 ml) followed by evaporation *in vacuo*. After trituration with petroleum ether and recrystallization from anhydrous ethanol, it yielded 11.5 g (45%); m.p. 185° (decomp.); $[\alpha]_D^{21}$: +82.3° (c = 1.02, methanol).

UV : λ_{max} 315 nm ($\log \varepsilon = 4.24$)
IR : ν_{NH} 3275; ν_{CO} 1670; ν_{COO^-} 1570; δ_{NH} 1684, 1395 cm^{-1}
Found: N, 10.60; K, 14.90

N-(1-Acetylpropen-2-yl)-L-asparagine dicyclohexylammonium salt (*AC-Asn-O$^-$DCHA·H$^+$ IIIb*). To 14.5 g (96.5 mmoles) of L-asparagine monohydrate suspended in 10 ml water was added a solution of 18.9 ml (96 mmoles) of dicyclohexylamine in 80 ml methanol, followed by the addition of a hot solution of 10 ml (96 mmoles) acetylacetone in 80 ml ethanol. The mixture was refluxed for 3 hours and filtered while hot, to remove any unreacted L-asparagine. The filtrate was concentrated *in vacuo* and the residue was dried by azeotropic distillations with two 100 ml portions of propanol-2 and 100 ml of benzene, respectively. The isolated crystalline product was recrystallized from methylene chloride (75 ml) and ether (125 ml). Yield 24 g (63.5%) ;mp. 148–149°; $[\alpha]_D^{27}$: +35° ($c = 1.32$, methanol).

N-(1-Acetylpropen-2-yl)-L-asparagine p-nitrobenzyl ester (AC-Asn-ONB, XVI). This compound was prepared in a similar manner as described before (by ester XV) from AC-Asn-O^-DCHA·H^+ (IIIb). Yield 63%, m.p. 153—155° (ethyl acetate); $[\alpha]_D^{23}$: +118.6° (c = 0.45, methanol).

Found: C, 55.15; H, 5.75; N, 12.00

Calcd. for $C_{16}H_{19}N_3O_6$: C, 55.01; H, 5.48; N, 12.03

N-(1-Benzoylpropen-2-yl)-L-asparagine p-nitrobenzyl ester (BA-Asn-ONB, XVII). 3.5 g (10 mmoles) BA-Asn-O^-K^+ (IV) in 40 ml acetone and 10 ml dimethylformamide was treated with 2.15 g (10 mmoles) *p*-nitrobenzyl bromide and worked up as described by CP-Asn-ONB (XV). Yield 4 g (97%); m.p. 171—172° (ethanol); $[\alpha]_D^{25}$: +113.8° (c=1, methanol).

Found: C, 61.36; H, 5.90; N, 10.40

Calcd. for $C_{21}N_{21}N_3O_6$: C, 61.31; H, 5.15; N, 10.21

L-Asparagine p-nitrobenzyl ester hydrobromide ($^+H_2$-Asn-ONB.Br$^-$, XXIIb). 1 g AE-Asn-ONB (XIV) suspended in 15 ml anhydrous ethanol was treated with hydrogen bromide in acetic acid (30%) to a pH value of 2.5—2 and heated to 55—60° under stirring. The formed solution was then filtered and treated with 20 ml anhydrous ether. Yield 0.7 g (76%). Recrystallized from ethanol-ether, m.p. 171—172°; $[\alpha]_D^{24}$; +10.4° (c = 1, methanol). Lit.[13] 170—171°.

L-Asparagine p-nitrobenzyl ester hydrochloride ($^+H_2$-Asn-ONB.Cl$^-$, XXIIa). 1 g AE-Asn-ONB (XIV) was deprotected with ethanolic hydrochloric acid (13%) as described before. Yield 80%; m.p. 184—185° (ethanol-ether); $[\alpha]_D^{24}$: +7.0° (c = 0.75, methanol).

Found: C, 43.59; H, 5.21; N, 13.43; Cl, 11,56;

Calcd. for $C_{18}H_{14}ClN_3O_5$: C, 43.50; H, 4.65; N, 13.83; Cl. 11.67

N-(1-Ethoxycarbonyl-propen-2-yl)-L-glutamine-p-nitrobenzyl ester (AE-Gln-ONB, XVIII). 3 g (10 mmoles) AE-Gln-O^-K^+ and 2 g *p*-nitrobenzyl bromide in 40 ml acetone and 10 ml dimethylformamide were refluxed for 2 hours and diluted with 400 ml water. The filtered and dried precipitate (2.4 g, 62%) was recrystallized from ethyl acetate — ether; m.p.120—121°; $[\alpha]_D^{23}$: +41.3° (c = 0.7, dioxan).

Found: C, 54.56; H, 6.00; N, 10.60

Calcd. for $C_{18}H_{23}N_3O_7$: C, 54.95; H, 5.89; N, 10.68)

N-(2-Ethoxycarbonyl-cyclopenten-1-yl)-L-glutamine p-nitrobenzyl ester (CP-Gln-ONB, XIX). The synthesis was executed according to the model described by CP-Gln-OPAc (XIII). Yield 2.3 g (52.5%); m.p. 120—122°, recrystallized from ethanol-water 118—120°; $[\alpha]_D^{28}$: +67° (c = 1, methanol).

Found: C, 57.60; H, 6.24; N, 10.28

Calcd. for $C_{20}H_{25}N_3O_7$: C, 57.27; H, 6.01; N, 10.01)

AZLACTONES OF CAROTENOIDS. II[1]

RETINAL AZLACTONE AND TRANSFORMATION PRODUCTS

V. TĂMAŞ and C. BODEA

Department of Biochemistry, Institute of Agronomy, Str. Mănăştur 3, Cluj, Romania

Received June 23, 1973

By condensation of retinal (I) with hippuric acid the oxazolonic compound III was obtained with high yield. Opening of the oxazolonic ring by action of nucleophilic reagents such as water, hydrazine hydrate or phenylhydrazine on III resulted in the formation of the benzylamide-carotenoic acid IV and the hydrazides V and VI. The properties of these compounds are described.

Retinal (vitamin A_1 aldehyde) is a metabolite of some carotenoids and a usual component of human and animal organisms.[2,3,4] Various physical[5,6] and chemical[7,8,9] methods for the identification and determination of retinal in natural products have been described. Among the chemical methods, condensation with rhodanine is commonly used to identify retinal.[9] The efficiency of this method is rather low because of the formation of numerous *cis-trans* condensation products.

These last years researches have been carried out on condensation of retinal with indene, to obtain fulvenes,[10] with dicarboxylic acids[11] and with several other compounds having an active methylene group.[12]

In a previous paper[1] we have reported on the condensation of some aldehyde-carotenoids (β-apo-carotenals and diapo-carotenodials) with hippuric acid leading to carotenoid-azlactones. These compounds are obtained with good yields and can give valuable indications about the structure of aldehyde-carotenoids.

Continuing these investigations we have submitted retinal (retinaldehyde) to the condensation with hippuric acid in acetic anhydride. Carrying out the reaction for two hours at 85°, we obtained as principal product the azlactone of all-*trans*-retinal (III), accompanied by smaller quantities of a *cis-trans* isomer (II).

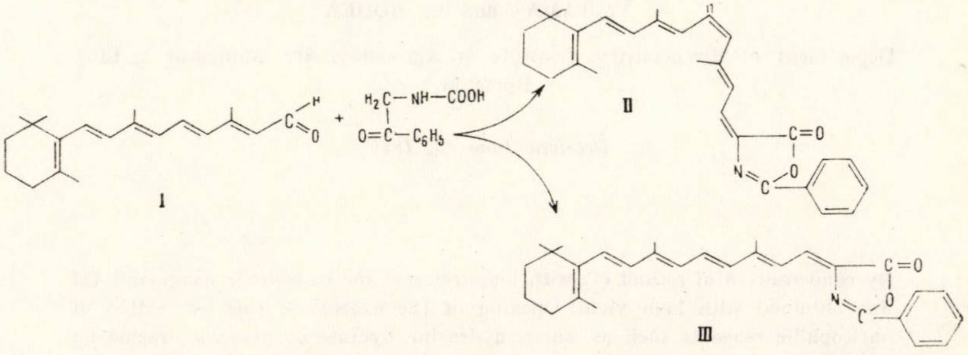

Fig. 1

It is known that among the *cis-trans* isomers of retinal formed under the action of various reagents the 11-*cis*-retinal is predominant. This isomer occurs also in the natural visual pigments. Acting only with acetic anhydride upon all-*trans*-retinal under the conditions leading to the formation of azlactones, part of the all-*trans* form proved by its characteristic absorption spectrum[13] to be converted into the 11-*cis* isomer. The difference between λ_{max} of all-*trans*- and 11-*cis*-retinal is about 4 nm, identic with the difference between the azlactone III and its isomer II. We therefore believe that isomer II should be the azlactone of 11-*cis*-retinal.

Azlactone III being the principal reaction product in the condensation with hippuric acid we have studied its chemical behaviour.

It has been demonstrated that the C=N group in azlactones is an acceptor of electrons, thus preventing the adjacent oxygen atom to interact with the carbonyl group of C-5. Therefore, exposing this carbonyl group to the action of nucleophylic reagents the azlactonic ring opens in the way shown in fig. 2.[14,15,16,17,18]

According to this mechanism the hydrolysis of azlactone III in dimethylformamide at room temperature resulted in the formation of 15′-N-benzylamide-β-apo-14′-carotenoic acid, IV. Through hydrazinolysis and phenylhydrazinolysis the azlactone III has been transformed with high yields into hydrazide V and phenylhydrazide VI, respectively (see fig. 3 and table 1).

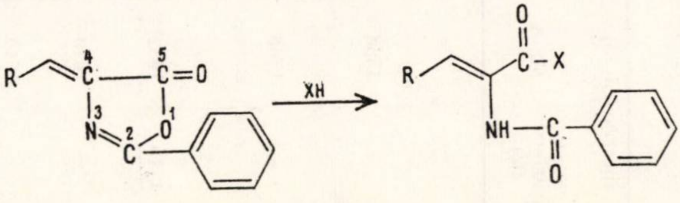

Fig. 2

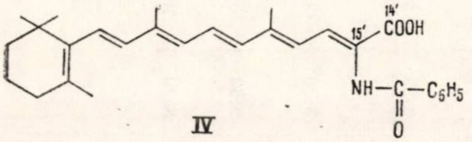
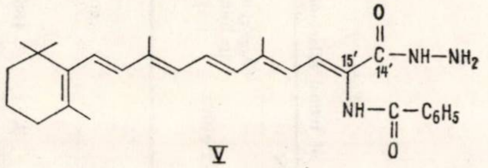
The absorption spectra in ultraviolet and visible light of compounds III, IV, V and VI in benzene shows no fine structure (see fig. 4).

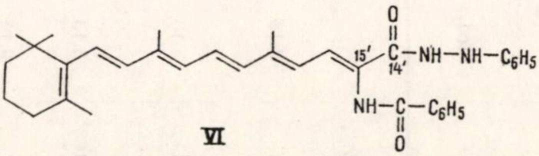
Comparing the position of λ_{max} of III with those of IV, V and VI there is to be noticed a hypsochromic shift of 100 nm in the case of λ_{max} III. This can serve as a valuable criterion for their differentiation and identification.



IV



V



VI

Fig. 3

As compared to retinal, compounds IV, V and VI have an additional C=C group, which explains the bathochromic shift of about 10—16 nm in the absorption spectra of these compounds.

The I.R. spectra recorded in CCl_4 show the presence of the characteristic peaks for the C=O and C=N groups (see table 1). It is worth mentioning that some of the bands are very strong, i. e. in the spectrum of III the band at 1638 cm^{-1}, of V and VI at 1615 cm^{-1} characteristic for the an C=N group and in the spectrum of IV the band at 1715 cm^{-1} assigned to the C=O group.

Compounds IV, V and VI are structurally related both to vitamin A_1 and to carotenoids, enriching the chemistry of carotenoids with new

synthetical nitrogen containing derivatives. Eventually biological activities of these compounds are under investigation.

EXPERIMENTAL

MATERIALS AND METHODS

The retinal used in the condensation reaction with hippuric acid was a synthetical product from Badische Anilin-Soda Fabrik A.G., Ludwigshafen/Rh, West Germany.

The reaction products were separated by means of thin layer chromatography, using as absorbent silica gel G. All the absorbent and solvents used had analytical and proanalysis purity.

Electronic spectra were recorded on a Spectrophotometer Zeiss VSU-1 and IR spectra on a – Unicam SP. 200 G.

Melting points uncorrected were determined on a Boëtius apparatus.

Azlactone of Retinal. Retinal (100 mg), hippuric acid (85 mg) and anhydride sodium acetate (80 mg) were thoroughly mixed in a test tube and acetic anhydride (0.75 ml) was added. The test tube was introduced in a drying oven and kept for 2 hours at 85°. After about 15 minutes, the mixture started to darken. After 2 hours, the mixture was cooled down at the room temperature, placed in a G_3 filtrant crucible and washed 5–6 times with water. From the residue the pigments were extracted till colourless with a mixture of benzene and ethylic ether (1 : 1). The solution of the pigments was concentrated to a small volume (1–2 ml).

The pigments were precipitated by adding 50 ml petroleum ether. The precipitate was filtered and washed with 30 ml petroleum ether. Yield about 90 %.

For the purification of the pigments, thin layer chromatography was used. The chromatoplate was developed with a mixture of benzene and petroleum ether (1 : 1). The R_f values are shown in table 2.

Table 2

Thin layer chromatography; zones and R_f values

Zones		R_f
colour	compound	
pink-violet (A)	azlactone of 11-*cis*-retinal (II)	0.85
violet (B)	azlactone of all-*trans*-retinal (III)	0.80
pink	retinal (I)	0.65

— *Pigment II.* Zone A was eluated with ethylic ether; after evaporation of the solvent, violet crystals were obtained. The characteristics are shown in table 1.

— *Pigment III.* The pigment of zone B was eluated in the same manner as the pigment of zone A. Violet crystals (70—75 mg), soluble in benzene, $CHCl_3$, CCl_4, ethylic ether, ethanol, insoluble in water.

Transformation of pigment III.—Hydrolysis. III (100 mg) was solved in dimethylformamide (20 ml) and 5% NaOH (10 ml) was added. The mixture was homogenized and kept for 15 minutes at room temperature. The solution was poured into ether and washed with water containing 2% acetic acid. The ether solution was dried with Na_2SO_4 sicc. and the ether evaporated. Compound IV was obtained with an almost quantitative yield.

Compound IV is soluble in $CHCl_3$, ethylic ether, benzene, CCl_4, ethanol and NaOH solution. Characteristics are shown in tables 1 and 3.

Table 3

R_f values of compounds IV, V and VI (thin layer chromatogram with silica gel G)

Compound	R_f	The developing mixture
IV	0.45	benzene-ether-ethanol (10 : 0.5 : 0.1)
V	0.30	benzene-ethanol (10 : 0.5)
VI	0.50	benzene

— *Hydrazinolysis.* Solving III (100 mg) in dimethylformamide (3 ml) or better in absolute ethanol (10 ml) and adding hidrazine hidrate (2 ml), a yellow precipitate appears immediately. The precipitate was filtered and washed with petroleum ether (5—10 ml). The transformation of III into V is almost quantitative.

Compound V is easily soluble in $CHCl_3$ and ethanol, but less in CCl_4 and insoluble in water. Characteristics are shown in tables 1 and 3.

— *Phenylhydrazinolysis.* A solution of III (100 mg) in dimethylformamide (3 ml) was treated with phenylhydrazine (2 ml). The formed precipitate was filtered off and washed with some ml of petroleum ether. The transformation III into VI was quantitative. Characteristics of hydrazide VI are shown in tables 1 and 3.

Acknowledgements. The authors are indebted to Dr. Horst Schumacher from Badische Anilin-Soda Fabrik AG, Ludwigshafen, West Germany, for providing a sample of retinal.

Eingegangen am 20. März 1973

3H-Phenothiazin-3-[4-anilsulfonsaures Kalium] (Ia), 3H-Phenothiazin-3-[3-anilsulfonsaures Kalium] (Ib) und 3H-Phenothiazin-3-[2-anilsulfonsaures Kalium] (Ic) können als Säure-Basen-Indikatoren zur Titration einer starken Säure mit einer starken Base und umgekehrt, sowie zur Titration einer schwachen Säure mit einer starken Base benützt werden. Diese drei Verbindungen, entsprechend Chamäleonblau I(Ia), II(Ib) und III(Ic) genannt, sind in Wasser löslich und haben zwei Protonierungsstufen. Der pK_s-Wert der monoprotonierten Form ist bei 21° gleich 7,7 für die Indikatoren Ia und Ic und 7,93 für den Indikator Ib.

EINFÜHRUNG

In einer vorhergehenden Arbeit[1] synthetisierten wir 3H-Phenothiazin-3-[4-anilsulfonsaures Kalium] (Ia), 3H-Phenothiazin-3-[3-anilsulfonsaures Kalium] (Ib) und 3H-Phenothiazin-3-[2-anilsulfonsaures Kalium] (Ic) über die Oxydation des Phenothiazins mit Eisen-3-chlorid in Anwesenheit der Kaliumsalze der Sulfanil-, Metanil- und Ortanilsäure. 3-Anil-3H-Phenothiazin, von welchem die Salze Ia, Ib und Ic abkommen, wurde von Kehrmann und Vesely noch im Jahre 1902 erhalten[2].

Die Synthese und Reinigung dieser drei Substanzen ist äußerst einfach; sie bilden mit Wasser blaue Lösungen und bieten in Abhängigkeit vom pH-Wert zwei Protonierungsstufen, welche durch eine zweifache Farbänderung bemerkbar sind.

DER MONOPROTONIERUNGSGRAD α UND DER FARBUMSCHLAGSBEREICH

Die Absorptionsmaxima und die entsprechenden Extinktionsmolarkoeffizienten des Chamäleonblau I, II und III in der basischen und monoprotonierten Form sind in der Tabelle 1 wiedergegeben.

Der Monoprotonierungsgrad α wurde auf spektrophotometrischem Wege in Abhängigkeit vom pH-Wert bestimmt. Zu diesem Zwecke wurden die Absorptionen der Farbstoffe bei den Wellenlängen von 660 nm für Ia, 640 nm für Ib und 620 nm für Ic, in Betracht gezogen. Der Protonierungsgrad des Chamäleonblau I, II und III als Funktion des pH ist in Tab. 2 – 4 illustriert.

Tabelle 1

Die Absorptionsmaxima und die entsprechende Extinktionsmolarkoeffizienten des Chamäleonblau I, II und III in der basischen und monoprotonierten Form

	Chamäleonblau I	Chamäleonblau II	Chamäleonblau III
pH = 11 basische Form	$\lambda_{max(1)} = 560$ nm $\varepsilon_{560} = 27.370$	$\lambda_{max\,(1)} = 560$ nm $\varepsilon_{560} = 23.050$	$\lambda_{max\,(1)} = 546$ nm $\varepsilon_{546} = 22.900$
	$\lambda_{max\,(2)} = 294$ nm $\varepsilon_{294} = 37.620$	$\lambda_{max\,(2)} = 290$ nm $\varepsilon_{290} = 27.740$	$\lambda_{max\,(2)} = 290$ nm $\varepsilon_{290} = 29.310$
pH = 5,80 säure Form	$\lambda_{max\,(1)} = 660$ nm $\varepsilon_{660} = 50.620$	$\lambda_{max\,(1)} = 648$ nm $\varepsilon_{648} = 36.000$	$\lambda_{max\,(1)} = 640$ nm $\varepsilon_{640} = 49.750$
	$\lambda_{max\,(2)} = 308$ nm $\varepsilon_{308} = 42.370$	$\lambda_{max\,(2)} = 304$ nm $\varepsilon_{304} = 28.920$	$\lambda_{max\,(2)} = 304$ nm $\varepsilon_{304} = 33.620$

Tabelle 2

Der Protonierungsgrad α des Chamäleonblau I in Verhältnis zum pH (im Falle einer $1{,}6 \times 10^{-5}$ M Lösung bei 21°)

pH	E_{660}	α
2,20	0,8100	1,0000
5,90	0,8100	1,0000
6,10	0,7960	0,9802
6,55	0,7700	0,9434
7,00	0,6680	0,7993
7,40	0,5690	0,6594
7,70	0,4560	0,4997
7,80	0,4260	0,4573
8,00	0,3716	0,3804
8,30	0,2366	0,1895
8,40	0,2007	0,1389
8,60	0,1549	0,0742
8,95	0,1308	0,0401
9,95	0,1024	0,0000
11,00	0,1024	0,0000

Der Protonierungsgrad α wurde über folgenden Ausdruck berechnet :

$$\alpha = \frac{E_a - E_2}{E_1 - E_2}$$

in welchem :

E_a — die Extinktion des Gemisches beider Formen, basisch und monoprotoniert, darstellt ;

E_1 — die Extinktion der monoprotonierten Form (für Ia bei pH = = 2,2, für Ib bei pH = 6 und für Ic bei pH = 3) ist;

E_2 — die Extinktion der basischen Form (für Ia, Ib, Ic bei pH = = 11) ist.

Tabelle 3

Der Protonierungsgrad α des Chamäleonblau II im Verhältnis zum pH (im Falle einer 1,25 × 10^{-5} M Lösung bei 21°)

pH	E_{640}	α
6,60	0,4440	1,0000
6,55	0,4440	1,0000

In den Abbildungen 1–3 sind die charakteristischen Kurven des Chamäleonblau I, II und III wiedergegeben. Aus diesen ersieht man die Farbumschlagsintervalle (für $0{,}10 \leqslant \alpha \leqslant 0{,}90$) der drei Indikatoren

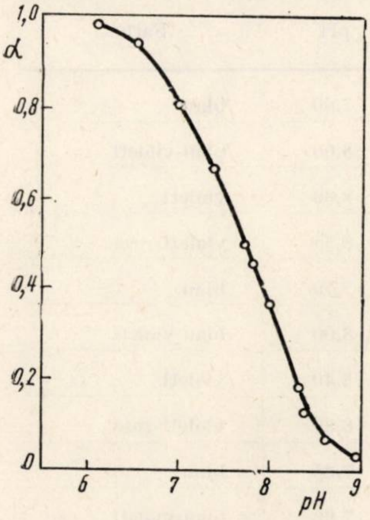

Abb. 1.—Die charakteristische Kurve des Chamäleonblau I.

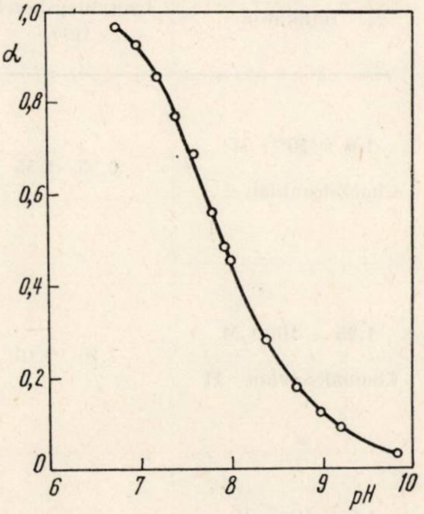

Abb. 2.—Die charakteristische Kurve des Chamäleonblau II.

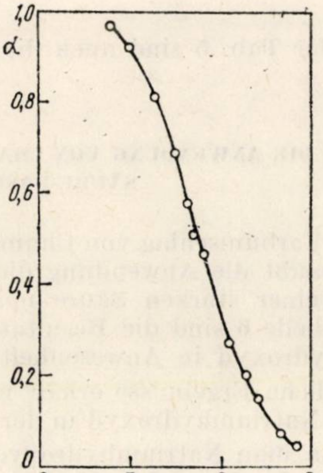

Abb. 3.—Die charakteristische Kurve des Chamäleonblau III.

(Tab. 5), sowie den pK_s-Wert der monoprotonierten Form, der für das Chamäleonblau I und III gleich 7,7, und für das Chamäleonblau II gleich 7,93 ist.

Tabelle 5

Die Farbumschlagsintervalle des Chamäleonblau I, II und III für $0{,}10 \leqslant \alpha \leqslant 0{,}90$

Indikator	Umschlagsbereich (pH)	Farbänderung im Umschlagsbereich	
		pH	Farbe
$1{,}6 \times 10^{-5}$ M Chamäleonblau I	6,75–8,55	7,60	blau
		8,00	blau-violett
		8,30	violett
		8,55	violett-rosa
$1{,}25 \times 10^{-5}$ M Chamäleonblau II	7,10–9,10	7,70	blau
		8,00	blau-violett
		8,40	violett
		8,80	violett-rosa
$1{,}6 \times 10^{-5}$ M Chamäleonblau III	7,05–8,50	7,25	blau
		7,80	blau-violett
		8,05	violett-rosa
		8,40	rosa-violett

In der Tab. 5 sind auch die Farbänderungen der Indikatoren angegeben.

DIE ANWENDUNG VON CHAMÄLEONBLAU I, II UND III ALS SÄURE-BASEN-INDIKATOREN

Der Farbumschlag von Chamäleonblau I, II und III von blau nach violett erlaubt die Anwendung dieser Indikatoren mit gutem Erfolg zur Titration einer starken Säure mit einer starken Base und umgekehrt. In der Tabelle 6 sind die Resultate der Titration von Schwefelsäure mit Natriumhydroxyd in Anwesenheit von Chamäleonblau I wiedergegeben.

Ähnliche Ergebnisse erhält man auch beim Titrieren der Schwefelsäure mit Natriumhydroxyd in der Gegenwart der Indikatoren Ib und Ic.

Wenn man Natriumhydroxyd mit Schwefelsäure in Anwesenheit der Indikatoren Ia, Ib und Ic titriert, ist der Äquivalenzpunkt durch einen umgekehrten Farbumschlag, von violett nach blau angezeigt, während die Titrationsfehler von der gleichen Größenordnung sind wie jene die in der Tabelle 6 angegeben sind.

Der gut sichtbare Farbumschlag des Chamäleonblau I und II von blau nach violett-rosa erlaubt auch die Bestimmung des Äquivalenzpunktes im Falle der Titration einer schwachen Säure mit einer starken Base (Tabelle 7).

Tabelle 6

Die Titration von Schwefelsäure mit Natriumhydroxyd in Anwesenheit von Chamäleonblau I (Farbumschlag von blau nach violett)

H_2SO_4 N/10 zur Titration (in ml)	Verbrauch an NaOH N/10 (in ml)	Abweichung in ml	Abweichung in %
10	9,98	−0,02	−0,20
10	9,99	−0,01	−0,10
10	10,01	+0,01	+0,10
10	10,01	+0,01	+0,10
10	10,00	0,00	0,00
10	10,01	+0,01	+0,10
10	10,00	0,00	0,00
10	10,01	+0,01	+0,10

$\overline{X} = 10{,}00125$

$s_{\overline{x}} = 0{,}00375$

$\varepsilon = t_{95}\, s_{\overline{x}} = 2{,}37 . 0{,}00375 = 0{,}00889$

$\overline{X} \pm \varepsilon = 10{,}00125 \pm 0{,}00889$

Tabelle 7

Titration von Essigsäure mit Natriumhydroxyd in Anwesenheit von Chamäleon blau I (Farbumschlag von blau nach violett-rosa)

CH_3COOH N/10 zur Titration (in ml)	Verbrauch an NaOH N/10 (in ml)	Abweichung in ml	Abweichung in %
10	9,99	−0,01	−0,10
10	9,98	−0,02	−0,20
10	10,00	0,00	0,00
10	9,99	−0,01	−0,10
10	9,99	−0,01	−0,10
10	9,98	−0,02	−0,20
10	10,01	+0,01	+0,10
10	9,99	−0,01	−0,10

$\overline{X} = 9{,}99125$

$s_{\overline{x}} = 0{,}0048$

$\varepsilon = t_{95} . s_{\overline{x}} = 2{,}77 . 0{,}0048 = 0{,}0114$

$\overline{X} \pm \varepsilon = 9{,}99125 \pm 0{,}0114$

Tatsächlich erhält man beim Titrieren der Essigsäure mit Natriumhydroxyd in der Gegenwart der Indikatoren Ia und Ib Fehler der gleichen Größenordnung wie in der Tabelle 6.

Zwecks einer guten Wahrnehmung des Äquivalenzpunktes, setzt man zu 10 ml Probe 1 ml wäßrige 1×10^{-4} M Lösung Chamäleonblau I oder III, oder 1 ml $1{,}25 \times 10^{-5}$ M Lösung Chamäleonblau II.

Wir stellten fest, daß die neuen Indikatoren zeitlich stabil sind, so im sauren als auch im basischen Medium. Im sauren Medium werden sie aber von manchen starken Reduzierungsmitteln entfärbt (z. B. Ascorbinsäure, Schwefelwasserstoff, Merkaptane, u.s.w.) und gehen in ihre Leukoderivate über. Schwefeldioxyd entfärbt aber diese Indikatoren viel schwerer.

ZUSAMMENFASSUNG

Zur Titration einer starken Säure mit einer starken Base und umgekehrt können die Indikatoren Ia, Ib und Ic ohne Vorzug mit den gleichen Ergebnissen verwendet werden, weil der Äquivalenzpunkt sehr leicht zu bemerken ist.

Im Falle der Titration einer schwachen Säure mit einer starken Base wird empfohlen als Indikator nur das Chamäleonblau I und II zu verwenden, weil in Anwesenheit von Chamäleonblau III der Äquivalenzpunkt schwer zu bemerken ist, bzw. das Übergehen von violett-rosa nach rosa-violett.

REGISTRIERUNGSBEDINGUNGEN DER ABSORBTIONSSPEKTREN

Die Pufferlösungen mit verschiedenen pH-Werten wurden nach Sörensen und Mc.Ilvain hergestellt. Der pH-Wert wurde ständig mit einem pH-meter geprüft.

Zur spektralen Absorptionsprüfung wurden 1,6 $\times 10^{-5}$ M Lösungen von Chamäleonblau I und III und 1,25 $\times 10^{-5}$ M Lösungen von Chamäleonblau II verwendet. Die Extinktionen wurden mit einem Beckman DB Spektrophotometer bei 21° bestimmt.

AN ION-EXCHANGE PROCESS FOR GOLD RECOVERY

SEVER A. TĂTARU

Department of Technological Research for Radioactive Metals, Bucharest —
Măgurele, P. O. Box 35, Romania

Received October 27, 1972

An ion-exchange process has been developed for gold recovery from cyanide solutions. It is shown that strongly basic ion-exchange resins, having a high adsorption capacity but a low selectivity for gold, offer the possibility to recover besides precious metals also the alkaline cyanide, which can finally be recycled to leaching. By using a mixture of hydrochloric acid and thiourea, a total elution of the precious metals and cyanide was obtained. The hydrocyanic acid resulting from the elution and the decomposition of the cyanides was wholly converted into sodium cyanide by contacting it with a sodium hydroxide solution. Lead cementation and electrolytic precipitation of hold have been tested for gold recovery from thiourea eluates. Two possible procedures using the resin-in-pulp process for gold recovery are described.

1. INTRODUCTION

The only known hydrometallurgical procedure for the recovery of gold and silver from ore, cyanidation, followed by reduction with zinc and refining, has several disadvantages and this has led to the use of combined and diversified processing technologies and also to research work aiming at improving the process.

One possible recovery technique is by use of ion-exchange resins. The first attempts to adsorb gold on ion exchange resins are very probably due to Gans,[1-2] but later the preparation of better quality resins offered the possibility of obtaining better results,[3-5] and of applying the procedure in practical industrial purposes.[6-9] The lack of selectivity of strongly basic

ion-exchange resins for precious metals, noted in all papers, has hindered their use in gold hydrometallurgy, although in some cases, this lack of selectivity leads to the possibility of using ion exchange resins in cyanidation, because, after complete adsorption of all the complex cyanides and of the free cyanide, not only the precious metals can be recovered but also the alkaline cyanide,[10-12] which then can be recycled to leaching.

The aim of this work is to show how can ion exchange non-selective resins be used for gold recovery, in conjunction with cyanidation.

2. EXPERIMENTAL

2.1. RAW MATERIALS

The gold bearing raw material, on which the present research work was carried out, was the residue coming from an industrial plant in which the major part of the chalkophile elements, of gold and silver contained in the ore has been separated by flotation. These residues are commonly processed on an industrial scale by cyanidation to extract the remaining gold and silver. In the present investigation the feed material ground to 0.1 mm has cyanided for 6 hours with solutions containing 0.06% NaCN and 0.05% CaO, and the leach solutions after filtration had the following composition (in g/l):

Cu – 0.033
Fe – 0.0178
Zn – traces
SiO_2 – 0.007
NaCN – 0.34
CaO – 0.154
Au – 6 g/m^3
Ag – 0.8 g/m^3

The study of the adsorption was undertaken on different ion-exchange resins, chosen between those which, as the result of previous trials, had been shown to have the best adsorption characteristics and the best kinetics for gold and silver. All the resins used in the experiments were initially in the chloride form.

2.2. GOLD ADSORPTION BY ION EXCHANGE RESINS

The relatively simple composition of the solution obtained by cyaniding has allowed us to examine the use of highly basic resins. Previous research work has shown that these have a high adsorption capacity, but exhibit a law selectivity for gold. A typical highly basic resin AV–17 is the copolymerization product of chloromethylated styrene, having divinylbenzene as cross-linking substance. This resin was contacted with the gold-bearing solution under both staic and dynamic conditions, to determine the adsorption capacity and the saturation isotherms.

In the static conditions the resin was stirred with clarified solution or with pulp directly after cyaniding. From the chemical point of view the results were almost identical but the rate of adsorption from pulp solutions was lower. This, however, was due to the fact that resin size of the resin beads was larger in the RIP tests. The results obtained have made it possible to conclude that the main technological parameters are actually the same for the adsorption of the gold from clear and from pulp solutions.

2.2.1. Influence of the accompanying elements on gold adsorption

The tests in which the ion-exchange resin and the industrial gold-bearing solution were contacted under dynamic conditions, passing the solution through a fixed resin bed at a constant rate of 1 l solution/1 l resin per minute, have shown that copper and iron saturate the resin rapidly, their concentrations in the effluent being equal to their concentration in the initial solution after passing about 600 volumes of solution through a single volume of resin. Once the saturation is reached, one notices a partial elution of the adsorbed copper and iron, their place being very probably taken by the free cyanide. The saturation of the resin by CN ions was observed after having passed about 1800 volumes of the solution. At this point some cyanide is present in the exit solution. The maximum dynamic capacity for gold was reached after having passed about 3 000 volumes of the solution for each volume of resin, and it was equal to 5.54 kg Au/m^3 resin. Under these conditions the resin contained the following quantities of other adsorbed components :

— silver	1.2 kg/m^3
— cooper	80 ,,
— iron	34 ,,
— NaCN	100 ,,

Because of the low selectivity of the resin regarding gold and silver, the proportion of precious metals on the resin is low.

2.2.2. Influence of the flotation reagents

As the majority of the flotation reagents pass into the pulp submitted to ion exchange, they can influence the adsorption of the gold by ion-exchange resins. To study this influence, controlled quantities of reagent were added, after cyanidation, to the industrial solution and adsorption tests then carried out under dynamic conditions.

The results obtained (figure 1) show that the collecting reagents have a negative influence on the adsorption of gold, by reducing the adsorption capacity for gold. This is very probably due to the adsorption of the reagents themselves by the resin.[13]

[13] S. TĂTARU, *Studii și Cercetări de Metalurgie*, **2**, 139 (1965).

2.3. THE ELUTION

2.3.1. Elution by means of hydrochloric acid

With HCl solution (0.5 N) as the elution reagent it is possible to recover the cyanide after its decomposition in the resin phase, by the action of the acid. In the present work the equipment was operated at 600 mmHg pressure and the released hydrocyanic acid was entirely captured by the solution of the first flask.

The quantity of sodium cyanide determined in the Tishtchenko absorber exceeded by 36% the whole quantity of free cyanide adsorbed by the ionite resin, which infers that partial destruction of the adsorbed complex cyanides has taken place. The hydrochloric effluent, however, contained only 2% of the adsorbed copper and only traces of iron and the gold and silver were not eluated at all. It is, therefore, highly probable that the cyanide excess in the eluent is due to the formation, in the resin phase, of the iron and copper cyanides, poorer in CN.

By further adsorption into resin, partially eluated by HCl, it was possible, after 3 adsorption-eluation cycles, to obtain a higher degree of adsorption of gold and silver, and a more favourable proportion of precious metals in the resin phase, namely:

— gold . . . . . 8.8 kg/m^3 — cooper 112 kg/m^3
— silver . . . . . 2.7 ,, — iron . . . . 57 ,,
— NaCN . . . 41 ,,

This saturation procedure is however inconvenient, as it requires very strict measures to avoid release of hydrocyanic acid, and, having a fairly low efficiency, has been considered as lacking in practical importance.

2.3.2. Elution with a mixture of hydrochloric acid and thiocarbamide

Attempts have been made to eluate the resin by means of different mixtures containing a mineral acid and a salt, or a mineral acid and an organic solvent. Total elution has not been achieved but the best results were obtained by using a mixture containing 2% HCl and 6% $CS[(NH_2)_2]$ as first suggested by Davankow.[14] By passing a solution having this composition over the bed of a saturated resin, at a rate of 0.3 l/l resin-minute, it was possible to obtain total elution of the precious metals and copper, a recuperation of the cyanide and 93.2% elution of the adsorbed iron.

The partial elution of iron necessitated supplementary research work.

It is highly probable that, while the precious metals and the copper adsorbed on the resin are converted, under the action of the hydrochloric and thiocarbamide solution, into complex cationic type combinations which are not retained by the anionic resin:

$$R\,Au(CN)_2 + 2CS(NH_2)_2 + HCl = RCl + Au[CS(NH_2)_2]Cl + HCN \qquad (1)$$

the complex cyanides of iron are not totally decomposed by the mixture and remain in the resin phase.

Increasing the hydrochloric acid concentration in the elution mixture did not increase the quantity of eluated iron, but stimulated the formation of molecular sulphur.

[14] A. B. Davankov and V. M. Laufer, *Zhur. priklad. Khim.*, **32**, 117 (1959).

2.3.3. Elution by means of sodium cyanide

The total elution of the iron retained by the resin has been achieved by means of 2N NaCN solutions. By working in conditions identical to those mentioned above using concentrated cyanide solutions, a total elution of the iron that remained in the resin was possible. Though elution by means of concentrated sodium cyanide solutions, before or after elution by hydrochloric thiocarbamide solutions, is not very desirable, it has the advantage of being periodical, according to the accumulation of iron in the resin phase, and to imply only a consumption of hydrochloric acid and sodium hydroxide. The relevant elution curves are shown in figure 2.

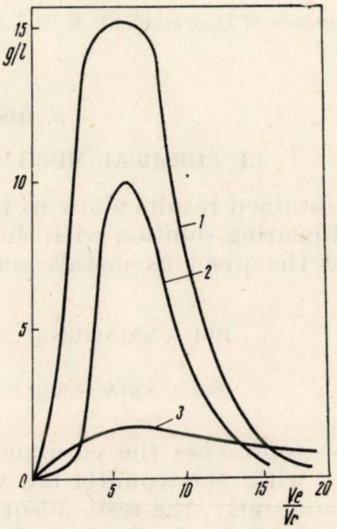

Fig. 2. — Elution of the ion exchange resin AV−17

1, Fe, by means of NaCN; *2*, Au, by means of HCl + CS(NH$_2$)$_2$; *3*, Fe, by means of HCl+CS(NH$_2$)$_2$: V_e/V_r is the ratio: volume of exit solution/volume of resin.

2.4. RECOVERY OF GOLD

The recovery of gold from hydrochloric thiocarbamide solutions after elution is possible by displacement with any less noble metal. Iron and copper were tested and have shown positive results but the precipitates obtained could not be conveniently treated by the existing technology.

2.4.1. Cementation with lead

The precipitation of gold by cementation with lead was tested both by passing an eluate solution containing 8.34 g Au/l over a granular lead bed and by stirring the solution thoroughly with lead powder. These experiments have shown that the lead surface has a preponderant role and that cementation by stirring is more advantageous since a finer powder can be used with no difficulties of a hydrodynamic nature.

The minimal lead consumption was 7.5 g Pb/g Au. This was obtained by contacting the eluate with lead particles having a 43 micron diameter.

Under these conditions the cementation by stirring had the advantage that the eluate was fully stripped and that of securing the depolarization of the cathodes of the system microelements through a continuous flow of solved oxygen fixing the released hydrogen.

The precipitate obtained by lead cementation was treated by cupellation and a "Dore" alloy was obtained which could be turned into good use.

2.4.2. Electrolytic precipitation of gold

The electrolytic precipitation of gold has proved more advantageous than other procedures. It has been achieved in several ways under different technological conditions. The use of pure gold cathodes has proved valuable for practical use but other materials are also suited for cathodes.[15]

The presence of thiocarbamide in the electrolyte has favoured the production of dense precipitates.[16]

3. DISCUSSION

3.1. CHEMICAL MECHANISM OF THE PROCESS

The obtained results allow us to conclude that during the contacting of the gold-bearing solution with the ion-exchange resins these adsorb the cyanides of the precious metals according to reactions of the following type :

$$\mathrm{RCl} + \mathrm{Na[Au(CN)_2]} \rightleftarrows \mathrm{RAu(CN)_2} + \mathrm{NaCl} \tag{2}$$

$$\mathrm{RCl} + \mathrm{Na[Ag(CN)_2]} \rightleftarrows \mathrm{RAg(CN)_2} + \mathrm{NaCl} \tag{3}$$

where : R — represents the cationic frame of the resin initially charged with the counter-ion Cl.

Concomitantly, the resin adsorbs the complex cyanides of the heavy metals contained in the feed to the ion exchange step :

$$\mathrm{RCl} + \mathrm{Na[Cu(CN)_2]} \rightleftarrows \mathrm{R[Cu(CN)_2]} + \mathrm{NaCl} \tag{4}$$

$$\mathrm{RCl} + \mathrm{Na[Cu(CN)_3]} \rightleftarrows \mathrm{R[Cu(CN)_3]} + \mathrm{NaC} \tag{5}$$

$$\mathrm{2RCl} + \mathrm{Na_2[Cu(CN)_3]} \rightleftarrows \mathrm{R_2[Cu(CN)_3]} + \mathrm{2NaCl} \tag{6}$$

$$\mathrm{2RCl} + \mathrm{Na_2[Zn(CN)_4]} \rightleftarrows \mathrm{R_2[Zn(CN)_4]} + \mathrm{2NaCl} \tag{7}$$

$$\mathrm{4RCl} + \mathrm{Na_4[Fe(CN)_6]} \rightleftarrows \mathrm{R_4[(Fe(CN)_6]} + \mathrm{4NaCl} \tag{8}$$

Taking into account the possible presence in the cyaniding solution of other complex cyanides and the different forms these may adopt, the above relationships can be synthetized in a more general form according to the equation :

$$\mathrm{nRCl} + \mathrm{Me(CN)}_i^{n-} \rightleftarrows \mathrm{R_nMe(CN)_i} + \mathrm{nCl^-} \tag{9}$$

---

[16] S. Tătaru, Brevet R.S.R. N° 48367 (1963).

where :

Me — is the dissolved metal ;

n — is the valence of the complex anion ;

i — is the coordinative number.

It is worth mentioning that ion-exchange resin also adsorbs, concomitantly with the complex cyanides, the free cyanide in the solution :

$$RCl + NaCN \rightleftarrows RCN + NaCl \quad (10)$$

The lack of selectivity of the strongly basic ion-exchange resins for precious metals is not in this case, a disadvantage, as the acid thiocarbamide elution allows the recovery and recirculation of cyanide which occupied the major part of the active groups of the resin.

The contacting of the acid eluent with the saturated resin has permitted the replacement of the hydrocyanic ions by Cl^- ions :

$$RCN + HCl = RCl + HCN \quad (11)$$

The hydrocyanic acid thus released was absorbed in sodium hydroxide solution and transformed into an alkaline cyanide, which could then be recycled :

$$HCN + NaOH = NaCN + H_2O \quad (12)$$

The experiments undertaken have shown that the hydrocyanic acid resulting through the elution and the decomposition of the complex cyanides was totally converted into sodium cyanide.

The complex combinations of the copper adsorbed by the resin are eluted by the mixture of hydrochloric acid and thiocarbamide, and a complex cationic combination $Cu[CS(NH)_2]_2$ is formed. This is not held by the anionic resins. This elution of copper enables us to obtain a supplementary quantity of hydrocyanic acid, which, reacting with sodium hydroxide, forms the alkaline cyanide according to reaction (12).

The pecipitation of gold by means of lead powder takes place very probably according to a reaction [17,18] :

$$2Au[CS(NH_2)_2]_2Cl + Pb \longrightarrow Pb[CS(NH_2)_2]_4Cl_2 + 2Au \quad (13)$$

3.2. POSSIBILITIES OF CARRYING OUT THE PROCESS

There are several ways in which ion-exchange resins can be used in cyanidation, and the best way is determined by local conditions.

It is to be expected that the most difficulties will arise when the process is applied to the cyanidation of auriferous concentrates obtained

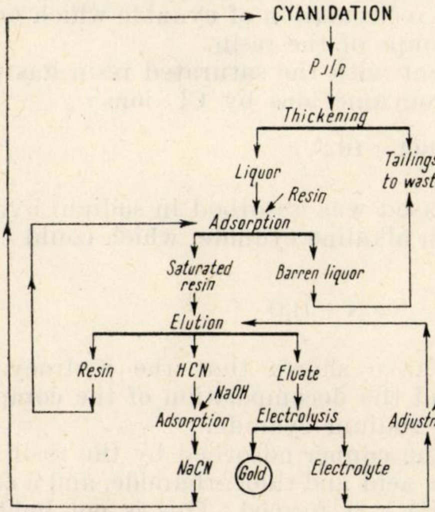
[18] N. S. Kurnakov, *Zhur. rusk. fiz. Khim. Obschch*, 1891, 559.

by flotation. Indeed these have a high content of sulphur and of chalcophile elements, which form complex cyanides that can be adsorbed by the resin.

Conversely, one of the most favourable cases is very probably to be found when the process is applied to the cyanidation of auriferous tailings, as the tenor of sulphur and accompanying metalls is then at its lowest.

The results obtained enable us to suggest several possible variants for the use of ion-exchange resins in cyanidation ; two of these variants are presented below :

A — Cyanidation of auriferous raw material followed by separation of the phases and adsorption of the gold by ion-exchange resins from clarified solutions. This process is illustrated in figure 3.



CYANIDATION
Pulp
Thickening
Liquor
Tailings to waste

Fig. 4. — Flowsheet for gold recovery from pulps.

In this case the adsorption is not selective, the ionite resin adsorbs, besides the gold cyanide, the complex cyanides of common metals and the free cyanide. The barren liquor can be sent to the waste-dump, together with the tailings from the last stage of the phase separation.

The saturated resin is submitted to elution by means of a 2 % HCl + +6% $CS(NH_2)_2$ solution. The hydrocyanic acid released in gaseous form is absorbed by a 20% NaOH solution, and the resulting sodium cyanide is recycled to leaching. The liquid eluate is submitted to electrolysis.

B. A second technological variation (figure 4) differs from the preceding one by the fact that the adsorption on the ion exchange resin does not take place from the clarified solution, but directly from the pulp, by the RIP (resin in pulp) procedure.

A technology without phase separation has positive repercussions on the economy of the procedure but its practical use is conditioned by the existence of ion exchange resins with high granulation and mechanical resistance, comparable, for instance, to those used in uranium hydrometallurgy ("RIP" procedure).

The efficiency of the procedure and exhaustion degree of the liquid phase depend on the number of devices in the adsorption chain, on the quality of the proportioning of the substances, and on the maintaining of the ratio resin/pulp.[19,20]

The economy of the process is influenced by the fact that a certain loss of resin in unavoidable after contacting it with a rather dense pulp, but the loss of gold with the macerated resin is immaterial, as it comes out of the apparatus with the poorest solution (the last contacting of the pulp before draining into the waste-dump).

The "Resin in Pulp" variant allows the use of the "counter-current" principle for the saturation of the resin, and a different retention time in each stage for the resin and for the pulp has proved favourable. The elution may also be carried out in counter-current (after a previous washing to remove the dirt) with a good-enough ruling of the gold content in the eluent.

We must point out that variant B offers obvious advantages compared to variant A as the resin totally adsorbs the gold of the liquid phase and ensures a better exhaustion of it, without requiring rather costly and difficult operations, such as tickening or washing on filters.

[20] S. TĂTARU, Romanian Brevet N° 45311 (1963).

In the case the adsorption B, not selective, the entire resin adsorbs, besides the gold cyanide, the complex cyanides of common metals and the free cyanide. The barren liquor can be sent to the waste dump, together with the tailings from the last stage of the phase separation.

The saturated resin is submitted to elution by means of a $2\,N$ HCl + 6% NH_4Cl solution. The hydrocyanic acid released in gaseous form is adsorbed by a 20% NaOH solution, and the resulting sodium cyanide is recycled to leaching. The liquid eluate is submitted to electrolysis.

D. A severe technological variation (Figure 4) differs from the preceding one by the fact that the adsorption on the ion exchange resin does not take place from the clarified solution, but directly from the pulp by the "RIP" (resin in pulp) procedure.

A technology without phase separation has positive repercussions on the economy of the procedure but its practical use is conditioned by the existence of ion exchange resins with high granulation and mechanical resistance, comparable, for instance, to those used in uranium hydrometallurgy ("RIP" procedure).

The efficiency of the procedure and exhaustion degree of the liquid phase depend on the number of devices in the adsorption chain, on the quality of the proportioning of the substances, and on the maintaining of the ratio resin-pulp.[27,28]

The economy of the process is influenced by the fact that a certain loss of resin is unavoidable after contacting it with a rather dense pulp, but the loss of gold with the uncaptured resin is immaterial, as it comes out of the equipments with the poorest solution (the last contacting of the pulp before draining into the waste dump).

The "Resin in Pulp" variant allows the use of the "counter-current" principle for the saturation of the resin, and a different retention time in each stage for the resin and for the pulp has proved favourable. The elution may also be carried out in counter-current (after a previous washing to remove the dirt) with a good enough raising of the gold content in the eluent.

We must point out that variant B offers obvious advantages compared to variant A as the resin totally adsorbs the gold of the liquid phase and ensures a better exhaustion of it, without requiring rather costly and difficult operations, such as thickening or washing on filters.

CATALYTIC DEHYDROGENATION KINETICS OF *n*-BUTENES TO BUTADIENE

GEORGETA ANDREI, GHEORGHE ŞERBAN, CORINA FLORIŢA

Petrochim Research Institute, B-dul Republicii N° 291, Ploieşti, Romania

Received March 24, 1973

The present paper investigates the kinetics of dehydrogenation reaction of *n*-butenes to butadiene at temperatures ranging between 440–480°, at *n*-butenes partial pressures of 0.03 to 0.12 atm in the presence of water vapour, over a $Cr_2O_3-Fe_2O_3-ZnO$ catalyst. From the reaction rate data determined experimentally by the technique of a continuous differential reactor, it was found that the rate determining step is the surface reaction which is taking place on dual sites based on a Langmuir – Hinshelwood mechanism. The reaction rate constants, the adsorption equilibrium constants of *n*-butenes and hydrogen as well as the apparent activation energy for the transformation reaction on the catalyst, were calculated.

INTRODUCTION

Butadiene, one of the basic monomers used to obtain synthetic rubber is manufactured in industry by *n*-butenes catalytic dehydrogenation.

The practical and scientific importance of *n*-butenes catalytic dehydrogenation to butadiene is illustrated among others by a great number of papers referring to this item.

Thus, even since 1948, Beckberger and Watson have carried out a kinetic study on *n*-butenes dehydrogenation in the presence of water vapour and of a catalyst made of an oxides mixture.[1]

Using an integral reactor and a corresponding technique the authors have discovered experimentally that the rate-determining step is the surface reaction on dual active sites.

Another remarkable contribution to the elucidation of this reaction was brought by Balandin's papers.[2,3]

[3] O. K. Bogdanova, A. P. Scheglova and A. A. Balandin, *Doklady Akad. Nauk S. S. S. R.*, **129**, 1293 (1959).

Important contributions to the study of the kinetics of *n*-butenes dehydrogenation to butadiene in the presence of water vapour and catalysts of oxide mixture type were brought by Liubarskii, Pşejetskii[4] and Tiuriaev.[5]

In all the above papers, the kinetic studies were performed on continuous integral reactors at high temperature.

Quite recently the researchers have started to use more and more frequently for the study of the kinetics of organic compounds dehydrogenation the technique of the continuous differential reactor at low conversions.

The authors of the present paper intend to apply this technique to the study of the kinetics of *n*-butenes dehydrogenation in the presence of water vapours on a catalyst made of a mixture of chromium, iron and zinc oxides.

The experimental data were read using the Langmuir-Hinshelwood mechanism, admitting that the *n*-butenes dehydrogenation rate is determined by the surface reaction which takes place on dual active sites.

EXPERIMENTAL

EQUIPMENT AND PROCEDURE

Chemical kinetics experiments were performed in a continuous type unit (fig. 1), in a microreactor with an inside diameter of 22 cm, equipped with a serpentine for preheating the gas mixture and heated with a bronze block furnace.

The reaction temperature was measured at the middle of the catalytic bed using a Philips microthermocouple and was kept constant with a precision of ±1°.

[5] I. Ia. Tiuriaev and V. A. Kolobihin, *Kinetika i Kataliz.*, **2**, 429 (1961).

The mixture between *n*-butenes and water vapour, corresponding to the different partial pressure of the hydrocarbon, was achieved in an evaporator (1) heated by a thermostat (2).

At the reactor outlet, after condensing the water vapour, the reaction products were analysed using a Willy-Giede chromatograph equipped with a cell for thermal conductivity.

The chromatographic column had a length of 6 m, an inside diameter of 5 mm and was stuffed with celit of 100 – 200 mesh, impregnated with 20 % dimethylsulfolane.

Hydrogen was used as the carrier.

In all kinetic determinations 2 g were used of an industrial catalyst of the type Cr_2O_3, Fe_2O_3 and ZnO mixture, at a granulosity of 0.3 – 0.6 mm brought at the same activation conditions. The catalyst has BET surface area of 25 m^2/g and pores bulk volume of 0.342 cm^3/g. To avoid temperature gradients in the catalytic bed the catalyst was diluted with 10 cc quartz of the same granulosity.

The catalyst was heated up to the working temperature in a stream of inert gases (nitrogen or argon). After introducing the mixture of *n*-butene and water vapour in the reaction area, at a certain partial pressure for the *n*-butenes, gas samples were withdrawn from time to time in order to be analysed by chromatography up to the moment when a constant activity of the catalyst was reached. In order to check the kinetic data reproducibility the gas sampling was repeated several times. After finishing the kinetic experiments, at a certain temperature the regeneration of the catalyst with air and water vapour was performed up to the total disappearance of the carbon dioxide from the gaseous effluent at the reactor outlet.

The reaction rate was calculated from the value of *n*-butenes conversion to butadiene and the time factor using the following formula

$$r = x/w/F \tag{1}$$

where

r — reaction rate, mole/h g

x — butene conversion to butadiene, % moles

w — catalyst weight, g

F — *n*-butene feed rate, mole/h

The results of an analysis obtained at the dehydrogenation of a mixture of *n*-butene having a concentration of 98.8 % mole on $Cr_2O_3 - Fe_2O_3 - ZnO$ catalyst are given in table 1.

Table 1

An example for a typical analysis

Reaction temperature, °C	440
n-butenes partial pressure, at	0.05
n-butenes feed rate, l/h	1.8
n-butene/water, molar ratio	1 : 19
Catalyst weight, g	2
Chromatographic analyses for reaction products, % mole :	
Ethane + ethylene	—
Propane	—
Propylene	0.0014
1-butene	38.364

cis-2-butene	38.047
Butadiene	0.505
n-butene conversion to butadiene, % mole	0.511
Selectivity, % mole	99.730
Reaction rate, mole/h g catalyst	0.000205

EXPERIMENTAL RESULTS

PRELIMINARY RUNS

In order to establish the reaction conditions, in which the catalyst keeps its activity constant, preliminary studies were made on the variation of *n*-butenes conversion as function of the reaction temperature and *n*-butenes partial pressure.

Thus, maximum conversions of 3% moles were determined by experiment at temperatures ranging between 440 to 480° and *n*-butenes partial pressures of 0.03–0.12 at, corresponding to some dilution ratios of 1 : 32.3 – 1 : 7.3 mole of *n*-butene/water vapour.

The preliminary runs also included those which aimed at checking the catalyst stability in the most favourable conditions for cracking reactions. In this case it was found experimentally that after a reaction time of 280 min, the conversion for transforming *n*-butenes into butadiene remained practically constant.

By passing *n*-butenes over quartz, under favourable conditions for the cracking reaction, it was found by experiment that *n*-butenes conversion is negligible in comparison with that obtained in *n*-butenes catalytic dehydrogenation.

Thus, at *n*-butenes dehydrogenation at the maximum reaction temperature of 480° and *n*-butene feed rate of 1.08 l/h, the *n*-butenes total conversion under 0.02% mole was achieved.

INFLUENCE OF EXTERNAL DIFFUSION

To evaluate the effect of external diffusion on *n*-butenes dehydrogenation rate to butadiene, the value of the $\Delta P_B/P_B$ ratio was calculated in the reaction conditions, where ΔP_B represents the difference between *n*-butenes partial pressure in the gas stream and the partial pressure of the same gas at the surface of the catalytic particles.[6]

The $\Delta P_B/P_B$ ratio was calculated employing the following relation

$$\Delta P_B/P_B = r/a_m\, k_g P_B \tag{2}$$

where

P_B — *n*-butenes partial pressure, atm,

r — *n*-butenes transforming rate into butadiene, mole/h g, catalyst,

a_m — catalytic particles external surface, cm^2/g catalyst,

k_g — *n*-butenes mass transfer coefficient, mole/sec cm^2 atm.

The *n*-butenes mass transfer coefficient (k_g) was determined using the mass transfer factor J_D[7]. The value $\Delta P_B/P_B$ thus calculated of 0.000335 for the experimental determinations, performed on the catalyst studied, shows that the partial pressure decrease on catalyst is so small that the external diffusion effect can be neglected.

---

[6] S. Carra, L. Forni and C. Vintani, *J. Catalysis*, **9**, 154, (1967).

[7] J. De Acetis and G. Thodos, *Ind. Eng. Chem.*, **52**, 1003 (1960).

INFLUENCE OF INTERNAL DIFFUSION

The influence of *n*-butenes internal diffusion inside the catalyst particles was studied on Thiele modulus [8] calculated with the following formula

$$\O = r_p^2\ \rho_p r/\mathrm{Deff}\ C_B \tag{3}$$

in which

r_p — catalyst particle mean radius, cm,
ρ_p — catalyst density, g/cm³,
r — reaction rate, mole/h g catalyst,
Deff — the effective diffusion coefficient, cm²/sec,
C_B — the surface concentration of *n*-butenes.

For an effective diffusion coefficient of 0.0985 cm²/sec, at a temperature of 480°, the following values for Thiele modulus were found which correspond to different partial pressures

$$\begin{aligned} \O &= 0.00113, \text{ at } P_{C_4H_8} = 0.03 \text{ atm.} \\ \O &= 0.000467, \text{ at } P_{C_4H_8} = 0.12 \text{ atm.} \end{aligned} \tag{4}$$

The practical effectiveness factor is equal to unity for such small values of the Thiele modulus and thus it can be asserted that the internal diffusion does not influence the reaction rate.

REACTION KINETICS

The kinetics of *n*-butenes dehydrogenation to butadiene was studied by following the influence of *n*-butenes partial pressure upon the reaction rate at temperatures of 440°, 460°, 480° and $P_{C_4H_8} = 0.03-0.12$ atm.

From the values obtained for the reaction rates plotted in fig. 2 it can be noticed that the determining step for the reaction rate is the surface reaction which involves two active centres in compliance with the Langmuir — Hinshelwood mechanism.

The reaction rate equation corresponding to this mechanism in the case of *n*-butenes dehydrogenation reaction is

$$r = \frac{k_r b_B\ (P_B - P_D P_H/K)}{(1 + b_B P_B + b_D P_D + b_H P_H + b_A P_A)^2} \tag{5}$$

---

[8] C. N. Satterfield, "Mass Transfer in Heterogeneous Catalysis" M.I.T. Press, Cambridge, Mass, 1970, Chap. 4, p. 164–207.

where

k_r — reaction rate constant (mol/h g catalyst),

P_B, P_D, P_H, P_A — n-butenes, butadiene, hydrogen and water partial pressures, atm,

b_B, b_D, b_H, b_A — adsorption equilibrium constants for n-butenes, butadiene, hydrogen and water, atm^{-1},

K — equilibrium constant in gas phase, atm.

As by this technique low conversions (up to 3% vol) were obtained, working in conditions which were far from being in equilibrium (n-butenes conversions to butadiene were of 60—80% as compared with the equilibrium values) the influence of the reverse reaction and of the reaction products was neglected.

Equation (1) in a simplified form becomes

$$r = \frac{k_r\, b_B\, P_B}{(1+b_B P_B)^2} \tag{6}$$

From the plot of equation 6, under linearized form, both the reaction rate constants and the adsorption equilibrium constant of n-butenes for each reaction temperature (fig. 3) may be calculated.

Table 2 gives the values of n-butenes rate constants and adsorption equilibrium constants for the temperatures studied.

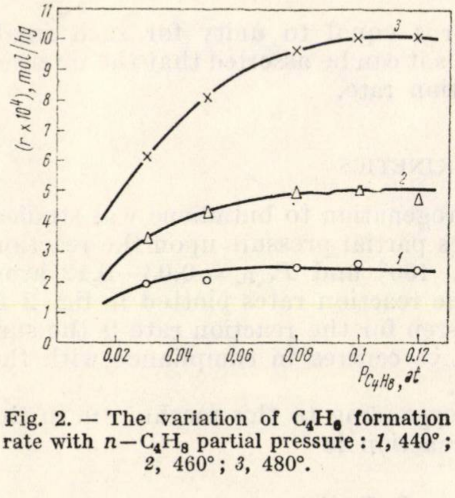

Fig. 2. — The variation of C_4H_6 formation rate with $n-C_4H_8$ partial pressure : *1*, 440° ; *2*, 460° ; *3*, 480°.

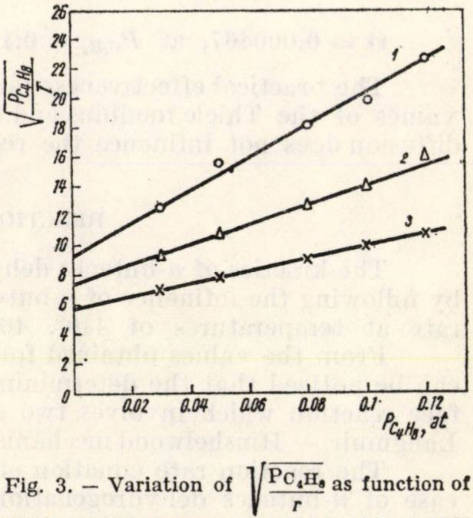

Fig. 3. — Variation of $\sqrt{\frac{P_{C_4H_8}}{r}}$ as function of n-C_4H_8 partial pressure : *1*, 440° ; *2*, 460° ; *3*, 480°.

To follow how the rates achieved by equation (6) verify the experimental results, the reaction rates were calculated using the values established for k_r and b_B (table 2).

From fig. 2 a good agreement can be noticed between the reaction rate values experimentally determined and the calculated values (solid-lines).

Using the Arrhenius plot, made in the well-known way (fig. 4), the activation energy of 36.840 cal/mol was obtained for *n*-butenes transformation reaction, on the studied catalyst, as well as the equation for $\log k_r$ determined by the absolute reaction temperature (T).

Table 2

Reaction rate and adsorption equilibrium constants

Temperature (°C)	$k_r \times 10^4$ (mol/h g catalyst)	b_B (atm^{-1})	b_{H_2} (atm^{-1})	$\frac{b_{H_2}}{b_B}$
440	10.00	12.345	10.646	0.86
460	20.20	9.279	8.556	0.92
480	40.48	7.782	6.656	0.85

$$\log k_r = 8.3 - \frac{36.840}{2.303\,R} \cdot \frac{1}{T} \tag{7}$$

In view of calculating the adsorption equilibrium constant for hydrogen, the reaction was performed at a constant partial pressure for *n*-butenes of 0.08 atm and hydrogen was introduced into the reaction zone at H_2/C_4H_8 molar ratios of 1 : 10 : 1 : 30.

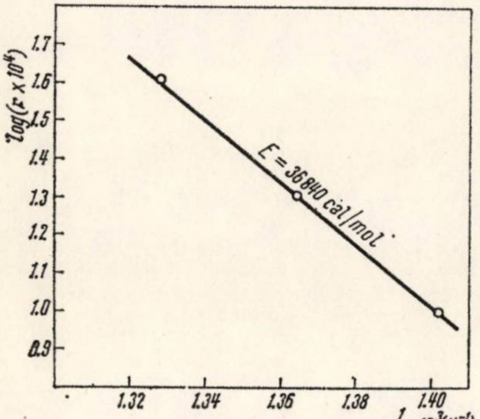

Fig. 4. — Variation of $\log (k_r \times 10^4)$ as function of $1/T$.

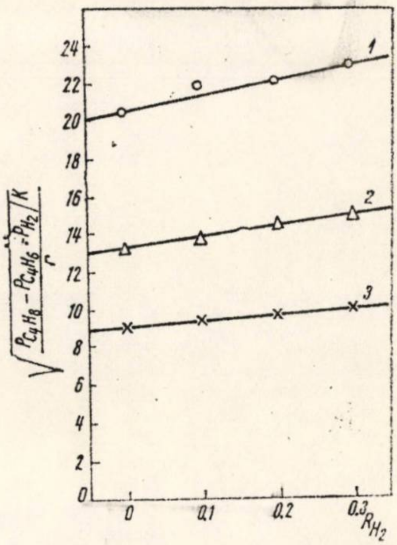

Fig. 5. — $\sqrt{\frac{P_{C_4H_8} - P_{C_4H_6}\ P_{H_2}/K}{r}}$ as function of R_{H_2}. (hydrogen/*n*-butenes molar ratio in the feed mixture) *1*, 440°; *2*, 460°; *3*, 480°.

Revue Roumaine de Chimie, **19**, *4*, 727–734 (1974)

In such a case equation (5) can be written

$$r = \frac{k_r b_B (P_B - P_D P_H / K)}{(1 + b_B P_B + b_H P_B R_H)^2} \tag{8}$$

in which R_H is the molar ratio for hydrogen and *n*-butene.

From the graphical representation of equation (8) under linearized form, the hydrogen adsorption equilibrium constants were calculated for the temperatures at which the reaction was performed (fig. 5).

Table 2 shows the hydrogen to *n*-butenes equilibrium constants ratios which are of 0.86 ; 0.92 ; 0.85 for the temperatures of 440°, 460°, 480°, these values being comparable with those from literature.[9]

CONCLUSIONS

From the present paper it may be seen that it is possible to use a continuous differential microreactor technique to study the kinetics of *n*-butenes catalytic dehydrogenation, a reaction frequently studied on an integral continuous reactor.

The kinetic data were read using the Langmuir-Hinshelwood mechanism.

COMPTE RENDU

ZENO SIMON, *Quantum Biochemistry and Specific Interactions*, Editura ştiinţifică, Bucharest, 1973, 270 p.

The book of Simon Zeno from the University of Timişoara fills a gap in the rather scarcely available literature in this field of interest. The particular concern manifested in recent years for the application of quantum chemistry to applied biochemistry studies proves the usefulness of a theoretical discipline in the development of applicative sciences. Only a quantitative handling of interactions occurring between highly complicated molecules found in living organisms can explain some of the experimentally obtained effects. The quantitative evaluation of interaction energies and also of spatial configurations of biologic macromolecules largely accounts for the properties of biomolecules. The extremely high specificity of living biomolecules still sets particularly difficult problems in front of biochemists who want to influence processes occurring within organisms.

The seven chapters of the book provide a balanced coverage of the proposed thematic field and the relevant bibliography is richly illustrated for those wishing to get an in-depth insight into the field.

1. *Introduction*. The reader is introduced to the problem area of biochemistry and of quantum chemistry, basic concepts of kinetics and chemical thermodynamics and also notions regarding the structural organization of biomolecules are presented.

2. *Molecular orbitals*. As shown by its title, the chapter deals with the theory of molecular orbitals and the types of chemical bond. Theories advanced by Hückel, Hoffman, Del Re, Pariser-Parr-Pople are presented alongside with some more up-to-date approaches. A particular emphasis is laid on molecular reactivity.

3. *Intermolecular forces*. The semi-empirical handling of intermolecular forces is presented through various approximations and their perturbational handling is mentioned in relation to electronic structure indices. Various types of possible interactions in biomolecules are treated, insisting on amino acids and nucleic acids.

4. *Electronic structure and biomolecular reactivity*. The author elaborates on the close relationship between the two factors, for proteins and amino acids, nitrate bases and nucleic acids, various active biological substances (cancerigenous, medicines). Enzymatic reactions and coenzymes (cofactors) are explained with reference to the electronic aspects of the enzymatic activity.

5. *Spatial structure of biomolecules*. A geometrical characterization of the spatial structure of biopolymers is made and energetic calculations related to the structure are performed. In conclusion the chapter deals with spatial structure of nucleic acids and with structural transitions.

6. *Specific interactions*. The chapter deals with the quantitative characterization of interaction specificity and with the role of spatial structure and of intermolecular forces. It is completed by 5 appendices explaining some calculations of relations being used and of the method of multiple correlation applied by the author.

7. *Analysis of some processes of recognition*. The last chapter reviews some enzymatic reactions, the precision in ADN replication and in the synthesis processes of proteins as well as hybridization — a competition between nucleic acids. The chapter ends with repressor-operator interactions, the specificity in immunity phenomena and with some ideas on cancer therapy.

The book leads to the conclusion that in our days quantum chemistry may be of use to biochemistry in explaining the magnitude of rate constants of various elementary reactions and their variation determined by molecular changes, and in sometimes predicting semiquantitatively the variations in question. Quantum chemistry may provide data on elementary reaction processes and on associative interactions between biomolecules.

The 4th National Conference of Pure and Applied Physical Chemistry will be held in Bucharest, Romania, between 2 and 5 Septembre, 1974.

TOPICS

The Conference will be organized in Sessions, covering the topics listed below :

1. Quantum chemistry ; theory of chemical bond ; molecular structure ; reactivity.

2. States of matter ; transport phenomena ; colloids ; chemical kinetics ; photochemistry ; radiochemistry.

3. Chemisorption ; homogeneous and heterogeneous catalysis ; catalytic reactions.

4. Chemical thermodynamics ; thermochemistry ; statistical thermodynamics ; thermodynamics of metallurgical processes ; thermodynamics of irreversible processes.

5. Electrochemistry ; solutions of electrolytes ; ionic liquids (molten salts) ; electrode processes ; electrometallurgy ; corrosion and anticorrosion protection.

6. Chemical engineering ; mass and heat transfer ; effect of surface phenomena ; kinetics of unit processes ; modelling, optimization and automation of processes in chemical industry.

7. Physico-chemical analysis ; automation of physicochemical analysis and control.

The official language of the Conference is Romanian ; foreign authors may deliver their papers in English, Russian, French, Spanish or German. No arrangements will be made for simultaneous translation.

The papers presented by Romanian authors will have their abstracts published in one of the above mentioned languages.

The Organizing Committee invites applications from prospective participants who wish to attend the Conference.

We hope that the Fourth National Conference of Pure and Applied Physical Chemistry will be of most interest to you and/or your colleagues, and would be happy to welcome you at our Conference.

Prof. dr. docent I. G. MURGULESCU

AN EQUATION OF STATE FOR METALLIC LIQUIDS

I. G. MURGULESCU and A. LEIBOVICI

Center of Physical Chemistry,
str. Galaţi 31, Bucharest, Romania

Received December 7, 1973

It is shown that, assuming the validity of the Haber-Thomson model, the Buehler-Hirschfelder-Curtis equation of state leads to satisfactory results for liquid metals near their melting points.

It was shown in a previous paper[1] that, for liquids whose energy can be expressed by a relationship of the form:

$$a_M \frac{e^2}{V}, \tag{1}$$

the Lennard-Jones and Devonshire approximation:

$$\Psi(\rho) - \Psi(0) = \sum_n m_n \frac{1}{2}\int_0^\pi [\varphi(\sqrt{a_n^2 + \rho^2 - 2\rho a_n \cos\theta}) - \varphi(a_n)] \sin\theta \, d\theta, \tag{2}$$

in which the various symbols have well-known meaning[2], becomes equal to zero. Under these circumstances, the free volume v_f, generally defined by:

$$v_f = \int e^{-\frac{\Psi(\boldsymbol{r}_i) - \Psi(0)}{kT}} \, d\boldsymbol{r}_i,$$

takes a simple form:

$$v_f = \frac{4\pi}{3}(a - \sigma)^3, \tag{3}$$

---

[2] J. A. Barker, "Lattice Theories of the Liquid State", Macmillan, New York, 1966, p. 50.

where σ is the diameter of the particles and a is a distance defined by :

$$a = \gamma^{1/3}\left(\frac{V}{N}\right)^{1/3} \tag{4}$$

In this expression V is the molar volume and N is the Avogadro number. γ can be 1, $3\sqrt{3}/4$, or $\sqrt{2}$ for simple cubic, body-centered cubic, face-centered cubic structure of the liquid, respectively.

The method of the partition functions leads to the following equation of state :

$$PV\left(1 - \frac{\sigma}{a}\right) = RT$$

This is the Buehler-Hirschfelder-Curtis equation [3], which was successfully applied to ionic liquids (molten salts) [4]. If we introduce eq. (4) in the previous one, we obtain :

$$PV\left(1 - \frac{2N^{1/3}}{\gamma^{1/3}\,V^{1/3}}\,r\right) = RT, \tag{5}$$

where r is the radius of particles in the liquid.

Therefore, we know that in the Haber-Thomson [5] model, the lattice energy of metals can also be expressed by an equation of the form (1), with r representing the distance between ions and electrons, unlike its meaning in eq. (1) where it denoted ion-ion distance. Extending the validity of the cell model to metallic liquids, we find out that eq. (5) can approximate the behaviour of these liquids as well.

In order to check up the validity of eq. (5) for metallic liquids, the expansion coefficients α_P and the compressibility coefficients β_T of some metallic liquids are calculated in the present paper and they are compared with the corresponding experimental data. We obtain from eq. (5):

$$\alpha_P = \frac{1}{V}\left(\frac{\partial V}{\partial T}\right)_P = \frac{1}{T}\cdot\frac{1 - \dfrac{2N^{1/3}}{\gamma^{1/3}V^{1/3}}\,r}{1 - \dfrac{2}{3}\,\dfrac{2N^{1/3}}{\gamma^{1/3}\,V^{1/3}}\,r}, \tag{6}$$

$$\beta_T = -\frac{1}{V}\left(\frac{\partial V}{\partial P}\right)_T = \frac{V}{RT}\cdot\frac{\left(1 - \dfrac{2N^{1/3}}{\gamma^{1/3}\,V^{1/3}}\,r\right)^2}{1 - \dfrac{2}{3}\cdot\dfrac{2N^{1/3}}{\gamma^{1/3}V^{1/3}}\,r} = \frac{V}{R}\,\alpha_P\left(1 - \frac{2N^{1/3}}{\gamma^{1/3}\,V^{1/3}}\,r\right) \tag{7}$$

The experimental values for the expansion coefficients can be derived from the densities ρ by means of:

$$\alpha_P = \frac{1}{\rho}\left(\frac{\partial \rho}{\partial T}\right)_P \tag{8}$$

Within intervals of temperature of several hundred degrees, the densities can be expressed by linear equations of the form:

$$\rho = a - bT \tag{9}$$

where a and b are constant for the same metal. In table 1 these constants are given for the metals we shall refer to in the following;

they have been evaluated from the existing data concerning metal densities. The temperature interval, starting from the melting point, within which the constants a and b are valid, is given in the last column of the table.

Table 2 allows us to compare the expansion coefficients of several metallic liquids, calculated by eq. (6), with the experimental values, derived from the densities by means of eq. (8) and eq. (9), for the melting temperature. We chose this value of the temperature for comparison since under these circumstances the liquids respond best for the demands of the cell model, which is the basis for eq. (5).

Table 2

Expansion coefficients of metallic liquids, at the melting temperature

	T_m K	ρ_m g/cm^3	V_m cm^3	r A	$\alpha_m \cdot 10^4$ degree^{-1} exp., eq. (8)	$\alpha_m \cdot 10^4$ degree^{-1} calcd., eq. (6)

Cu	1356.15	7.990	7.95	1.278	1.89	0.75
Ag	1239.95	9.138	11.82	1.444	1.07	1.02
Au	1336.15	17.280	11.40	1.442	0.68	0.74
Mg	932.15	1.585	15.33	1.598	1.53	0.97
Zn	692.65	6.560	9.97	1.332	1.63	2.61
Cd	594.15	7.923	14.19	1.489	1.10	2.98
Hg	234.25	13.691	14.65	1.502	1.78	8.24
Al	933.15	2.370	11.39	1.432	1.31	1.25
Ga	302.95	6.100	11.43	1.221	1.19	13.32
Sn	505.05	6.946	17.09	1.405	0.83	7.83
Pb	600.55	10.895	19.02	1.750	1.50	0.64
Bi	544.15	10.079	20.74	1.547	1.36	6.44
Fe	1810.15	7.030	7.93	1.241	2.20	0.94
Co	1765.15	7.673	7.677	1.253	1.65	0.69
Ni	1726.15	7.760	7.565	1.246	1.48	0.71

The value $\sqrt{2}$ was adopted for γ, which agrees with what is likely to come out from the X ray analysis of the molten metals. The significance of various columns of table 2 needs no explanation.

As one can see in table 2, the expansion coefficients of the alkaline metals, silver and aluminium, calculated according to eq. (6), are in good agreement with those derived from the densities using eq. (8). A good agreement is found in the case of many metals as Cu, Au, Zn, Cd, Pb, and Fe, Co, Ni too. Hg, Ga, Sn, and Bi present very high theoretical values compared with the experimental ones. As it is known, these elements form complex lattices, which suggests they are far from ideal metallic state. These are the metals, the limit molecular volumes of which, found from the viscosity equation of Bacinski, display striking anomalies, as it was shown in a previous paper[17].

---

[17] I. G. Murgulescu and M. Şerban, *Rev. Roumaine Chim.*, **17**, 431 (1972).

The compressibility coefficients were evaluated from the propagation speed of ultrasound v_l. The adiabatic compressibility β_S is given directly by eq.:

$$\beta_S = \frac{1}{\rho v_l^2}, \tag{10}$$

where ρ is the fluid density. The value of the isothermal compressibility, which is to be the object of the following considerations, is given by eq.:

$$\beta_T = \gamma \beta_S = \frac{\gamma}{\rho v_l^2}$$

where γ is the ratio of the heat capacities C_P/C_V. Taking into account the Lewis equation:

$$C_P - C_V = \frac{\alpha_P^2 V}{\beta_T} T,$$

the previous relation becomes:

$$\beta_T = \frac{1}{\rho v_l^2} + \frac{\alpha_P^2 V}{C_P} T \tag{11}$$

We shall use this relation within our computations.

In table 3 the compressibility coefficients of several metallic liquids derived from eq. (7), are given together with those obtained from the speed of ultrasound, according to eq. (11).

The expansion coefficients and the other magnitudes needed (T_m, ρ_m, etc.) in eq. (11) were taken from table 2.

Examination of table 3 shows that the agreement of theoretical and experimental values of the compressibility coefficients is hardly satisfactory. For real metals, the calculated values are generally much lower than the experimental ones. But for elements whose behaviour is far from that of the metallic state, such as Hg, Sn, Bi, the theoretical values of the liquid state compressibility coefficients are largely higher than the corresponding experimental values.

Such a behaviour is contrary to what we found when studying the respective expansion coefficients.

The behaviour of Zn and Cd is to be placed between the two indicated extreme behaviours; in this case, the agreement between the calculated and experimental values is satisfactory.

All these results are in full agreement with those derived from the study of the metallic liquid viscosity [17].

Table 3

Compressibilities of metallic liquids at the melting points

In order to extend the validity of Buehler-Hirschfelder-Curtis equation to metallic liquids, let us observe that the ratio of experimental compressibility over the respective calculated value stays, for ideal metallic liquids of constant valence, within the 4—5 interval and, for those of variable valence, within 4—5 times their maximum valence. Then eq. (5) becomes:

$$PV\left(1-\frac{2N^{1/3}}{\gamma^{1/3}V^{1/3}}r\right)=\frac{RT}{5n_v}, \tag{12}$$

where n_v is, for the liquids of the elements of variable valence, equal to the maximum valence (the number of unpaired electrons).

The expression for the compressibility coefficient takes the form:

$$\beta_T=\frac{5n_v V}{R}\cdot\frac{\left(1-\frac{2N^{1/3}}{\gamma^{1/3}V^{1/3}}r\right)^2}{1-\frac{2}{3}\,\frac{2N^{1/3}}{\gamma^{1/3}V^{1/3}}r}=\frac{5n_v V}{R}\,\alpha_P\left(1-\frac{2N^{1/3}}{\gamma^{1/3}V^{1/3}}r\right) \tag{7'}$$

The values in table 4 were calculated by using this equation. The data needed were taken out of the preceeding table 3.

The accordance between the values derived from eq. (7′) and the experimental ones is satisfactory and prove the validity of eq. (12). It

THE ELECTRONIC STRUCTURES OF BH_3 and BH_4

D. R. ARMSTRONG, P. G. PERKINS and K. S. SORBIE

Department of Pure and Applied Chemistry, University of Strathclyde,
Glasgow Gl 1XI, Scotland

Received August 27, 1973

The electronic structures and energies of the species BH_3 and BH_4^- have been examined by *ab initio* calculations. The effect of surrounding the anion by four cationic point charges ont its electronic properties is reported. Vibrational frequencies calculated from the data are in good agreement with experiment. The thermodynamics of the reaction $BH_3 + H^- \rightarrow BH_4^-$ was also studied and heat of formation ΔH_f in the gas-phase was calculated to be -278.6 kJ mol^{-1}.

BH_3 and BH_4^- are the simplest boron-hydrogen species although the former exists only as the dimer B_2H_6 in the laboratory. Nevertheless BH_3 has been postulated to occur as an intermediate in a number of boron hydride degradation reactions [1], and low-temperature matrix isolation may yet detect this unstable species. Hence, it is of some interest to study its electronic structure particularly in relation to its coordination complexes. The simplest of these is the borohydride anion : borohydrides (*e.g.* $NaBH_4$) are frequently good, mild, selective, reducing agents and, as such, find common use in organic synthesis. Determination of the crystal structure of $NaBH_4$ shows that it possesses a face-centred cubic lattice [2]. However, it is also observed that the BH_4^- ion is sterically free to rotate in its environment. Hence, the ion experiences a symmetrical distribution of positive cationic charges.

The purpose of this paper is to present results of *ab initio* calculations on the electronic structures of the two species BH_3 and BH_4^- and on the thermodynamics of the reaction.

$$BH_{3(g)} + H^-_{(g)} \rightarrow BH^-_{4(g)}$$

The calculations were performed within the standard LCAO-MO-SCF formalism [3] in which all atomic orbitals are represented by Gaussian functions [4]. In the case of the boron atomic orbitals, nine *s* and five *p* Gaussian primitive orbitals [5] were contracted to four *s* and two *p* orbitals respectively, whilst two contracted orbitals were formed from four primitive *s* Gaussian orbitals simulated the hydrogen 1*s* orbital.

RESULTS AND DISCUSSION

a. BOND LENGTH OPTIMISATION AND CALCULATION OF SELECTED VIBRATION FREQUENCIES

The optimum bond lengths for both species were obtained by minimising the total energy with respect to the B—H bond distances. For obvious reasons all of these were simultaneously varied in phase. When this is carried out for BH_3 the calculated bond length is 0.119 nm a value very similar to that found for terminal B—H bonds in the higher boron hydrides. [6] The computed bond length in the borohydride ion spans 0.124 nm, in good agreement with that in sodium borohydride [2] (0.125nm). The longer bond length in the tetrahedral case is rationalised on the basis that the higher coordination number in the ion introduces powerful interelectronic repulsions which are relieved mainly by the expansion of the electron cloud and hence the whole anion.

Changes in bond length for optimisation purposes simulate the bond stretching vibrations of the system, in this case the totally symmetric breathing frequencies. For small atomic displacements Δx, the change in energy is given by,

$$\Delta E = \frac{1}{2} k (\Delta x)^2$$

The force constant, k, also interconnects the vibrational frequency, ν, and the reduced mass m^* of the system thus

$$\nu = \frac{1}{2\pi} \sqrt{\frac{k}{m^*}}$$

Hence, the vibrational frequency of the symmetrical stretching mode should be obtainable from the energy *vs* bond length calculations. It is of course the whole normal coordinate for ν_1 we should deal with here but it is possible to introduce a reasonable simplification *i.e.* as it is the force constant of one bond that is involved, we use the approximation that the energy required to stretch one bond in BH_3 and BH_4^- is one-third and one-quarter of the energy needed to stretch all the bonds in BH_3

[6] W. N. Lipscomb, "Boron Hydrides", W. A. Benjamin, New York, 1963.

and BH_4^-, respectively. The calculated vibrational frequencies are then 2405 cm^{-1} and 2100 cm^{-1} for the borohydride and borane entities, respectively. Considering the approximations involved, the agreement with the experimental values (2264 cm^{-1} for BH_4^- [7] observed in the Raman, and 2400 cm^{-1} for BH_3[8]) is very satisfactory.

A further calculation of the E; ν_2 deformation mode of BH_4^- was next attempted. In a similar way to the calculation of the ν_1 mode the force constant is again defined by the equation cited. In this case, however, the change in energy ΔE is caused by small angle displacements $\Delta\theta$ and hence Δx can be equated to $R_0 \sin \Delta\theta$. It is assumed that, during this mode of vibration, the bond length R_0 remains constant at the optimal value. Hence, the energy of the BH_4^- anion was computed in a number of cases incorporating small variations in the $H\hat{B}H$ bond angle (for example, 2° contraction and 3° expansion) in a manner consistent with the motion of the hydrogen atoms in the ν_2 vibrational mode. We again made the assumption that there was a simple relation between the deformation energy of one bond and that of the whole molecule. For the ν_2 mode of BH_4^- we obtained the values 1308 cm^{-1} and 1300 cm^{-1} for the 2° contraction and 3° expansion, respectively. These values are in reasonable agreement with experiment (1205 cm^{-1} [7]).

We can reasonably project that this approach to calculating vibrational modes of molecules will give good agreement with experiment in other cases. This is of particular value when the computation involved in a more accurate model for a certain molecule is very heavy. For BH_3 and BH_4^- we expect that employment of a larger basis set could yield very accurate values for the energies of these vibrational modes.

b. BH_4^- IN A CRYSTAL LATTICE

In the crystal lattice the BH_4^- ion is associated with a gegenion. A natural question is how the crystal lattice influences the electronic properties of the borohydride ion. In an attempt to obtain a picture of BH_4^- surrounded by cationic species, as in the crystal, four positive charges of magnitude 0.25 were placed at a distance of 0.307 nm from the boron atom each along a line projected from the B—H bonds. This model was chosen as it is simple yet presents a fairly accurate picture of the sodium borohydride lattice. Although the lattice has a face-centred cubic structure, the borohydride ion is free to rotate and so an essentially spherically symmetrical distribution of positive charge is experienced by the anion.

The optimum B—H bond length was redetermined from a number of calculations and a value of 0.125 nm was obtained. The length is in better agreement with the experimental value than the distance calculated in section (*a*). Utilising these results the symmetric stretch vibrational mode ν_1 was recalculated and a value of 2240 cm^{-1} was obtained. This is closer to experiment than the non-ionic model. Thus, we can conclude that our simple model is a reasonable representation of the ionic borohydride ion.

Imposition of a tetrahedral array of positive charges about BH_4^- lowers the total energy of the system by 357.4 kJ mol^{-1}. This stabilisation energy is related to the lattice energy although clearly not equal to it since our model only simulates the immediate environment of BH_4^- and does not attempt to describe an infinite lattice. Nevertheless, it clearly illustrates the order of energy gain by an anion due to the introduction of positive charges.

The eigenvalues of BH_4^- are also dramatically lowered in value by the surrounding cations. Figure 1 shows the increase in stability of each molecular orbital due to superimposition of the point charges. At the optimum bond length the $1t_2$ and $2a_1$ levels become more stable to the extent of 5.21 eV whilst the $1a_1$ orbital loses 3.90 eV. This is to be expected as the higher energy molecular orbitals are more diffuse and interact more strongly with the positive charges. A chemical effect which may well arise from this anion stabilisation occurs in reactions which proceed readily with $M^+ X^-$ but much less well with M'^+X^- although X^- is known to be the important reacting species. For instance, the chemistry of the

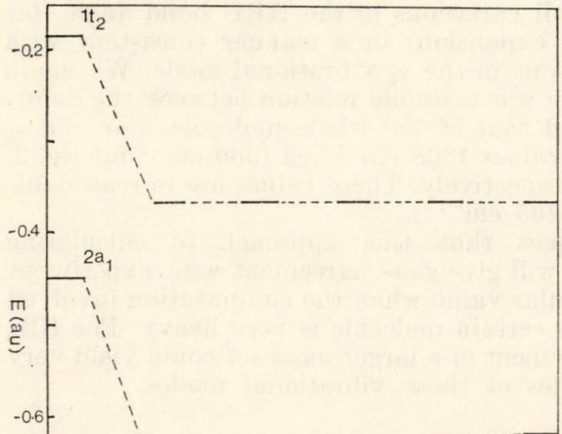

Fig. 1. — Effect on energy levels of BH_4^- of change in r(B — H) in a lattice.

borohydride salts[9] depends largely upon the cation present. Addition of certain metal ions to sodium borohydride enhances the reducing power and produces a more selective reagent. We expect that these different spheres of positive charge will exert a different influence on the eigenvalues for BH_4^- and hence alter the reduction potential of the hydrogen atoms.

A survey of the change in energy of the two occupied a_1 orbitals with the B–H bond length (figure 1) reveals that the lowest filled orbital becomes stabilised whilst the $2a_1$ level gains energy when the B–H bond length is increased. The $1a_1$ orbital, which is largely composed of boron $1s$, must become more stable due to smaller interelectronic repulsion energy as the hydrogen atoms move away from the central atom. The $2a_1$ orbital is a bonding orbital involving the boron $2s$ orbital and the hydrogen s orbital and so becomes destabilised as the overlaps of the boron-hydrogen orbitals diminish. The $1t_2$ level remains constant while the bond length is varied and so the change in the various energy terms must effectively be neutralized.

c. MULLIKEN POPULATION ANALYSIS [10]

The overlap and gross atomic populations of BH_3, BH_4^- and BH_4^- in a lattice are presented in table 1. In BH_3 there is no polarisation of electronic charge whereas on the addition of the hydride ion, the excess electronic charge builds up mainly on the boron atom. On surrounding the BH_4^- ion by positive charges an appreciable electron flow from the boron to the hydrogen atoms is caused with a resulting weakening in the bonding framework.

Table 1

Electronic populations of BH_3, and BH_4^-

	Atomic populations		B–H overlap population
	boron	hydrogen	
BH_3	−0.078	+0.026	0.408
BH_4^-	−0.307	−0.173	0.401
BH_4^- [a]	−0.038	−0.241	0.382

[a] in this calculation the ion was enclosed in a lattice of positive charges.

d. THERMODYNAMICS OF COMPLEX ION FORMATION

The heat of the reaction

$$H^-_{(g)} + BH_{3(g)} \rightarrow BH^-_{4(g)}$$

at $T°$ K is given by

$$\Delta H_T = \Delta E_T - RT$$

where ΔE_T is the difference in total energy between BH_4^- and the combined total energies of BH_3 and H^-. The total energy of a species is made up of the following terms

$$E_T = E_{HF} + E_{vib} + E_{trans} + E_{rot} + E_{corr} + E_{rel}$$

where E_{HF} is the computed Hartree-Fock energy, E_{vib} is the zero-point vibrational energy, E_{rot} is the rotational energy, E_{trans} is the translational energy, E_{corr} is the correlation energy, and E_{rel} is the relativistic energy.

At 0° K the rotational and translational energies are zero. The vibrational energy is of course not zero and was calculated from

$$E_{vib} = \frac{1}{2} h \sum_i \nu_i$$

where the ν_i are the fundamental vibration frequencies. These are known for BH_4^-[7,11]: for BH_3 the vibration species were obtained from ref. 8. The correlation energy was obtained by using the pair population method of Hollister and Sinanoglu[12]. In this procedure the energy is evaluated in terms of the gross atomic populations ρ_i and the atomic orbital correlation energies,[13] e_{ij}

$$E_{corr} = \frac{1}{2} \sum_i e_{ii} \rho_i + \sum_{i>j} \sum e_{ij} \rho_i \rho_j$$

The relativistic energy was not evaluated as it has been shown[14] that it is an atomic constant independent of the chemical environment and so ΔE_{rel} will be zero.

The calculated energies refer to the absolute zero and we must adjust them to a more convenient reference temperature. This can be

[14] E. Clementi and A. D. McLean, *Phys. Rev.*, **133**, 4419 (1964).

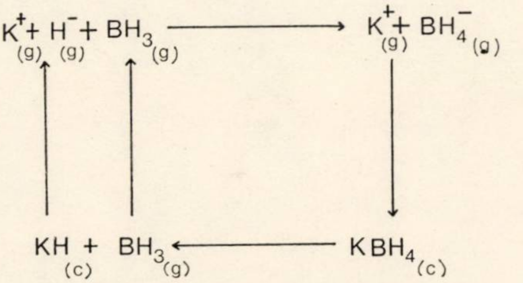
accomplished *via* the integrated form of Kirchoffs equation

$$\partial(\Delta H)/\partial T = \Delta C_P$$

The necessary specific heats for BH_3, H^- and BH_4^- can readily by estimated [15]: the correction term is then similar to those calculated for BF_3 complexes [16]. The resulting energy terms (in kJ mol^{-1}) for the reaction at 298 K are given below

ΔE_{HF}	ΔE_{vib}	ΔE_{corr}	$\Delta C_P \Delta T - RT$	ΔH_{calcd} (298 K)
−269.0	+19.3	−20.2	−8.7	−278.6

The results show that the reaction is exothermic and illustrate the strong affinity of BH_3 for the H^- ion. In order to estimate the experimental energy for this process we need a Born-Haber cycle (figure 2). With regard to the terms in the cycle the heat of formation of KBH_4 from solid KH and gaseous BH_3 is not known but, by analogy with other complexes of BF_3 and BH_3, one would expect it to be little different from that of KBF_4 (121 kJ mol^{-1} [17]). The lattice energy of KBH_4 is also unknown but we may reasonably employ a value scaled from those of KBF_4 [18], KF [19], and KH [19]. This yields a value of 568 kJ mol^{-1}. If these figures are now combined in the cycle we arrive at a value of −267 kJ mol^{-1} for the heat of the reaction



$K^+_{(g)} + H^-_{(g)} + BH_{3(g)}$
$K^+_{(g)} + BH^-_{4(g)}$
$KH_{(c)} + BH_{3(g)}$
$KBH_{4(c)}$

Fig. 2. — Thermodynamic cycle for the energy of $BH_3 + H^- \rightarrow BH_4^-$.

$$H^-_{(g)} + BH_{3(g)} \rightarrow BH^-_{4(g)}$$

The agreement with the calculated value is very satisfactory.

ESR SPECTRA OF SOME ANION-RADICALS FROM DIBENZO-[b, e]-THIEPINONE AND RELATED COMPOUNDS

ELENA VOLANSCHI*, C. VLĂDESCU** and C. VOLANSCHI*

Department of Physical Chemistry, Bd. Republicii 13,
University of Bucharest, Romania
**Institute of Internal Medicine of the Academy for Medical Sciences,
Şos. Şt. cel Mare, 19, Bucharest, Romania

Received July 3, 1973

Chemical and electrochemical reduction in DMF and DMSO of seven derivatives in the dibenzo-[b,e]-thiepinone series was performed. It was found that in these conditions a cleavage of the molecule occurs, leading to the anthraquinone anion-radical. This process is dependent on time, method of reduction and sulphur- or ring-substitution.

Dibenzo-[b, e]-thiepin-11-one, DBTP [b, e], (fig. 1) is known for its antialergical activity, but there is no information about its structural and spectral properties.

The single paper of which we are aware is concerned with the ESR spectrum of a related compound, dibenzo-[b, f]-thiepinone [1]. Since the sulphur atom is out of the plane of the aromatic rings, we thought that the study of its anion-radicals, if at all, will provide information about the sulphur conjugation in nonplanar systems.

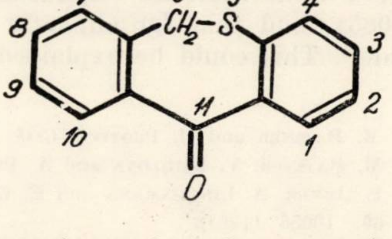

Fig. 1.— Dibenzo-[b, e]-thiepinone and the numbering used in this paper.

In this paper, we present the experimental results concerning the behaviour of dibenzo-[b, e]-thiepinone and some related compounds by the chemical or electrochemical reduction.

---

[1] M. M. Urberg and E. T. Kaiser, *J. Amer. Chem. Soc.*, **89**, 5931 (1967).

EXPERIMENTAL PART

The thiepinone derivatives were synthetized by literature methods, as follows: (numbering as in fig. 1)

- dibenzo-[b, e]-thiepin-11-one [2], m.p. = 86°
- dibenzo-[b, e]-thiepin-11-one-5-oxide [2], m.p. = 98°
- 2-chloro-dibenzo-[b, e]-thiepin-11-one [3] m.p. = 136°—37°
- 2-methyl-dibenzo-[b, e]-thiepin-11-one [4] m.p. = 121°
- 8-chloro-dibenzo-[b, e]-thiepin-11-one [5] m.p. = 152°—3°
- 9-chloro-dibenzo-[b, e]-thiepin-11-one [3] m.p. = 88°—90°
- dibenzo-[b, e]-oxepin-11-one [6] m.p. = 69°—71°

The anion-radicals were prepared by reduction with metallic sodium in anhydrous dimethyl-formamide (DMF), or by simple dissolution in strongly alkaline dimethylsulphoxide (DMSO + KOH).

The electrochemical reduction was performed directly in the ESR cavity, in a cell with two platinum electrodes. The potential was controlled with an Ag-wire, passed through a glass capillary and dipped into the solution till above the cathode [7].

Anhydrous DMF was used as solvent, and tetrabutylammonium-iodide (TBAI) 0.1 M as supporting electrolyte.

The ESR spectra were recorded on a JES-3 B Spectrometer in the X-band frequency, and the optical ones on a Beckmann DK-2 spectrophotometer.

RESULTS AND DISCUSSION

The parent compounds and the parameters of the ESR spectra of the thiepinone derivatives are collected in table 1.

By the chemical reduction of DBTP-(b, e) two radicalic species with different g-values are obtained; the first one, having a g-factor of 2.0096 points out a sulphur-containing radical. This value is in the range indicated in literature for sulphur aromatic systems like thianthrene ($g = 2.0085$), and that for aliphatic sulphides ($g = 2.0263$) for dimethylsulphide [8]. This could be explained by the localization of the unpaired

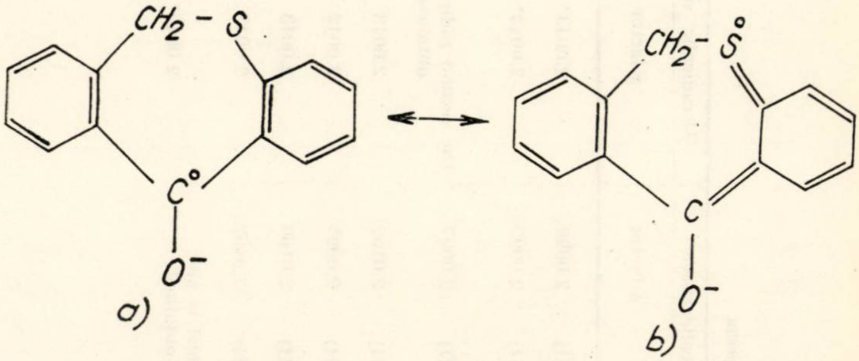
($a_H = 0.33$ G (4H)).

electron on the sulphur atom, as it is implied by a resonating formula of type (b), that is :



A splitting of 1.39 G due to 4 equivalent protons was evidenced Further splitting is apparent in strongly alkaline DMSO solutions, but at this poor resolution the hyperfine constant could not be determined.

From the 4 protons observed we can assign only two, to positions 2 and 9, respectively, since in the spectra of the 2-or 9-chloro-DBTP only three quasiequivalent protons are apparent (4 lines in the intensity ratio 1 : 3 : 3 : 1).

The 7-lines spectrum of the 2-methyl-thiepinone supports the same idea. As the spectrum of the 8-chloro derivative is nearly the same as that of the parent compound, (table 1) it is probably that the proton 8 is not one of the four equivalent protons in the molecule ; however, we do not possess sufficient experimental data to assign the other hfs constants.

The second radical with a g-value of 2.0043 evidences a splitting of 8 protons, with the a_{H} given in table 1.

The general pattern of the spectrum and the values of the hfs constants point out the identity of this spectrum to that obtained in aprevious work starting from anthrone [9].

In a recent paper [10], Tabner and Zdysiewicz proved that the chemical or electrochemical reduction of anthrone at room temperature leads to the anion-radical of anthraquinone. It seems probable therefore that dibenzo-[b, e]-thiepinone undergoes a desulphuration leading, *via* anthrone, to the 9,10-anthrasemiquinone anion.

The desulphuration of [b, e]-DBTP was observed to occur in other reactions too, as it was proved byVlădescu and Maior [11], who obtained 9,10-dichloroanthracene from DBTP and thyonil chloride, and not 11,11-dichlorodibenzo-[b, e]-thiepine as it was expected.

In order to check the mechanism proposed here, we started from anthrone and anthraquinone in strongly alkaline DMSO solutions and in both cases ESR spectra identical to those of the DBTP — second radicalic species were obtained.

---

[9] V. Em. Sahini, L. Ciurea and E. Volanschi, *Rev. Roumaine. Chim.*, **12**, 355 (1967).

[10] B. J. Tabner, and J. R. Zdysiewicz, *J. Chem. Soc.*, **1971 B**, 1659.

[11] C. Vlădescu and O. Maior, *Rev. Chim.* (*Bucuresti*), **22**, 197 (1971).

It was also observed that starting from three different compounds, that is 2-chloro, 8-chloro and 9-chloro-DBTP, the same spectrum of the second radicalic species is obtained. This fact supports also the idea that 9,10-anthraquinone is the second anion-radical formed, because only in such symmetrical molecule, positions 2,8 and 9 are equivalent.

It was proved by chemical methods too that anthraquinone is the main final product of the reduction of [b, e]-DBTP, by performing its synthesis from DBTP in DMSO + KOH and analysing the reaction mixture by thin layer chromatography *.

We observed also that the desulfuration process of thiepinone is influenced by the reduction method, time and ring — or sulphur-substitution. Thus, the electrochemical reduction in DMF leads to a low percent of anthraquinone — *vs.* thiepinone radical, while in the KOH + DMSO mixture the ratio is reversed. In every case the quotient of the 9,10-anthrasemiquinone-*vs.* the thiepinone — radical is increased the day following the preparation.

The 2- or 9-chloro or methyl-substitution leads to higher amounts of anthraquinone-anion relatively to the first radicalic species.

The substitution at the sulphur atom in dibenzo-[b, e]-thiepinone-sulphoxide does not affect much the ESR spectrum leading to the both radicalic species observed for the sulphur-unsubstituted analogue, the ratio being clearly favourable to the first one. It was however remarked

---

* In a flask fitted with a condenser 1 g of dibenzo-[b, e]-thiepin-11-one was dissolved in 5 ml of dimethylsulphoxide and 0.5 g of solid potassium hidroxide were added. The mixture was warmed on a steam bath for 4 hrs; it was then decomposed with water, acidulated with concentrated HCl and extracted with benzene. The extract was washed with water and dried over calcium chloride (on acidulation, H_2S was identified, proving that sulphur is leaving as suphide).

The benzenic extract was analysed by thin layer chromatography on silicagel G (eluant benzene : petroleum ether 3 : 1). The chromatogram was studied in u.v. or after development in concentrated H_2SO_4.

The u.v. study evidences the following compounds in the order of their migration *versus* marking substances :

— not reactioned dibenzo-[b, e]-thiepinone (green fluorescence)

— a dark spot of anthraquinone (not fluorescent)

— two fluorescent compounds near the start.

The study of the developed chromatogram evidences the [b, e]-DBTP as a red spot and behind it anthraquinone as a yellow spot. The remaining two compounds are not coloured in concentrated H_2SO_4.

After chromatography, the benzenic solution was evaporated and recrystallized several times from benzene, alchool and acetic acid (1 : 1) alternatively, and anthraquinone crystals with m.p. 285—86° were obtained.

The melting point of a mixture with authentic anthraquinone does not give depression. The yield after the first recrystallization is 0.8 g and the m.p. becomes 268—75° *vs.* 86° for the initial compound.

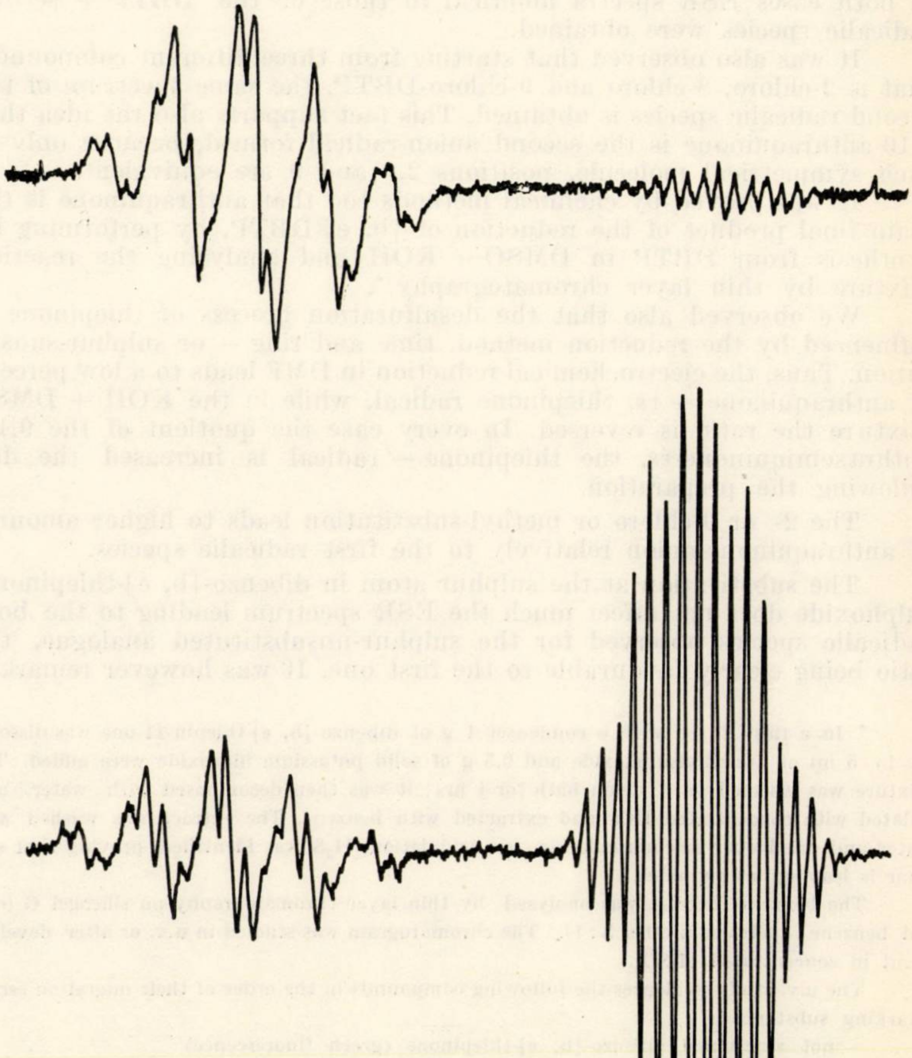


Fig. 2. — The two radicalic species obtained from [b, e]-DBTP : *a*) on electrochemical reduction in DMF. *b*) in the KOH + DMSO mixture.

that in the electrochemical reduction, the second radical could not be detected in our conditions.

The replacement of sulphur by oxygen in dibenzo-[b, e]-oxepinone leads to an ESR spectrum identical to that obtained from anthrone at room temperature [10] not depending on the reduction agent employed.

To obtain more data about the radicalic species provided by thiepinone, optical spectra were also recorded. All the radicals studied present two absorption bands in the visible range (one at about 500 nm and another at *ca.* 530 nm). Since anthrone and anthraquinone recorded in similar conditions present maxima in the same range, no assignment of the peaks to the different radicalic species was possible.

In conclusion, it was found that by chemical or electrochemical reduction-[b, e]-DBTP undergoes a desulphuration process leading to the anthrasemiquinone ion. The mechanism was not yet elucidated step by step, but, as it was observed that the sulphur is leaving as sulphide, it seems probable that the desulphuration occurs *via* anthrone, which, under the influence of traces of dissolved oxygen leads to anthraquinone.

INTERDIFFUSION AND SELF-DIFFUSION OF MONOVALENT CATIONS IN FUSED ALKALI NITRATES AND CHLORIDES

S. STERNBERG and CONSTANȚA HERDLICKA
Institute of Physical Chemistry, str. Galați 31, Bucharest, Romania

Received May 17, 1973

A corrected form of Stokes-Einstein equation applicable to inter- and self-diffusion of monovalent cations in fused alkali nitrates and chlorides is suggested. The correction term increases exponentially with the volume change on melting (ΔV) of the diffusion medium. A critical discussion of several diffusion theories on the basis of which the preexponential factor and activation energy for cationic diffusion in alkali nitrates and chlorides have been calculated is also given.

Some experimental data regarding silver ion interdiffusion in alkali nitrates [1–5] and alkali chlorides, [6] as well as alkali cations self-diffusion in these solvents, [7–10] have already been published.

These data allow us to make an extensive discussion on the diffusion mobility in molten salts.

A first generalization of these data may be done by using Stokes-Einstein equation:

$$D_i = \frac{KT}{a \pi \eta r_i} \tag{1}$$

where D_i is the diffusion coefficient of a r_i radius particle moving in a medium having the viscosity η, a is a constant and the other magnitudes have known significances. In the classical formulation the constant a has the value 6 and corresponds to cases for which the diffusing species are much larger than those of the medium. For smaller diffusing particles, Li and Chang[11] have reported a modificated S–E equation with $a=4$.

In the following, we shall try to analyse the applicability of the S–E equation for cationic self-diffusion and Ag^+ interdiffusion in alkali nitrates and chlorides, over a large temperature range of at least 100° above the solvent melting point.

The experimental data of self-diffusion coefficients for alkali cations in alkali nitrates and chlorides are plotted in figure 1 together with the values resulting from S–E equation.

The experimental self-diffusion coefficients were obtained by using Arrhenius equations indicated by Dworkin and co-workers[7] for alkali nitrates and Bockris and co-workers[9,10] for alkali chlorides.

To calculate the viscosity values use has been made of experimental Arrhenius equations for alkali nitrates[12] and chlorides[13] available in literature.

The alkali ionic radii were assimilated to the crystallographic radii given by Pauling[14].

As can be seen from figure 1, the experimental data for nitrates are in fairly good agreement with the calculated ones, but large deviations occur in alkali chlorides. These deviations seem to be systematic and to depend on the volume change on melting.

In the alkali nitrates series except for $LiNO_3$, all the other nitrates give small volume changes[15], ΔV, being even negative in $RbNO_3$. The deviations of experimental self-diffusion coefficients from S–E equation are also small. They become important for D_{Cs^+} in $CsNO_3$ which has the second largest ΔV (12%) after $LiNO_3$.

In the alkali chlorides series the deviations increase from CsCl to LiCl, as ΔV[16] does.

The proportionality between the diffusion coefficient D and the $T/\eta r$ ratio holds for alkali chlorides but the straigth lines which result present two sorts of deviations : a) each straight line intersects the ordinate at distances from the origin having considerable values for NaCl, KCl and smaller for RbCl and CsCl, b) the slopes of experimental straight lines differ from the theoretical one in the case of RbCl and CsCl, but they are almost equal for NaCl and KCl.

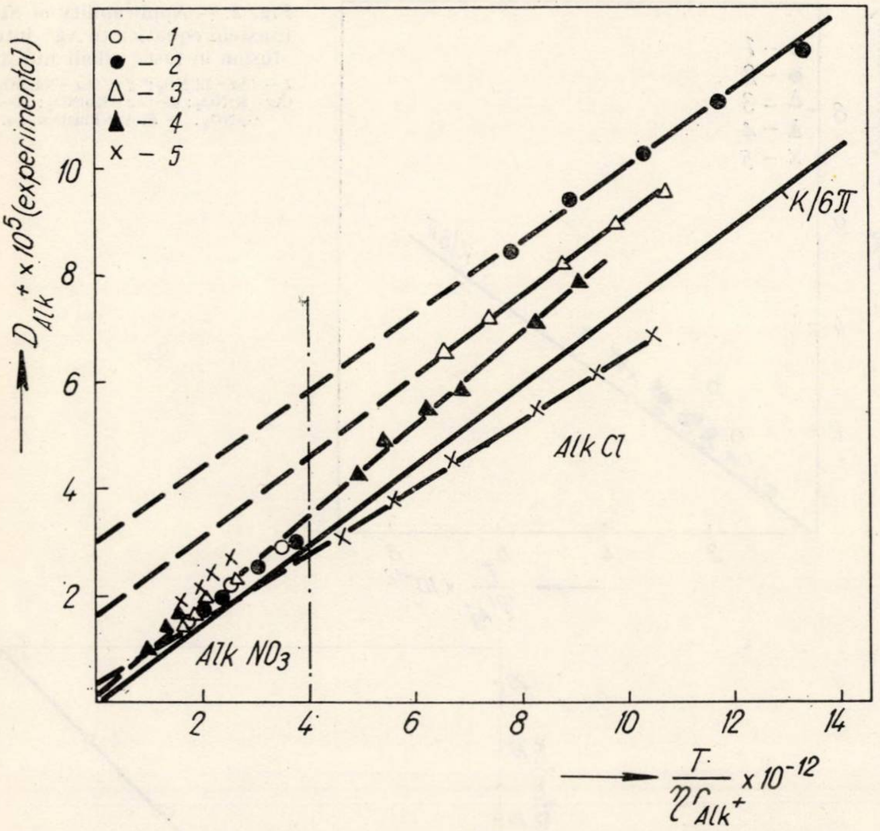

Fig. 1. — Applicability of Stokes-Einstein equation to cationic self-diffusion in fused alkali nitrates and chlorides:
1 – Li+; 2 – Na+; 3 – K+; 4 – Rb+; 5 – Cs+; — Stokes-Einstein eq.

In figures 2 and 3 the interdiffusion coefficient of Ag^+ in alkali nitrates and chlorides resulted both from S—E equation and experimental measurements are plotted.

Interdiffusion coefficients of Ag^+ ion were obtained by us from chronopotentiometric measurements [3,4,6,17]. The concentration of silver ion being very small (10^{-5}—10^{-4} mol/cm^3) the viscosity of the system was considered as equal to that of the diffusion medium. The silver ion radius published by other authors [12,18,19] is smaller than 1.26 Å (given by Pauling [14]) and 1.13 Å (according to Ketelaar [20]) and very close to that of sodium ion. In our calculations we have taken an average value of 0.98 Å.

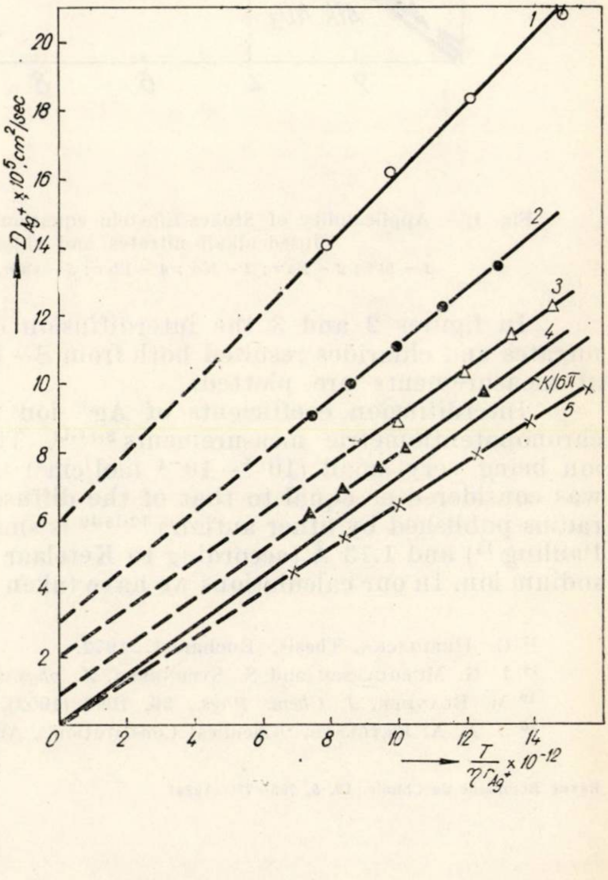

Fig. 3. — Applicability of Stokes-Einstein equation to Ag^+ interdiffusion in fused alkali chlorides:

1, $(Ag-Li)Cl$; 2, $(Ag-Na)Cl$; 3, $(Ag-K)Cl$; 4, $(Ag-Rb)Cl$; 5, $(Ag-Cs)Cl$; — Stokes-Einstein eq.

The experimental Arrhenius equations for Ag^+ diffusion in alkali nitrates, we have already referred to (references [3] and [4]), have subsequently been processed [17] by I.M.B. 360/30 computer so that the data show the standard deviations too.

Therefore, the complete equations we have used in this study are :

$AgNO_3 + LiNO_3$

$$D_{\mathrm{Ag}^+} = (8.36 \pm 4)10^{-3}\ \exp\left(\frac{7166 \pm 493}{RT}\right)$$

$AgNO_3 + NaNO_3$

$$D_{\mathrm{Ag}^+} = (0.96 \pm 0.18)10^{-3}\ \exp\left(\frac{4520 \pm 238}{RT}\right)$$

$AgNO_3 + KNO_3$

$$D_{\mathrm{Ag}^+} = (0.65 \pm 0.04)10^{-3}\ \exp\left(\frac{4340 \pm 93}{RT}\right)$$

$AgNO_3 + RbNO_3$

$$D_{\mathrm{Ag}^+} = (1.67 \pm 0.4)10^{-3}\ \exp\left(\frac{5620 \pm 306}{RT}\right)$$

$AgNO_3 + CsNO_3$

$$D_{\mathrm{Ag}^+} = (2.04 \pm 0.32)10^{-3}\ \exp\left(\frac{5920 \pm 228}{RT}\right)$$

As can be seen from figures 2 and 3 the experimental interdiffusion coefficients show deviations from S–E equation, behaviour which is similar to self-diffusion (fig. 1). The ordinates at origin given by the representative lines are larger than those for self-diffusion and depend both on volume change at melting and on the $r_{\mathrm{Alk}^+}/r_{\mathrm{Ag}^+}$ ratio.

It may be concluded from figures 1–3 that S–E equation is unsatisfactory for the explanation of experimental data and that besides $D_{\mathrm{S-E}}$ a supplimentary diffusion coefficient denoted by D_h, exists. The above figures suggest the existence of two contributions to D_h : the first and most important comes from the ordinate at origin of the straight lines, the second comes from the difference between experimental and theoretical slopes. The corresponding diffusion coefficients will be referred to as D_h' and D_h''.

Plotting of self-diffusion and interdiffusion coefficients, D_h', *versus* relative volume change on melting, ΔV, ($\Delta V = (V_l - V_s)/V_s$ with s and l subscripts indicating solid and liquid states of salt at melting point) leads to the representation in fig. 4.

From this figure it comes out quite clearly that D_h' is negligible for ΔV lower than 10% and increases exponentially with increasing ΔV.

The equation corresponding to the curve in fig. 4, is :

$$\log\,(D'_h - C) = A + B\,\Delta V \tag{2}$$

where A, B and C are constants.

The self-diffusion coefficients curve D'_h (fig. 4a) is described by the equation :

$$\log\,(D'_h - 0.15 \times 10^{-5}) = 7.37\ \ \Delta V - 6.17 \tag{3}$$

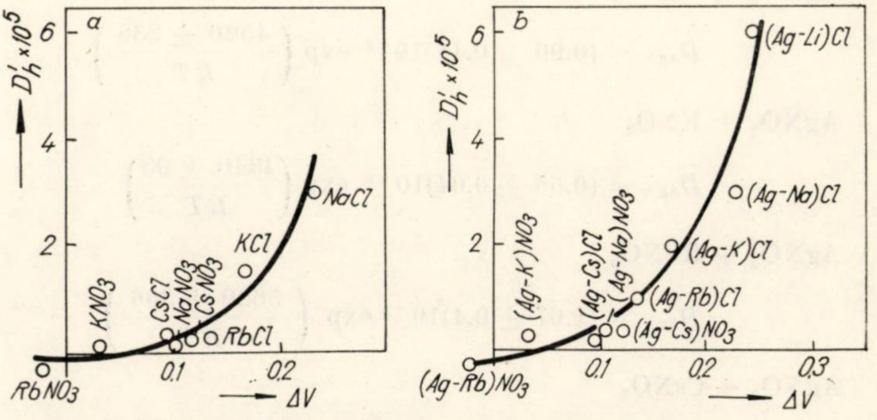

Fig. 4. — The variation of D'_h coefficient with volume change on melting for fused nitrates and chlorides :

a – Alk^+. self-diffusion ; b – Ag^+ interdiffusion.

The values D'_h (self) obtained by means of eq. (3) were used for correcting the D_{Alk^+} (self) experimental values.

A new plot of corrected experimental values shows a good agreement between the $(D_{\mathrm{Alk}^+} - D'_h)_{\mathrm{self}}$ experimental and D_{Alk^+} (self) calculated by S–E equation (fig. 5).

D'_h (inter) for Ag^+ interdiffusion has the same dependence on volume change ΔV as D'_h (self), and the higher its value, the bigger the ratio $r_{\mathrm{Alk}^+}/r_{\mathrm{Ag}^+}$ (fig. 4b).

In this case the following equation is valid :

$$D'_h\ (\mathrm{inter}) = D'_h\ (\mathrm{self})\,\frac{r_{\mathrm{Alk}^+}}{r_{\mathrm{Ag}^+}} \tag{4}$$

where D'_h (self) is given by equation (3).

Comparable results with those predicted by S–E eq. are obtained by making the correction $(D_{\mathrm{Ag}^+} - D'_h)_{\mathrm{inter}}$ (fig. 6) for interdiffusion.

The experimental data correction may be further improved by taking into account D''_h contribution arising from experimental and theoretical slope differences. This may be done by using the cubic cell model developed by Houghton [21] for self-diffusion in molecular liquids.

According to this theory :

$$D = \frac{\lambda^2 K T}{24\, m\eta} \tag{5}$$

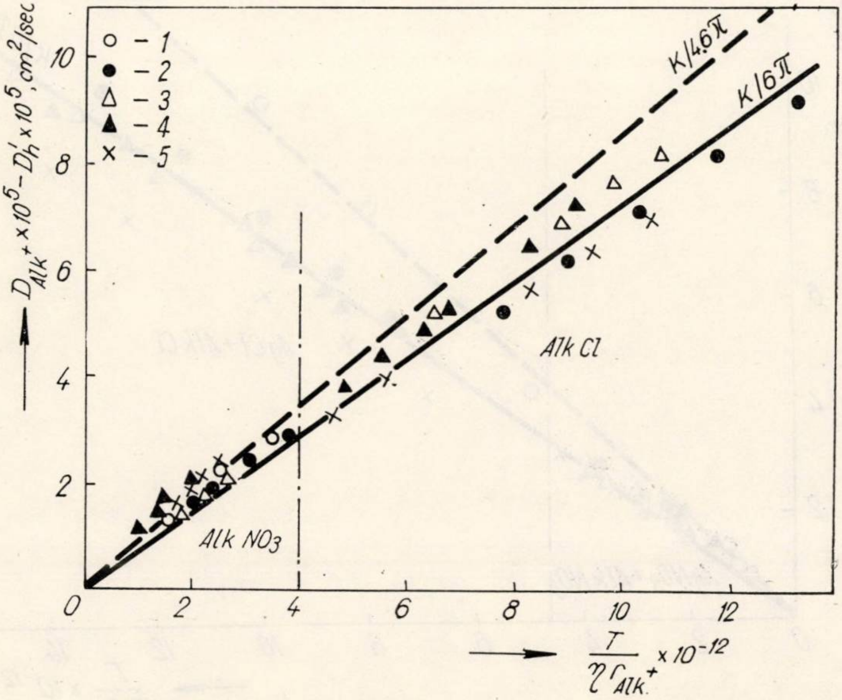

Fig. 5. — Corrected self-diffusion coefficients ($D_{\mathrm{Alk}^+} - D_h'$) for fused alkali nitrates and chlorides :

1 – Li$^+$; *2* – Na$^+$; *3* – K$^+$; *4* – Rb$^+$; *5* – Cs$^+$; ---- Stokes-Einstein eq.

where ρ is the liquid density, η the viscosity, *m* the diffusing particle mass and λ the linear dimension of a cubic cell in which the diffusing particle should accomodate. The theory approximates $\lambda = 2v^{1/3}$ where *v* represents the volume occupied by a single molecule. Equation (5) is equivalent to S—E equation when ρ and *m* refer to the same substance, in other words in the case of self-diffusion in a molecular liquid. Its employment for interdiffusion processes in molten salts involves some difficulties which we are not going to treat in this paper.

---

[21] G. Houghton, *J. Chem. Phys.*, **40**, 1628 (1964).

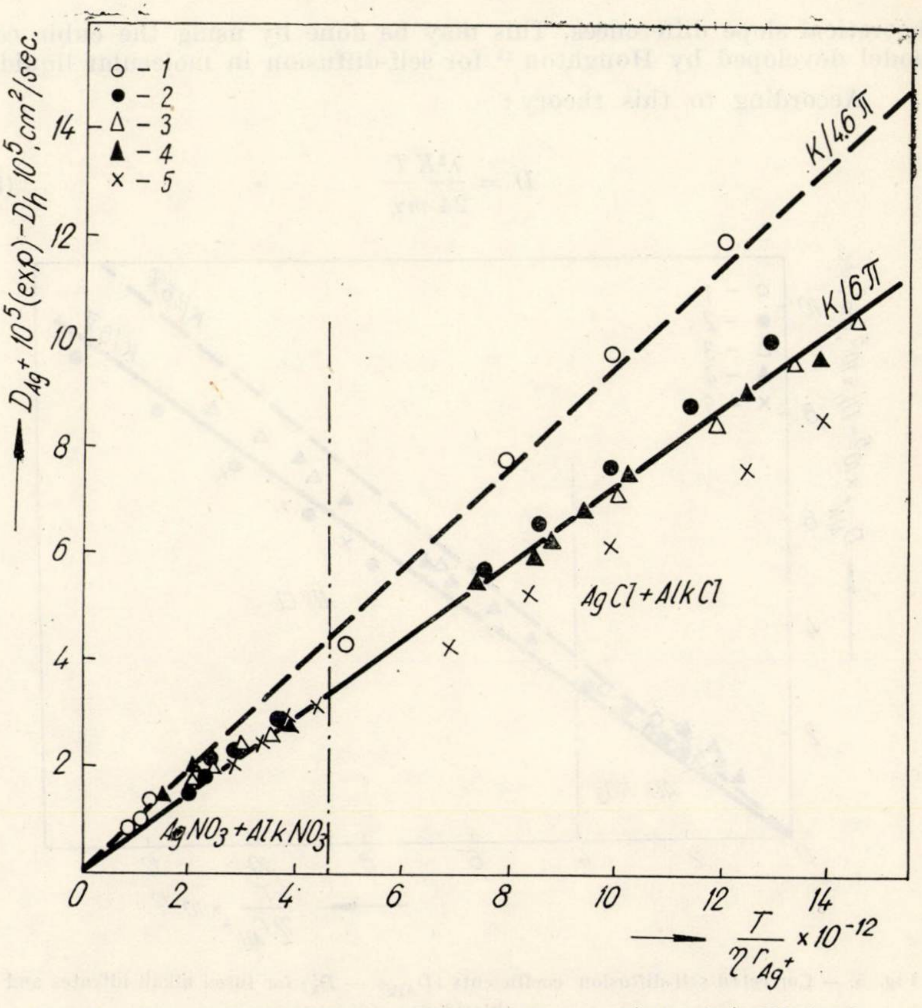

Fig. 6. – Corrected interdiffusion coefficients ($D_{Ag^+} - D'_h$) for Ag^+ diffusion in fused alkali nitrates and chlorides:
1 – Li^+ ; 2 – Na^+ ; 3 – K^+ ; 4 – Rb^+ ; 5 – Cs^+ ; ---- Stokes-Einstein eq.

However, we have tried a semiempirical equation similar to eq. (5):

$$D = \frac{(1.6+\alpha)^2\, KT}{48\eta r} = \frac{2.56\, KT}{48\eta r} + \frac{(3.2\,\alpha + \alpha^2) KT}{48\eta r} \tag{6}$$

where $\lambda = 1.6 + \alpha$ and has the same significance as above, namely the linear dimension of a cubic cell within which the diffusing ion is accomodated. In equation (6) λ is not a constant but is corrected by a value α depending on $\Delta V \cdot \lambda$ was considered equal to 1.6 in order to get Stokes-Einstein eq. (the first term of eq. 6). Therefore, the constant a from S–E eq. (1) appears in eq. (6) as a variable which depends on the structure of the diffusion medium. Assuming that the second term of eq. (6) is equal to D_h'' it was possible to calculate α values for each of the diffusion media (table 1).

From table 1 it results that the value of α parameter is a function of volume change ΔV, which may be considered as holes volume. For small values of ΔV, α becomes very small, even negative. If D_h'' were taken into account, better results would have been found for Cs^+ and Rb^+ self-diffusion and for Ag^+ interdiffusion is CsCl and RbCl which show deviations, even after the first correction has been applied (figs. 5, 6). In these cases D_h'' has negative values and making this second correction in addition to the first (D_h'), would result in a good agreement between corrected $D_{\text{exp.}}$ and $D_{\text{S-E}}$.

Table 1

Parameter α *versus* relative volume change on melting for cationic self-diffusion and Ag^+ interdiffusion in alkali nitrates and chlorides

Diffusion medium	α Alk^+ (self)	α Ag^+ (inter)	$\frac{V_l - V_s}{V_s}$
$LiNO_3$	0.15	0.75	0.21
$NaNO_3$	0.08	0.06	0.107
KNO_3	0.10	−0.11	0.033
$RbNO_3$	0.06	−0.3	−0.002
$CsNO_3$	0.01	0.04	0.121
LiCl	—	0.22	0.25
NaCl	0.06	0.079	0.23
KCl	0.009	0.01	0.168
RbCl	−0.05	−0.065	0.134
CsCl	−0.06	−0.17	0.098

The above observations show that adding up the S—E theory and cubic cell model, the experimental self-diffusion coefficient is defined by the sum of three terms, as follows:

$$D_{\text{self}} = D_{\text{S-E}} + D_h' + D_h''$$

where

$$D_{\text{S-E}} = \frac{KT}{6\pi\eta r} = \frac{2.56\,KT}{48\,\eta r}$$

$$D_h' = e^{-6.17 + 7.37\,\Delta V} - 0.15 \times 10^{-5} \tag{7}$$

$$D_h'' = \frac{(3.2\alpha + \alpha^2)\,KT}{48\,\eta r}$$

and for the diffusion of a foreign ion:

$$D_{\text{inter}} = (D_{\text{S-E}} + D_h' + D_h'')\,\frac{r^*_{\text{Me}^+}\,(\text{self})}{r_{\text{Me}^+}\,(\text{inter})} \tag{8}$$

The above equations allow the quantitative explanation of the deviations from S—E equation. The appearance of the additional term D_h, besides the diffusion coefficient $D_{\text{S-E}}$, might be explained by the fact that the volume of holes within the melt facilitates the ionic movements in the diffusion process more than in viscous flow.

Stokes-Einstein equation seems to be quite satisfactory for those salts having small ΔV (less than 10%). Salts with high volume changes on melting (LiCl, NaCl, KCl, RbCl, $CsNO_3$) have appreciable D_h values.

Further on we are going to show how different diffusion theories for liquids based on models might be applied to molten salts. These theories give the expression for self-diffusion coefficient and in order to extend them at the interdiffusion process we have considered as valid the next equation:

$$D_+\,(\text{inter}) = D_+\,(\text{self})\,\frac{r^*_{\text{Me}^+}\,(\text{inter})}{r_{\text{Me}^+}\,(\text{self})} \tag{9}$$

where D_+ (self) is given by every model.

In the free volume theory of Cohen and Turnbull [22] the self-diffusion coefficient in molecular liquides is expressed as:

$$D_i = ga^*\,(3\,K\,T/m)^{1/2}\exp\left[-\frac{\gamma v^*}{\bar{v}_m\,\alpha(T-T_0)}\right] \tag{10}$$

We have used this equation for self-diffusion in molten salts assuming that: the critical volume v^* needed by a hole to produce the diffusion of an ion is equal to the volume of diffusing ion itself considered as spherical. The average volume of an ionic hole $\bar{v}_m$ was $v_i - (V_1 - V_s)/2N$ where $v_i = 4\pi r_i^3/3$ (r_i is the diffusing ion radius and V_1 and V_s are the molar volumes of salts in solid and liquid states at melting point, respectively). The parameter a^* representing the jump distance was taken, according to the theory premises, as equal to the diameter of diffusing ion, g is a geometrical factor equal to 1/6 and γ a correction factor which was taken equal to 1/2. For the glass transition temperature T_0 we have used the values listed by Sjöblom [23] for some inorganic salts.

D_{Alk^+} (self) and D_{Ag^+} (inter) values, calculated by using eq. (10) for a few molten salts are listed in table 2.

As can be observed from this table, D_{Alk^+} (self) values calculated for alkali nitrates, except $LiNO_3$ are in good agreement with experimental data. This theory is unapplicable to alkali chlorides. A similar situation occurs in Ag^+ interdiffusion in the same solvents.

---

[23] C. A. Sjöblom, *Z. Naturforsch.*, **23a**, 933 (1968).

Quasi-lattice model (Eyring)[24] gives the kinetic-molecular significance of the pre-exponential coefficient D_0 and may thus be used as a verification criterion of D_0 coefficient from Arrhenius experimental equations.

Table 2

Applicability of the free volume model on the cationic self-diffusion and Ag+ interdiffusion in some molten salts

Solvent (nitrate or chloride)	Temp. K	Cationic self-diffusion		Interdiffusion	
		D (calcd.) cm²/sec	D (exp.) cm²/sec	D_{Ag^+} (calcd.) cm²/sec	D_{Ag^+} (exp.) cm²/sec
$LiNO_3$	623	$14.2 \cdot 10^{-5}$	$2.93 \cdot 10^{-5}$	$7.52 \cdot 10^{-5}$	$2.7 \cdot 10^{-5}$
$NaNO_3$	623	$2.74 \cdot 10^{-5}$	$2.35 \cdot 10^{-5}$	$2.65 \cdot 10^{-5}$	$2.5 \cdot 10^{-5}$
KNO_3	623	$1.63 \cdot 10^{-5}$	$1.54 \cdot 10^{-5}$	$2.21 \cdot 10^{-5}$	$1.95 \cdot 10^{-5}$
$CsNO_3$	623	$2.07 \cdot 10^{-5}$	$1.20 \cdot 10^{-5}$	$3.1 \cdot 10^{-5}$	$1.7 \cdot 10^{-5}$
NaCl	1093	$17.9 \cdot 10^{-5}$	$7.8 \cdot 10^{-5}$	$17.35 \cdot 10^{-5}$	$9.7 \cdot 10^{-5}$
RbCl	1018	$8.58 \cdot 10^{-5}$	$4.7 \cdot 10^{-5}$	$11.2 \cdot 10^{-5}$	$6.8 \cdot 10^{-5}$
CaCl	973	$19.8 \cdot 10^{-5}$	$4.0 \cdot 10^{-5}$	$29.5 \cdot 10^{-5}$	$5.5 \cdot 10^{-5}$

According to this model:

$$D = \frac{\lambda^2}{v_f^{1/3}} \left[\frac{KT}{2\pi m} \right]^{1/2} \exp\left(- \frac{E}{RT} \right) \tag{11}$$

where v_f is the free volume of liquid, m the mass of diffusing particle, λ the jump distance of the particle, the other symbols having the usual meanings. For the calculation of the pre-exponential coefficient D_0 (self) we have considered $\lambda = (V/N)^{1/3}$, where V is the molar volume of the melt[15] and the free volume $v_f = V_f/N$ values were those obtained from ultrasonic velocity measurements[25,26]. The calculations were carried out at 350° for nitrates and 850° for chlorides. The magnitudes in the expressions of D_0 (inter) and D_0(self) are identical except for the mass.

The quasi-lattice model gives the same order of magnitude for experimental and calculated D_0 (table 3). A very good agreement in the absolute values is observed for self-diffusion in alkali chlorides.

Another way to verify the above models is to control how the theoretical ratio D_+(self)/D_+(inter) corresponds to the experimental value. The ratio D_+(self)/D_+(inter) is, according to S−E eq., equal to $r^*_{Me^+}$ (self)/ /r_{Me^+} (inter) while, according to the free volume and quasi-lattice models, it is equal to $(m^*_{Me^+}\text{(self)}/m_{Me^+}\text{ (inter)})^{1/2}$. The first equality was confirmed

Table 3

Comparison between the experimental and calculated pre-exponential coefficient, according to quasi-lattice model for cationic self-diffusion and Ag+ interdiffusion in some molten salts

Salt	Cationic self-diffusion		Ag+ interdiffusion	
	D_0 (calcd.) cm²/sec.	D_0 (exp) cm²/sec	D_0 (calcd) cm²/sec	D_0 (exp) cm²/sec
$NaNO_3$	$5.63 \cdot 10^{-3}$	$1.13 \cdot 10^{-3}$	$2.58 \cdot 10^{-3}$	$1.07 \cdot 10^{-3}$
KNO_3	$4.89 \cdot 10^{-3}$	$1.48 \cdot 10^{-3}$	$2.93 \cdot 10^{-3}$	$0.65 \cdot 10^{-3}$
NaCl	$4.52 \cdot 10^{-3}$	$3.36 \cdot 10^{-3}$	$2.07 \cdot 10^{-3}$	$4.66 \cdot 10^{-3}$
RbCl	$2.47 \cdot 10^{-3}$	$2.51 \cdot 10^{-3}$	$2.17 \cdot 10^{-3}$	$1.86 \cdot 10^{-3}$
CsCl	$1.65 \cdot 10^{-3}$	$1.73 \cdot 10^{-3}$	$1.83 \cdot 10^{-3}$	$2.6 \cdot 10^{-3}$

by our results (table 4) for nitrates and chlorides having the same alkali cation, i.e. D_{Ag^+} (inter)/D_{Alk^+}(self) is nearly equal to r_{Alk^+}/r_{Ag^+}. From table 4 it results that a better agreement is obtained by making the D'_h correction to experimental diffusion coefficients. The ratio of diffusing ion masses in no case predict the experimental value of the ratio of diffusion coefficients.

Table 4

Relationships between Ag+ interdiffusion and cationic self-diffusion coefficients, ionic radii and masses in several diffusion media

Solvent (nitrate or chloride)	Nitrates		Chlorides		$\frac{r_{Alk^+}}{r_{Ag^+}}$	$\left(\frac{m_{Alk^+}}{m_{Ag^+}}\right)^{1/2}$
	D_{Ag^+}/D_{Alk^+} (exp)	$\frac{(D_{exp}-D'_h)\text{ inter}}{(D_{exp}-D'_h)\text{ self}}$	D_{Ag^+}/D_{Alk} (exp)	$\frac{(D_{exp}-D'_h)\text{ inter}}{(D_{exp}-D'_h)\text{ self}}$		
Li^+	0.66	0.61	—	—	0.61	0.24
Na^+	1.08	1.13	1.08	0.95	0.97	0.46
K^+	1.27	1.30	1.27	1.39	1.35	0.60
Rb^+	1.30	1.34	1.38	1.44	1.51	0.88
Cs^+	1.40	1.67	1.44	1.38	1.72	1.11

As for the diffusion activation energy, E_D, a comparison of the experimental values obtained from the Arrhenius equations with those for other transport processes shows that the interdiffusion activation energies are close to the self-diffusion and viscous flow activation energies and that they are quite different from those of the electrical conductivity (table 5).

According to the cubic cell model, the temperature dependence of the diffusion coefficient follows the equation:

$$D = CT \exp\,(-E_\eta/RT) \tag{12}$$

where C is a constant.

From eq. (12) it results that the activation energies of the diffusion process and viscous flow are equal. The experimental values E_η and E_D

E_η	7070	8690	6520	6080	5800	13
E_λ	1895	2530	3440	3750	4000	28
E_D(inter)/E_D(self)	—	1.06	1.12	0.83	1.01	
E_D(inter)/E_η	0.78	0.90	1.17	1.1	1.3	
E_D(inter)/E_λ	2.9	3.3	2.2	1.78	1.85	

from table 5 are in agreement with the cubic cell model predictions, in most cases the ratio E_D/E_η being almost equal to unity.

Quasi-lattice theory does not give a rigorous theoretical expression for the diffusion activation energy, E_D (eq. 11). According to Eyring [29] the activation energy may be considered as a fraction $1/n$ of the vaporization energy, the empirical factor n having values between 2 and 4. For molten salts the following empirical equation was proposed:

$$E_D = \Delta E_{\text{vap}}/n\nu \tag{13}$$

where ν is the number of ions per molecule resulting on melting. Expressions similar to eq. (13) were suggested by other authors by considering variants of the quasi-lattice model. Thus, McLaughlin [30] established the following expression for the activation energy:

$$E_D = E_{\text{vap}}(1/2 + 1/n\nu) \tag{14}$$

[31] H. A. Walls and W. R. Upthergrave, *Acta Met.*, **12**, 481 (1964).

Walls and Upthergrove[31] found an empirical relation between the activation energy and the viscous flow energy:

$$E_D = E_\eta + RT + \alpha RT^2 \tag{15}$$

where α is the thermal expansion coefficient.

From the above empirical equations it follows that, for the same diffusion medium, the activation energies for self-and interdiffusion processes are equal.

In figure 7 the E_D experimental values are compared with those resulting from eqs. (13)—(15). In our calculations we used the values of vaporization energies obtained by Topor[32] and the viscosity activation energies found by Murgulescu and Zuca[13]: n was taken as equal to 2.

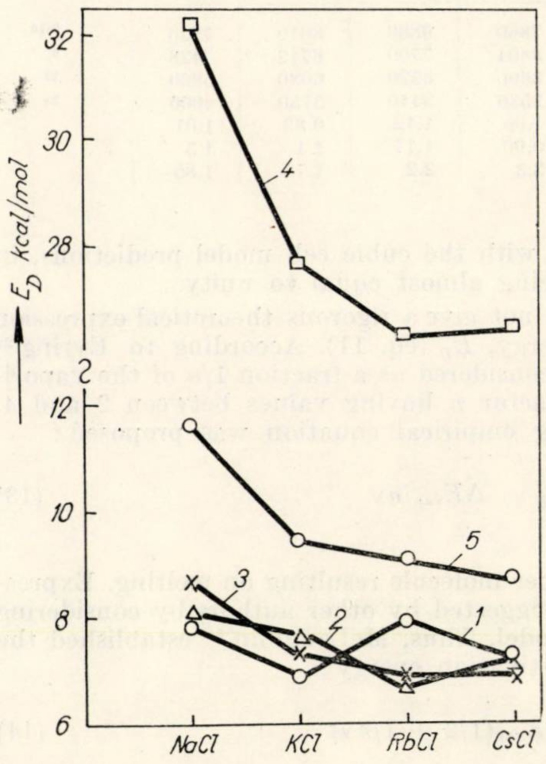

Fig. 7. — Activation energies for diffusion according to the quasi-lattice model: 1, E_D (exp.) for Alk$^+$ self-diffusion; 2, E_D (exp.) for Ag$^+$ interdiffusion; 3, eq. (13); 4, eq. (14); 5, eq. (15).

As can be observed from figure 7 our experimental data are in agreement with the predictions of the equation (13) only.

---

[32] L. Topor, Thesis, Bucharest, 1970.

The experimental data of self- and interdiffusion activation energies seem to be the best explained by the hole model [33]. Starting from the hole theory for liquids, Bockris and co-workers [34] found for the hole formation energy the equation :

$$E_D = 3.74\ RT_m \tag{16}$$

where T_m is the melting point of the solvent. The applicability of eq. (16) is illustrated in fig. 8.

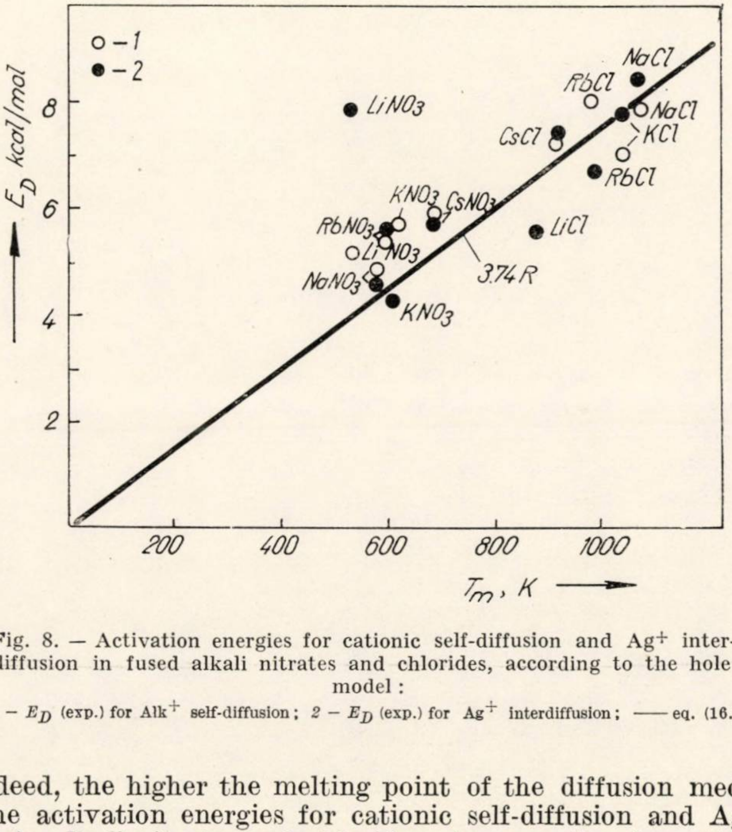

Fig. 8. — Activation energies for cationic self-diffusion and Ag^+ interdiffusion in fused alkali nitrates and chlorides, according to the hole model :

1 – E_D (exp.) for Alk^+ self-diffusion; 2 – E_D (exp.) for Ag^+ interdiffusion; —— eq. (16.)

Indeed, the higher the melting point of the diffusion medium the larger the activation energies for cationic self-diffusion and Ag^+ interdiffusion in alkali nitrates and chlorides. An exception from this rule is found for lithium salts.

It may be concluded that the diffusional mobility of monovalent ions in alkali nitrates and chlorides is mainly determined by the viscosity of the solvent, the diffusing ion and solvent cation radii and by the volume of the holes in the melt.

[34] J. O'M Bockris, S. R. Richards and L. Nanis, *J. Phys. Chem.*, **69**, 1627 (1965).

The experimental activation energies for cationic self-diffusion and Ag^+ interdiffusion in nitrates and chlorides are in a satisfactory agreement with the hole model predictions, suggesting that the main part of the activation energy is formed from the holes formation energy.

At the same time, our results suggest that a correction factor D_h, correlated with the volume of holes from the diffusion medium, should be added to the diffusion coefficient obtained from the Stokes-Einstein equation.

CHRONOPOTENTIOMETRIC STUDY OF Ag(I) IN MOLTEN MIXTURES OF ALKALI-ALKALINE EARTH METAL NITRATES

R. L. BHATIA and H. C. GAUR*

Department of Chemistry, University of Delhi, Delhi—110007, India

Received June 30, 1973

Interdiffusion coefficients of Ag^+ (D_{Ag^+}) in molten mixtures of alkali and alkaline earth metal nitrates have been studied by chronopotentiometry over a wide temperature range. The applicability of Sand's equation was examined. Temperature dependence of D_{Ag^+} was represented by Arrhenius type equations :

$D_{Ag^+} = 0.90 \times 10^{-3} \exp(-5015/RT)$ in (K, Sr)NO_3 90 : 10 mole %

$D_{Ag^+} = 0.41 \times 10^{-3} \exp(-4348/RT)$ in (K, Sr)NO_3 80 : 20 mole %

$D_{Ag^+} = 1.9 \times 10^{-3} \exp(-5998/RT)$ in (K, Ba)NO_3 90 : 10 mole %

$D_{Ag^+} = 1.43 \times 10^{-3} \exp(-5856/RT)$ in (K, Ba)NO_3 80 : 20 mole %

in the temperature range 310–418°, 331–402°, 309–409° and 356–416°, respectively.

The need for an insight into the transport phenomenon in ionic melts has led to the applicability of several electro-analytical techniques. Out of these, chronopotentiometry offers a convenient method of determining the interdiffusion coefficients in molten salt solutions.

A study on the interdiffusion coefficients of Ag^+ (D_{Ag^+}) in molten mixtures of $NaNO_3$ with alkaline earth metal nitrates was carried out previously in this laboratory. [1] In the present paper, this technique has been applied to study the effect of varying divalent ion concentration (10 and 20 mole %) on D_{Ag^+} in the molten mixtures of potassium nitrate with alkaline earth metal nitrates *viz.* strontium and barium nitrates. Data have been obtained over a sufficiently wide temperature range to enable calculation of the activation energy for the diffusion process. Changes in D_{Ag^+} with the melt composition have been examined.

EXPERIMENTAL

Potassium, strontium and barium nitrates were AnalaR (BDH) grade chemicals used without further purification. These were dried at 150–170° for several days before use. Silver nitrate also AnalaR (BDH) grade chemical was powdered and desiccated under vacuum. 150 to 200 g of the binary mixture $KNO_3-xM(NO_3)_2$ (M = Sr, Ba and $x = 10$, 20 mole%) was taken in a pyrex cylindrical vessel (*c.* 380 mm long, 68 mm o.d.) which was vertically held in an electrical furnace (750 W) and fused under an inert atmosphere. Melt temperature could be controlled within ± 1° of the set value and measured with a calibrated Chromel-Alumel thermocouple held in a glass sheath dipping into the melt. Melt densities were used from data of Petersen *et al.* [2] The melt was divided into several compartments by glass tubes with fritted bottom (porosity G–4).

A three electrode system was used. Ag/Ag^+ (*c.* 0.011 m) in melt was the reference system. A platinum foil (area *c.* 2.5 cm^2.) dipping into another compartment was the auxiliary electrode. The microelectrode was also a platinum foil (area *c.* 0.5035 cm^2) spot welded to a 26 gauge platinum wire which was sealed in soda-lead (Corning 0120) glass tubing. Electrode area was determined using an optical micrometer.

An oscilloscopic method of measuring transition time [3] was employed. The instrumentation and technique used have been described elsewhere. [4] The chronopotentiograms were observed on Hewlett & Packard (model 122 A) oscilloscope and photographed with a Fairchild Dumont (Type 450 A) 35 mm camera on an ORWO NP-7 panchromatic film. The time-base was provided by *z*-modulation of the electron beam with a square wave from an H & P function generator (3300 A). Measurements were made with enlarged traces (× 100) using a Nikon Profile Projector.

Blank runs showed that decomposition potential of melt was *c.* 0.5 volt *versus* Ag/Ag^+ (*c.* 0.010 m) reference. Weighed increments of $AgNO_3$ were added to the indicator half-cell with a small platinum scoop provided with a long glass handle. The current density was so adjusted that the transition time was within the range 0.5 to 1.5 sec.

RESULTS AND DISCUSSION

D_{Ag^+}'s were determined in molten mixtures of $KNO_3-Sr(NO_3)_2$ (90 : 10 mole %), $KNO_3-Sr(NO_3)_2$ (80 : 20 mole%), $KNO_3-Ba(NO_3)_2$ (90 : 10 mole %) and $KNO_3-Ba(NO_3)_2$ (80 : 20 mole%) in the temperature range 310–418°, 331–402°, 309–409° and 356–416°, respectively.

Diffusion coefficients (D_{Ag^+}) were computed using Sand's equation [5]

$$\tau^{\frac{1}{2}} = \pi^{\frac{1}{2}} nFD^{\frac{1}{2}}_{Ag^+} C/2i_0 \tag{1}$$

where τ is the transition time (sec); C, the depolarizer concentration (moles cm^{-3}); i_0, the current density ($A \cdot cm^{-2}$) and π, n, F are well-known constants. This equation holds good when the mass transfer towards the electrode is governed solely by linear diffusion.

Figure 1 shows a typical chronopotentiogram for the reduction of Ag^+ ion on PME in which the method of evaluating the transition time (cf. Thalmayer *et al.* [6]) has also been indicated. Table 1 gives the variation of $i_0\tau^{\frac{1}{2}}$ as a function of i_0 for a fixed depolarizer concentration ($0.873 \times \times 10^{-5}$ mole cm^{-3}). Variation of $i_0\tau^{\frac{1}{2}}$ with C in different molten mixtures is shown in figure 2 (A, B). All the plots are rectilinear and pass through the origin, indicating the applicability of Sand's equation. Each point in figure 2 denotes the average of $i_0\tau^{\frac{1}{2}}$ at 4 to 5 current densities.

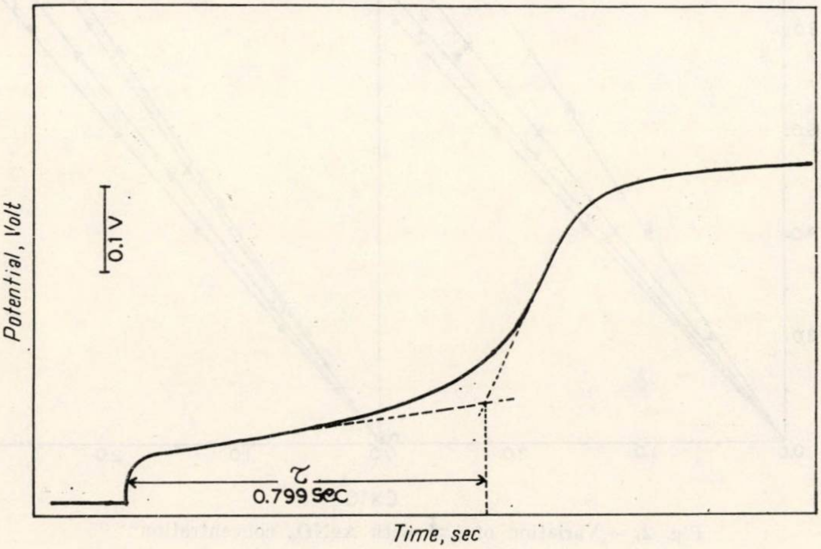

Fig. 1. — Potential-time curve for the reduction of silver ion in molten $KNO_3-Ba(NO_3)_2$ (90 : 10 mole %) at 333°.
$C = 0.873 \times 10^{-5}$ mole cm^{-3}; $i_0 = 3.20 \times 10^{-3}$ amp. cm^{-2}.

Table 1

Chronopotentiometric data for the reduction of Ag^+ ion in $KNO_3-Ba(NO_3)_2$ at 333°, $C = 0.873 \times 10^{-5}$ mole cm^{-3}

$i_0 \times 10^3$ A·cm^{-2}	3.00	3.21	3.50	3.85	3.92	4.00	3.20
$i_0\tau^{\frac{1}{2}} \cdot 10^3$ A·sec$^{\frac{1}{2}}$ cm^{-2}	2.90	2.88	2.89	2.91	2.86	2.92	2.86

AV $(i_0\tau^{\frac{1}{2}}) = 2.89 \pm 0.03$

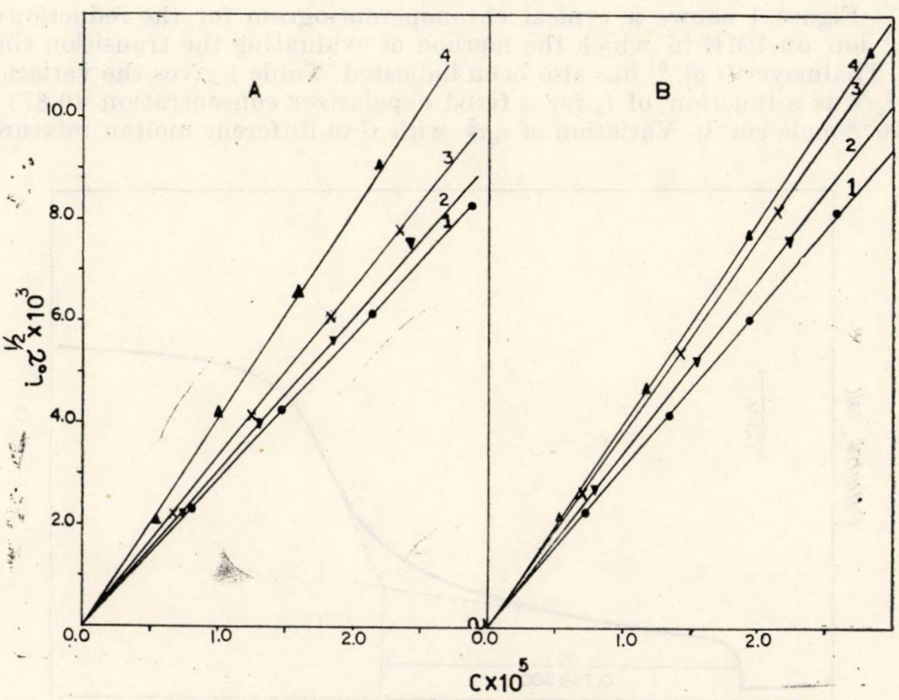

Fig. 2. — Variation of $i_0\tau^{\frac{1}{2}}$ with $AgNO_3$ concentration:

(A) in molten $KNO_3-Sr(NO_3)_2$ mixtures:
90 : 10 mole %; *2* (at 322°) and *4* (at 415°).
80 : 20 mole %; *1* (at 340°) and *3* (at 392°).

(B) in molten $KNO_3-Ba(NO_3)_2$ mixtures:
90 : 10 mole %; *2* (at 351°) and *4* (at 401°).
80 : 20 mole %; *1* (at 361°) and *3* (at 418°).

The temperature dependence of D_{Ag^+} (figure 3 (A, B)) could be represented by an Arrhenius type equation

$$D_{Ag^+} = D_0 \exp(-E_D/RT) \qquad (2)$$

where E_D is the activation energy for diffusion and D_0 the preexponential factor. The values of these parameters were determined by least square fitting of the data.

In table 2 the interdiffusion coefficients of Ag^+ at 384.7° as well as the values of Arrhenius parameters in various compositions of molten mixtures are given. For comparison, results of Sternberg and Herdlicka[7] in molten KNO_3 are also included. It is seen that there is a decrease in the magnitude of D_{Ag^+} with the increase in divalent ion concentration in the melt composition. This can be explained due to the change in cation field strength, $\sum \frac{n_i Z_i}{r_i}$ where n_i is the mole fraction, Z_i the ionic charge

and r_i the radius of ith ion, of the solvent. It is seen that with an increase in cation field strength, a decrease in D_{Ag^+} is observed.

It may be pointed out that in crystalline nitrates and chlorides the extent of ion migration is enhanced by the incorporation of divalent ions into their lattices [9] whereas melts being more compressible than the corresponding crystals, the increasing cation field strength due to the presence of the divalent ion in the molten mixtures causes a shrinkage of the free volume in them which probably hinders the diffusion of Ag^+ ion towards the electrode. Our observations are supported by the conductance measurements in halide [10] and nitrate, [11-13] which also show a decrease in ionic conductance, when a divalent cation replaces a univalent cation in the melt.

CALORIMETRIC KINETICS. IV[1]

THE REACTION OF BENZOYL CHLORIDE WITH SODIUM METHOXIDE AND ETHOXIDE

RODICA VÎLCU and I. CIOCĂZANU

Chair of Chemical Thermodynamics and Electrochemistry,
University of Bucharest, Bdul Republicii N° 13, Romania

Received June 14, 1973

The kinetic parameters of the reaction between benzoyl chloride and sodium methoxide and ethoxide were derived through an anisothermal calorimetric method. The reactions have been investigated within the 15–35° temperature range as pseudomonomolecular reactions and bimolecular reactions of equal initial concentrations.

INTRODUCTION

The reactions of the benzoyl chloride with certain sodium alkoxides have been studied by a thermal maximum method version. [2] The thermal maximum method consists in observing, in nonadiabatic conditions, the maximum (or minimum) temperature reached during the reaction, comparative to the environmental constant temperature.

Benzoyl chloride reactions with sodium alkoxides:

$$C_6H_5COCl + R - ONa \rightleftarrows C_6H_5COOR + NaCl$$

have been investigated as bimolecular reactions with equal initial concentrations. The rate constants and activation energy were computed.

These reactions were also studied as pseudomonomolecular reactions. In this case, the rate constants, the activation energy and other activation thermodynamic functions ($\Delta H^{\neq}$, $\Delta G^{\neq}$, and $\Delta S^{\neq}$) were calculated.

---

[1] Part III. R. Vîlcu and I. Ciocăzanu, *Rev. Roumaine Chim.*, **5**, 643 (1971).

[2] R. P. Bell and J. C. Clunie, *Proc. Roy. Soc. A*, **16**, 212 (1952).

THEORY

The rate constant of bimolecular reactions with equal initial concentration is given by the relation :

$$k_2 = \frac{1}{t}\left(\frac{1}{a - x} - \frac{1}{a}\right) \tag{1}$$

where a is the reactant concentration at the initial moment and x the decrease of concentration at the t moment of the reaction.

Correlating the reactants concentration at the various moments by the corresponding temperature variations, the following relation is obtained :

$$T = \frac{k_2\, t T_0^2}{1 + k_2 t T_0} \tag{2}$$

where T is the temperature at the moment t and T_0 is the changed temperature, in the adiabatic conditions and it is a measure of reactions of a moles of reactants.

Differentiating the equation (2) with respect to time and taking into account the thermal losses through the calorimetric vessel walls, the thermal equation of such a process is obtained :

$$\frac{\mathrm{d}T}{\mathrm{d}t} = \frac{k_2 T_0^2}{(1 + k_2 t T_0)^2} - k_2' T \tag{3}$$

where k'_2 is the cooling rate constant of the calorimeter.

The general solution of differential equation (3) well take the form :

$$T = A_0\, \mathrm{e}^{-k_2' t} + k_2 T_0^2\, \mathrm{e}^{-k_2' t} \int_{t_0}^{t} \frac{\mathrm{e}^{k_2' t}}{(1 + k_2 T_0 t)^2}\, \mathrm{d}t \tag{4}$$

The purpose of this relation is the computation of rate constant k_2 as function of the magnitudes that can be experimentally determined. Thus, by solving this relation for the lower limit it is obtained :

$$k_2 = \frac{k_2'}{2\, T_0(\mathrm{e}^{k_2' T_m} - 1)} \tag{5}$$

and for the upper limit :

$$k_2 = \frac{k_2'}{2\, T_0\left(\mathrm{e}^{k_2' T_m} - 1 - \dfrac{T_m k_2'}{2}\right)} \tag{5'}$$

In the relations (5) and (5′) T_m represents the maximum recorded temperature in nonadiabatic conditions during this process, and T_0 is the thermal effect recorded in adiabatic conditions by consumption of *a* moles of reactant.

The computation of the rate constants of pseudomonomolecular reactions was presented in a previous paper.[1]

The activation energy of reactions as well as the frequency factors were calculated by an Arrhenius type relation :

$$\ln k = \ln A - \frac{E}{RT} \tag{6}$$

The activation thermodynamic functions of reactions ($\Delta H^{\neq}$, $\Delta G^{\neq}$ and $\Delta S^{\neq}$) have been computed by the theory of the absolute reaction rate from the kinetic parameters of reactions.

Thus, in the activated complex theory it is shown that the activated complex entropy is correlated with the other parameters by the relation[3] :

$$k = x\frac{\mathbf{k}T}{h}\,\mathrm{e}^{\frac{\Delta s^{\neq}}{R}}\cdot \mathrm{e}\cdot \mathrm{e}^{-E/RT} \tag{7}$$

where **k** is the Boltzmann's constant, *h* is the Planck's constant and *x* is a corrective term (close to the unity).

By identification with Arrhenius' equation, the value of frequency factor is obtained :

$$A = x\frac{\mathbf{k}T}{h}\,\mathrm{e}\cdot \mathrm{e}^{\Delta S^{\neq}/R} \tag{8}$$

The other activation thermodynamic functions are computed by the well-known relations.

THE EXPERIMENTAL DEVICE AND REACTANTS

An anisothermal calorimeter formerly described was employed.[4] The calorimeter is immersed in a U 10 ultra-thermostat which maintains the water temperature within $\pm 2\cdot 10^{-2}$. Due to the calorimeter construction, a constant temperature within $\pm 1\cdot 10^{-3}$ in the calorimeter vessel was obtained. A platinum thermal resistance of 100 Ω ± 0.1 Ω at 0°C with a thermal coefficient of $3.8\cdot 10^{-3}$ Ω/degree was employed as thermal transductor.

---

[3] G. NIAC and E. SCHÖNBERGER, "Chimie fizică", vol. 3, Editura tehnică, Bucureşti, 1970, p. 382.

[4] R. VÎLCU and I. CIOCĂZANU, *Rev. Roumaine Chim.*, **14**, 429 (1969).

This thermal resistance was mounted in a D.C. Wheatstone bridge. The other three arms of the Wheatstone bridge are manganin resistances of 100 Ω each.

The temperature variation inside the calorimeter was observed by a Sefram recording galvanometer Type VAM (of $4 \cdot 10^{-9}$ A/mm sensitivity).

The benzoyl chloride employed was chemically pure (Analar). The purity of substance was checked by the refractive index.

Amounts of 0.1 – 0.15 g of benzoyl chloride have been sealed in ampouls. The alkoxides used were obtained in laboratory from metallic sodium and the respective alcohols. The alkoxides concentration has been determined by titration with salicylic acid 0.1 N in the presence of bromine-thymol blue.

EXPERIMENTAL RESULTS AND DISCUSSION

The temperature-time curves plotted for the studied reactions have the shape illustrated in fig. 1

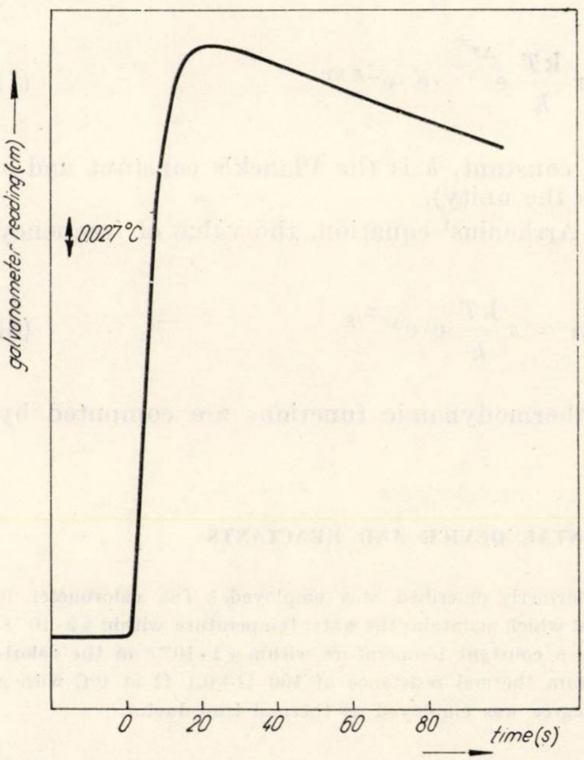

Fig. 1. – Temperature-time curve.

If the reactions have been treated as pseudomonomolecular reactions, the rate constants and the activation energy ($cal \cdot mol^{-1}$) are those given in table 1.

Besides these data, this table include also the working temperatures (°C), the time values for which the maximal temperatures (s) were recorded. These values are the mean of 4 or 5 determinations of each working temperature. The frequency factors computed according to Arrhenius' equation are $5.3\cdot10^{6}$ and $3.59\cdot10^{9}$ (s^{-1}) respectively.

Table 1

Rate constants, activation energies and the frequency factors corresponding to the reactions $C_6H_5COCl + RONa$

RONa	T°C	t_m(s)	$k_1(s^{-1})$	E cal·mol^{-1}	A_{exp} (s^{-1})
CH_3ONa	16 25 35	20 13 9	0.324 0.537 0.897	9540	$5.3\cdot10^{6}$
C_2H_5ONa	20 25 35	32 23 12	0.185 0.274 0.590	13820	$3.59\cdot10^{9}$

The representation in semi-logarithmical coordinates $\left(\log k = f\left(\frac{1}{T}\right)\right)$ leads to lines (fig. 2) from the slopes of which the activation energies of the reactions have been computed.

The activation thermodynamic functions of the two reactions, computed by relations (6) and (7) and the Gibbs-Helmholtz relations are given in table 2.

From the negative activation entropy values it may be concluded than an arrangement of the molecules is taking place during the reaction.

When reactions were studied in conditions of equal initial concentrations, the rate constants obtained are indicated in table 3 and presented as $\log k_2$ vs $\frac{1}{T}$ coordinates in figure 3.

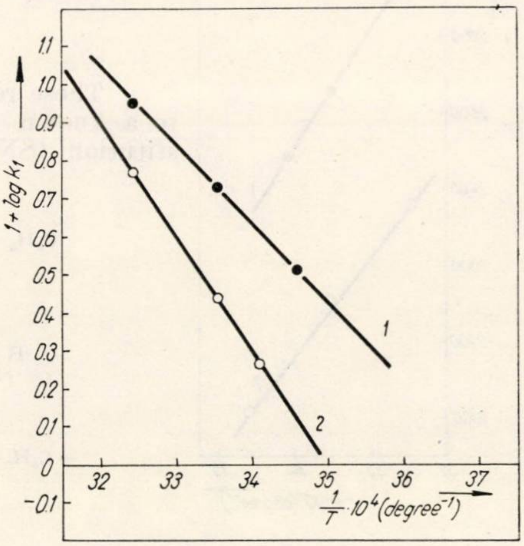

Fig. 2. — $\log k_1$ *versus* $1/T$:
1, $C_6H_5COCl + CH_3ONa$;
2, $C_6H_5COCl + C_2H_5ONa$.

From these rate constants the following values for the activation energies are calculated : 6300±800 and 7250±800 cal·mol^{-1}, respectively.

Table 2

Activation parameters of the reactions $C_6H_5COCl + RONa$

RONa	$\Delta H^{\neq}$ cal·mol^{-1}	$\Delta S^{\neq}$ cal·deg^{-1}·mol^{-1}	$\Delta G^{\neq}$ cal·mol^{-1}
CH_3ONa	8,950	−24.2	16,160
C_2H_5ONa	13,220	−21.20	19,540

Table 3

Rate constants of the reactions $C_6H_5COCl + RONa$ in conditions of equal initial concentrations

RONa	$a.10^3$ mol·l^{-1}	t°C	$10^{-1}\, k_2$ l·mol^{-1} min^{-1}	E cal·mol^{-1}
CH_3ONa	10.18	16	12.770	6300
	12.29	25	17.940

	13.64	35	50.119	

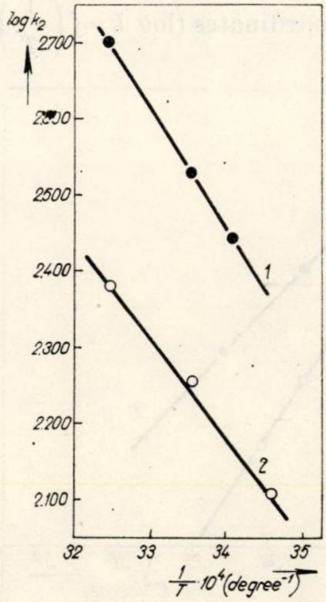

Fig. 3. — log k_2 *versus* $1/T$:

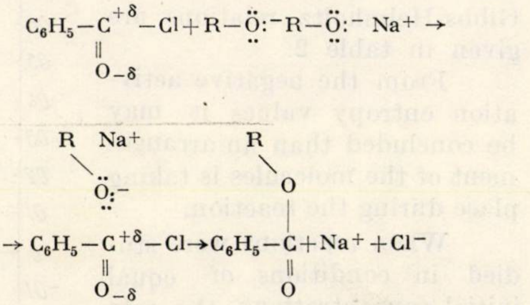
1, $C_6H_5COCl + C_2H_5ONa$; *2*, $C_6H_5COCl + CH_3ONa$.

These reactions are taking place according to a known mechanism of nucleophilic substitution (SN). [5]



$$C_6H_5-\underset{\underset{O_{-\delta}}{\|}}{C^{+\delta}}-Cl + R-\ddot{\underset{..}{O}}:^- R-\ddot{\underset{..}{O}}:^- Na^+ \rightarrow$$

$$\rightarrow C_6H_5-\underset{\underset{O_{-\delta}}{\|}}{\overset{\overset{R\diagdown\ddot{\underset{..}{O}}:^-\quad Na^+}{}}{C^{+\delta}}}-Cl \rightarrow C_6H_5-\underset{\underset{O}{\|}}{\overset{\overset{R\diagdown O}{|}}{C}} + Na^+ + Cl^-$$

It can be assumed, in conclusion, that the thermal method employed in studying these reactions is an easy and rapid procedure, allowing at the same time the determination of kinetic and thermodynamic magnitudes of great practical importance.

ENTHALPIES OF MIXING OF THE CARBOXYLIC ACID-WATER SYSTEMS

RODICA VÎLCU and ELENA LUCINESCU

University of Bucharest, Chair of Thermodynamic Chemistry,
Electrochemistry and Macromolecules, Bd. Republicii 13, Romania

Received June 14, 1973

The enthalpies of mixtures of the binary systems : formic acid-water, acetic acid-water and propionic acid-water were determined, at standard temperature, directly by the calorimetric methods. Variation with the composition was expressed by equations of the Redlich-Kister form and the corresponding curves were interpreted by means of structural data. It was pointed out that the behaviour of the formic acid differs from that of the other acids under consideration.

INTRODUCTION

In contrast with alcohols, which constituted the basic experimental and theoretical material in the study of the thermodynamic properties of associated systems, the carboxylic acids offer but a scanty information from this standpoint, because of the complexity of the association process both in a pure state and in some mixtures, in the case of mixed associated molecules.

In this paper, we deal with the behaviour of the first three acids in the aliphatic series, when mixed with water, by measuring their enthalpies of mixing. These effects will result from opposite contributions — — the breaking of the hydrogen bond from the pure components and the exothermal formation of bonds in the mixed acid-water associates, the magnitude and contribution of which vary widely with the mixture composition.

For these reasons, from the thermal data supplied by experiments, we can only suggest a few standpoints permitting to understand this behaviour on the basis of the available structural data about these aqueous solutions.

It is known for a long time that the association of acids is expressed by the equilibrium between monomer and dimer, but some researches propose equally, by virtue of experimental data, the formation of higher polymers-linear [1,5] or cyclic [6], the polymerization degree diminishing with increasing the chain length. But generally, the quantitative interpretations amount to the consideration of the dimer, or at most of the trimer.

The formic acid offers more probable proofs as to the association in linear polymers, [7,8] rather than in dimers, which would only characterize the vapour phase. The linking to the carboxyl of a hydrocarbon radical renders the dimerization more probable. The strength of the hydrogen bond increase in the order $HCOOH < CH_3COOH < CH_3-CH_2-COOH$. [9] Applying the LCAO-MO computation method, Schuster [10] found the same energy hydrogen bond in the cyclic as in the linear dimer, which can constitute the link in a chain.

For the aqueous mixtures where mixed associated molecules also appear, whose structure changes with the concentration, the most abundant data in the literature refer to the system acetic acid-water and are chiefly based on the study of the Raman spectrum. For the other acids, the literature presents many gaps. In the concentrated acetic acid solutions the cyclic dimeric form is predominant and by dilution this form tends to change in linear dimers [11,14], or to polymers. This change is taking place predominantly at the concentration under 60% moles acid. [15,16] For these solutions, the data supplied by the Raman spectra, infrared, as well as the dielectric properties, indicate the formation of hydrates. [12,13,17-23] In the case of equimolecular solutions and those with moderate

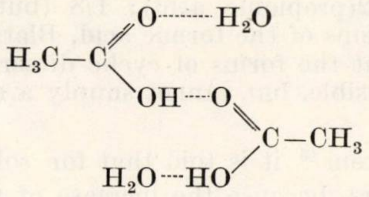
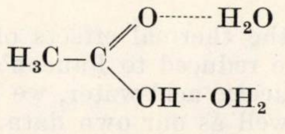
concentrations, the most probable structure seems to be[12,13]



while for more dilute solutions the dihydrated monomer



can equally appear. Campbell[23] and Shakaline[20] propose the formation first of the monohydrated dimer and then of dihydrated dimer. In the case of advanced dilutions ($x < 0.002$), there also appears an electrolytic dissociation, followed by the ion solvation of $>COO^-$ with coordination number 6 and the strength of the bond of 22 kcal/mol[24].

The following diagram supplied by Misčenko[15] summarizes the composition complexity of the aqueous mixtures of acetic acid.

100

For the aqueous solutions of the other acids, very few data are available and even those are rather uncertain.

From R.M.N. data[25] and dielectric properties[21] with anomalous values for the 50% acid volume composition, we deduce that this is the best composition for the formation of the propionic acid-water complex.

[25] B. N. Bahr and G. Lindström, *J. Chem. Phys.*, **23**, 1958 (1955).

From ultrasonic researches,[22] we have the following values for the ratio number of acid molecules/number of water molecules : 3(formic acid); 1(acetic acid); 2(propionic acid); 1/8 (butyric acid).

For aqueous solutions of the formic acid, Blatz,[16] based on Raman researches, supposes that the forms of cyclic dimers, which are as open as the hydrâtes, are possible, but cannot supply a reliable attribution of the frequencies.

For the same system[26] it is told that for solutions with $x < 0.1$, there are only monomers, because the increase of the concentration involves the decrease of the hydration degree; two water molecules for an acid molecule, for about $x < 0.2$, and afterwards a water molecule for an acid molecule.

The information about the thermal effects of the mixture in the case of acid-water systems, are reduced to Faucon's data[27] for the first four acids at 7°, while for the acetic acid-water, we have the more recent data of Gieskes,[28] at 25°, as well as our own data,[29] at three temperatures (17.4°, 25.4° and 34.2°).

APPARATUS

The calorimeter was described in a previous paper[29].

REAGENTS

The purity of the reagents was verified for the acetic acid by titration with a hydroxide solution. For the formic acid and for the propionic acid we found the refractive indices 1.3714 and 1.3871, in full agreement with the literature data.

The solution were prepared by weight, using twice distilled water.

EXPERIMENTAL RESULTS

The calorimetric measurements were made at 25°, at the atmospheric pressure for the following systems : formic acid-water, acetic acid-water, propionic acid-water. The solutions were obtained by successively mixing of the components, by concentrating in acid the solutions with a molar fraction lower than 0.4 or by adding water to the other solutions. The thermal effects observed during the successive mixings, appear equally in the case of the direct mixing of the components for a given composition. The right branch of the curve fitted perfectly with the left one.

For each system, we effected two series of measurements and the data intercalated perfectly in the graphical representations.

The enthalpies of mixing, accompanying the formation of a mole of solutions of various compositions, were computed with the help of the calorimetric data, by equation

$$H_r^M = \left\{\frac{(H^M)_{r-1}}{(n_2)_{r-1}}\,[(n_2)_{r-1} - x] + C_r\theta_r\right\}\frac{1}{(n_1)_r + [(n_2)_{r-1} - x + y]}$$

n — number of moles
1,2 — indices of components
r — the determination number
x — concentration diminution of component 2 (moles)
y — concentration increase of component 2 (moles)
C — heat capacity of the system
θ — temperature variation during mixing.

The successive mixtures were obtained by withdrawing a volume of mixture and by adding an equal volume of component 2.

The evaporation of the liquids, during their 8 hours in the thermostat, was avoided by maintaining a very small dead space. By weighing the solutions after the experiment, we have found that the liquid losses were quite small, owing probably also to their careful operating.

Since in the whole domain of heat capacities, the literature gives only the values concerning the acid acetic-water system, [30] we were compelled to proceed to the measurement of these quantities; we made them at about 25°.

The results of the calorimetric measurements were expressed as a function of the acid concentration, by equations of the Redlich-Kister form. The values of the empirical constants were determined by the method of least squares:

formic acid-water: $$H^M = x(1 - x)[-374.853 - 157.331\ (2x - 1) + 187.323\ (2x - 1)^2 + 49.072\ (2x - 1)^3]$$

acetic acid-water: $$H^M = x(1 - x)\ [315.740 + 152.870\ (2x - 1) - 28.417\ (2x - 1)^2 + 434.109\ (2x - 1)^3]$$

propionic acid-water: $$H^M = x(1 - x)[943.462 + 375.797\ (2x - 1) - 27.120\ (2x - 1)^2 + 529.878\ (2x - 1)^3]$$

The first table contains the values of the molar enthalpies of mixing both experimental and computed by one of the above equations, while in figure 1, these values are represented as a function of the acid molar fraction.

The continuous curve represents the computed values, while the spots supply the experimental data. The best concordance appears in the case of the formic acid-water system and the largest deviation is found in the case of the diluted solutions of propionic acid, when experimental data are negative while the respective equation supply positive values. A good concordance appears in the case of the compositions with

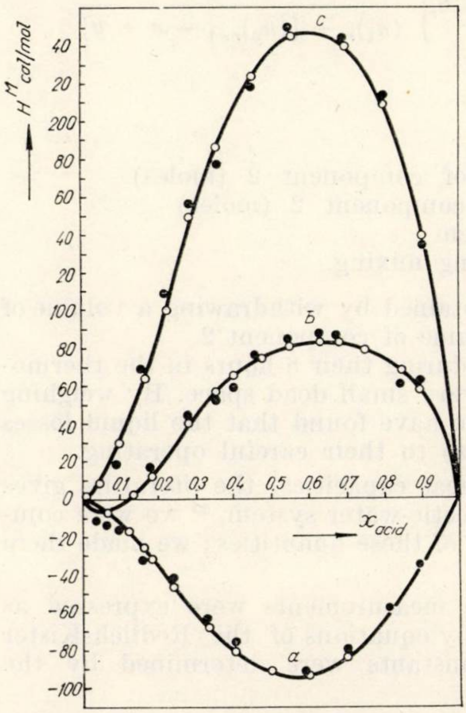

Fig. 1. — Enthalpies of mixing for the systems : *a*) $HCOOH-H_2O$; *b*) $CH_3COOH-H_2O$; *c*) $CH_3.CH_2.COOH-H_2O$; ● experimental data ; o calculated data.

$x > 0.22$. It should probably be added that, in the equation of this system, there is a term that vanishes when $x > 0.2$. However, for the sake of unitary treatment, we made use of an equation of the same form for all three systems.

For comparison, the literature supply data only for the acetic acid-water system. [28] The agreement is satisfying and the largest differences, reaching about 5%, appear in the range of the highest enthalpies.

DISCUSSION OF THE RESULTS

Our results represented by figure 1, just like those supplied by Faucon, [27] emphasize the exceptional behaviour of the formic acid as compared with the other acids of the series and also from the standpoint of the thermal mixing effects. Along the whole range of concentrations, the aqueous solutions of the formic acid are always formed with heat release, while the binding of a hydrocarbon radical to the carboxyl leads to endothermal water mixtures, except the very diluted solutions, where the exothermal effects reappear. Curves $H^M - x$ of the acetic and propionic acids are therefore of an S-form, the negative branch diminishing noticeably from the acetic to the propionic acid, while the positive branch offers an increase of about 3 times in the maximum region.

To establish that this behaviour is the rule, we must moreover make the measurements in the *n*-butyric-water system. According to Faucon's data, this system would deviate from the above rule and intercalate between the curves of the acetic and propionic acids. The extreme values of the enthalpies of mixing, in the case of these 3 systems, are however in the neighbourhood of a 0.6 molar fraction of the acid. Faucon made this study hoping to be able to deduce from the curves of the thermal effects, what hydrates should be formed corresponding to a maximum exothermal effect.

From the behaviour of these systems, it would be deduced that HCOOH alone could form a hydrate. Now, the enthalpy of mixing is a global value of thermal effects due to the breaking of the hydrogen bonds from the pure components and the formation of acid-water bonds either through the carboxyl or through the carboxylic oxhydryl. Therefore, this quantity can on no account constitute for these systems the criteria to decide whether or not hydrates of the carboxylic acids are formed. And that is why Faucon drew the erroneous conclusion that acids do not form associate molecules with water, a fact that cannot be called in question any more, nowadays. This was proved by the most adequate structural methods of the I.R. or Raman spectroscopy that lead to the direct study of the molecule, and reflect all the vibrations modifications due to changes in molecular bonds.

A quantitative interpretation of these thermal effects of the mixtures is impossible with the available data. All we can do, is to suggest a few qualitative aspects related to the known structural data. As a matter of fact, the acetic acid-water system is the only one that allows a qualitative discussion, the other two systems being insufficiently studied.

The endothermal effects, yielded by adding water to acids, indicate rather the prevalence of the processes of bond breaking, than the creation of new bonds.

On the basis of the explanation given by Joerges and Nikuradze, [31] we can admit that the energy necessary ot break an acid is at all events higher than that required by the depolymerization of the water, while the number of mixed associate molecules is in any case smaller than the total number of the dissociated molecules.

On the other hand, the endothermal contribution in the case of concentrated solutions can be due to the breaking of cyclic dimers into open ones, as it appears in the increase of the excess entropy [29] that indicates a loss of the system order when water is added. The exothermal contribution of the formation of hydrates seems to begin of being felt at concentrations lower than $x = 0.6$. According to Misčenko, [15] in this

0.905	−31.607	−30.375						

domain the hydrated forms are prevalent, the formation of which is accompanied by effects comparable with those of dissociation of the associated molecules ; when dissociating, the dimer absorbs *ca.* 13.8 kcal/mol, while the monomer releases 12.4 kcal/mol, [32] when the dihydrate is formed. Besides, in the case of very diluted solutions, the hydration of the acid radical yields the high enough energy of 22 kcal/mol.

In spite of very high positive values in the case of the propionic acid, according to the curve aspect, similar to that of the acetic acid, it seems that the propionic acid-water system would present a similar mechanism of the formation mixtures, to that of the acetic acid-water system, though much more pronounced. The same conclusion is arrived by Ramakrishna Rao [21] : discussing the dielectric behaviour of these two systems, he supposed the formation of hydrogen acid-water bonds.

As to the formic acid-water system, the exothermal effects along the entire domain of concentrations, suggest the predominance of formation effects of new associate molecules, probably hydrates, with regard to the dissociation effects. Indded, if we admit a chain structure of the acid, with the free oxhydryl and carbonyl groups, able to bond water molecules, the formation of mixed asssociated molecules is more probable than the breaking of the existent ones with loss of energy, than can occur, but in a much smaller measure.

COMPLEXES OF ANTHRANIL-N,N-DIACETIC ACID WITH TRIVALENT METALS. III[1]

ENTROPY CHANGE CALCULATION

C. DRĂGULESCU, S. POLICEC and T. SIMIONESCU

Center of Chemistry, Bd. Mihai Viteazul, 24, Timişoara, Romania

Received October 18, 1973

The entropy change during chelating reactions performed between each of the following Ga^{3+}, In^{3+}, Sc^{3+}, Y^{3+} and La^{3+} as central metal ion and the anthranil-N,N-diacetic acid (ANDA) as ligand, has been computed by means of the expression $\Delta S^\circ = \Delta H^\circ + 2.303\ RT \log K/T$ and the corresponding, previously determined ΔH° and K values have been used. As ΔS° values showed there is a big entropy increase during the reaction, accounting for the formation and stability of the metal chelates in spite of unfavourable reaction enthalpy. The complex stability was thus attributed to entropy factors only, particularly to the chelate effect. An interpretation of the entropy effect as well as of the chelate effect was next attempted for the investigated Me^{III}-ANDA complexes.

INTRODUCTION

In previous works concerning chelating equilibria in liquid phase of the anthranil-N,N-diacetic acid with Ga^{3+}, In^{3+}, Sc^{3+}, Y^{3+} and La^{3+} metal ions, the composition and stability of the chelate complexes formed in certain conditions as well as the amount of heat change during the reaction [2] were determined. [1]

The composition and stability study performed spectrophotometrically showed the formation in aqueous solution of mononuclear, equimolar complexes with a medium stability. The reaction enthalpy, determined thermometrically, has previously shown that the chelation process is endothermic, thus energetically unlikely to proceed.

As in a given system the sense of spontaneous transformations is indicated by the balance of the reaction enthalpy and the entropy change, an unfavourable enthalpy factor may be compensated by a favourable entropy one. In order to explain, in these conditions, the formation and stability of the investigated Me-ANDA complexes it was assumed that the reactions are accompanied by a positive entropy change, large enough to determine the sense of reaction towards the chelate complex formation. This had to be proved by the entropy change calculation, which has been performed in the present work and is next presented.

RESULTS AND DISCUSSION

COMPUTATION OF ENTROPY AND FREE ENERGY VARIATION

From the expression

$$\ln K = \frac{T\Delta S^\circ - \Delta K^\circ}{RT}$$

it follows that the stability constant K is thermodynamically a measure of the entropy change and reaction enthalpy.

The entropy change of the investigated chelating reactions was computed by introducing in the following expression

$$\Delta S^\circ = \frac{\Delta H^\circ + 2.303\ RT\ \log\ K}{T},$$

the ΔH° and K values, which were previously determined [1,2] (see table 1). The calculated ΔS° values, together with the temperature of the reaction medium are given in the same table.

Table 1

Thermodynamic functions of the $\mathrm{Me}^{\mathrm{III}}$-ANDA chelate formation reaction

Me^{3+}	T K	ΔH° joule/mol	K	ΔS° joule/mol·K	$-\Delta F^\circ$ joule/mol
Ga^{3+}	297	35,700	1.4×10^6	237.8	34.933
In^{3+}	299	28,600	1.8×10^6	215.3	35,792
Sc^{3+}	298	33,200	6.6×10^5	222.7	33.186
Y^{3+}	298	28,000	3.0×10^5	198.7	31,235
La^{3+}	299	20,600	3.4×10^5	174.7	31,649

$-\Delta F^\circ$ values (last column in the table) computed by means of the

$$-\Delta F^\circ = RT\ \ln K$$

relation, indicate an increase of the equilibrium constant, i.e. of the chelate formation.

As ΔS° values show, there is a remarkable entropy increase during the reaction which proves the formation of new species with an increased stability compared to the initial ones. In this large entropy increase resides the explanation of the formation and stability of the investigated Me-ANDA chelate compounds. It follows, therefore, that the stability cannot be attributed to the Metal-Ligand bonding energy but it may be attributed to entropy factors only and particularly to the chelate effect.

An interpretation of the large entropy effect exhibited by the investigated compounds is next attempted.

In a chemical reaction a favourable entropy effect is a measure of the amount of disorder of that particular system. In the chelating reactions of Ga^{3+}, In^{3+}, Sc^{3+}, Y^{3+} and La^{3+} with ANDA (a 3-charged anionic ligand) equimolar, chargeless chelate compounds are formed. In aqueous medium, prior to reaction, the Me^{3+} metal ions are causing a significant ordering of the solvent molecules in the hydration sphere. The chargeless reaction products will have a considerable lower solvent ordering effect, leading to a greater disorder, thus to an entropy increase of the system.

Bulky ions or molecules exert upon this same ordering process of solvent molecules a less important effect than small particles. Chelate compounds, usually having a larger size than the reactants, will determine by their formation a smaller ordering effect upon the solvent, thus a disorder increase, i.e. a positive entropy change.

An important contribution to the entropy growth of the investigated systems is brought by the chelate effect. Its value may be interpreted in two ways.

— The anthranil-N,N-diacetic acid as quadridentate ligand, having a suitable structure for strainless ring closure, is probably going — — after coordinating one position of the metal ion — to successively coordinate, all the remaining coordination sites of the same ion. According to the coordination number of the metal ion, 1 : 1 = Me : ANDA compounds are formed (the remainder coordination positions being probably occupied by solvent molecules).

— The investigated metal ions will coordinate, in the absence of the ligand, a certain number of solvent molecules. In the presence of the quadridentate ligand, one ligand molecule will determine by chelation the release of four solvent molecules.

One independent ligand molecule disappears thus and four solvent ones are liberated. This process should and does proceed with an entropy increase.

The chelate effect is dependent on a series of factors.

The nature of metal ions is one of them. Spike and Parry [3] showed that for chelate compounds of nontransition metals the heat content change being negligible, the chelate effects has to be essentially an entropy effect. Research concerning the reaction enthalpy of the investigated systems has shown [2] that the enthalpy has no contribution to the driving force leading to the chelation reaction. Consequently, the chelate effect, primarily responsible for the large entropy change, is in the case a pure entropy effect.

---

[3] Spike C. G. and Parry R. W., *J. Amer. Chem. Soc.*, **75**, 2726, 3770 (1953).

The number of chelate rings, as well as that of the atoms in a ring, is another factor having direct influence upon the complex stability. ANDA being able to act as a quadridentate ligand may close with the tervalent Ga^{3+}, In^{3+}, Sc^{3+}, Y^{3+} and La^{3+} metal ions as many as three chelate rings, two five-membered, with saturated bonds and a six-membered one with unsaturated, aromatic bonding. The stability of a six-membered ring with aromatic contribution — comparable with a five-membered one — may be attributed to some steric characteristics of the benzene ring.[4] The last is orienting the chelate ring into the benzene plane, thus providing a better approach of the donor atoms. Resonance of the aromatic carboxylic group and tertiary nitrogen with the benzene ring leads to a bond shortening and thus to an increase of ring stability.

Ligand structure is another factor the chelate effect is depending upon. Connected with the preferred stereochemistry of the metal ion it may or may not lead to a strained arrangement. The stability constant values of the investigated metal chelates prove that strainless steric arrangements are formed.

COBALT AND GERMANIUM DOUBLE OXIDES

CONST. GH. MACAROVICI, MARIA BIROU, EUGENIA PERȚE and M. STRĂJESCU
Institute of Chemistry, Cluj, Str. Donath 65–103, Romania

Received July 25, 1973

The paper covers the formation of cobalt and germanium double oxides starting from complex compounds, and their study by the following methods : the thermogravimetric, thermodifferential analysis, Roentgen and IR spectra.

It is known [1] that double oxides may be obtained through several approaches : starting from complexes, from metallic ion coprecipitates and through the reaction between various metallic oxides intimately mixed and subjected to high temperature.

In the present paper cobalt and germanium double oxides are prepared considering their properties as catalysts, semiconductors, etc.

Two complex compounds were synthesized, i.e. :

1. Starting from the ammonium germanium-oxalate, the ammonium was replaced by Co(III) hexamine. This type of complex was also investigated by Kurnevici and Saghisultanova. [2]

The above complex was obtained in crystalline form by mixing a concentrated aqueous solutions of both components, in various proportions. Regardless of the mixing order, a fine precipitate is separated and the analysis reveals in all the cases the formation of one single compound with a 1 Co : 1 Ge ratio.

The precipitate after filtration is washed with water alcohol and ether, and dried in a desiccator. The data obtained from the chemical analysis (table 1) permit the formulation of the complex as follows :

$$[Co(NH_3)_6]\,Cl.[Ge(C_2O_4)_3] \qquad (1)$$

The sum of the oxides was determined by calcining the product at 1100° ; after dissolving, the cobalt was determined as phosphate [3] while the germanium content was determined by the difference. Water was determined by an Abderhalden apparatus, at the boiling temperature of water, while chlorine, carbon, hydrogen and nitrogen were determined by classical approaches.

Table 1

Chemical analysis of the complexes

Substance	C_2O_4 %	Cl %	$CoO + GeO_2$ %	Co %	Ge %	N %	H_2O %
I $[Co(NH_3)_6]Cl.[Ge(C_2O_4)_3]$	*Calcd.* 49.52	6.65	33.67	11.05	13.60	15.76	—
P.M. = 533.2	*Found* 49.28	6.67	33.48	11.76	12.86	15.73	—
II $[Co(NH_3)_6]_4[Ge(C_6H_6O_8)_2]_3.4H_2O$	C %	H %	$CoO+GeO_2$ %	Co %	Ge %	N %	H_2O %
P.M. = 2171.07	*Calcd.* 19.92	5.38	28.26	13.81	14.46	15.49	3.31
	Found. 19.72	5.56	28.31	14.00	14.31	15.28	3.60

The calcination of the complex yielded the double oxide $CaO.GeO_2$ known in the literature.

2. Starting with the germanium saccharate :

$$Na_4[Ge(C_6H_6O_8)_2]\cdot 4H_2O$$

described by us in a previous paper, [4] we focused on the substitution of sodium by Co(III) hexamine.

To do this, the components were separately dissolved in water and then mixed in a 4/3 molar ratio

$$[Co(NH_3)_6]^{3+} : [Ge(C_6H_6O_8)_2]^{4-}$$

A yellow precipitate was separated immediately thereafter. It was filtered, washed with water, alcohol and ether and dried in a desiccator. The analysis was performed as in the case of the preceding complex (table 1).

The results provided by the analysis enable the following formulation of the complex :

$$[Co(NH_3)_6]_4\ [Ge(C_6H_6O_8)_2]_3\cdot 4H_2O \qquad \text{II}$$

By calcining the above complex we obtained the double oxide $4CoO.3GeO_2$ which has not been reported in the literature.

Both complexes were subjected to thermogravimetric and thermodifferential analysis, using an apparatus without automatic recording. The heating rate was 5°/min throughout the procedure (figs. 1 and 2).

Samples were subjected to IR spectral analysis and to Roentgen analysis. The IR absorption spectra were measured with an UR-10 Carl-Zeiss Jena instrument as potassium bromide pellets (figs. 3, 4).

The X-ray diffraction spectra were taken by a TUR-60 apparatus, applying the Debye-Scherrer powder method (fig. 5).

RESULTS AND DISCUSSION

Considering the similar behaviour of both complexes studied during thermal decomposition, we will study them together.

As seen in figs. 1 and 2, the gradual rise in the temperature leads to the loss of water, a phenomenon occurring concomitantly with hexamine decomposition and ending around 200°. The organic substance is then burnt with the elimination of CO_2 and H_2O and the formation of the corresponding oxides.

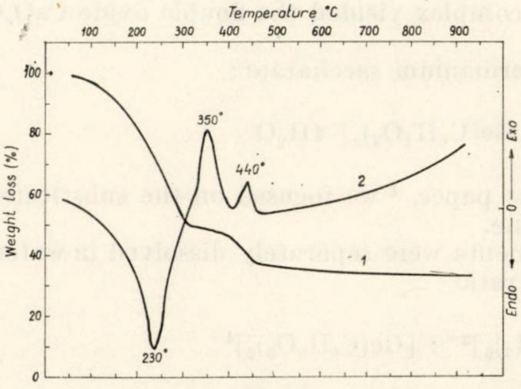

Fig. 1. — Thermogravimetric (1) and thermodifferential (2) curve of the complex $[Co(NH_3)_6]Cl[Ge(C_2O_4)_3]$.

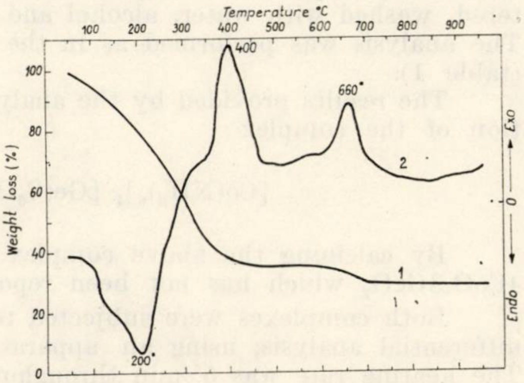

Fig. 2. — Thermogravimetric (*1*) and thermodifferential (*2*) curve of the complex $[Co(NH_3)_6]_4 \cdot [Ge(C_6H_6O_8)_2]_3 \cdot 4H_2O$.

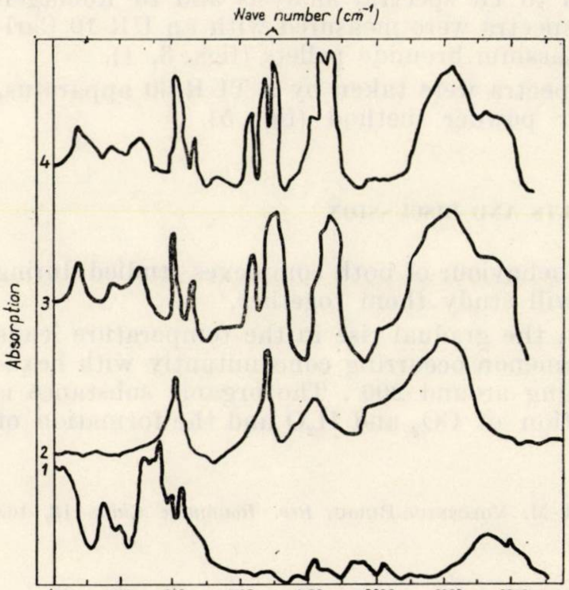

Fig. 3. — IR spectra of :1) $CoO \cdot GeO_2$; 2) $[Co(NH_3)_6]Cl_3$; 3) $[Ge(C_2O_4)_2](NH_4)_2 \cdot 4H_2O$; 4) complex I.

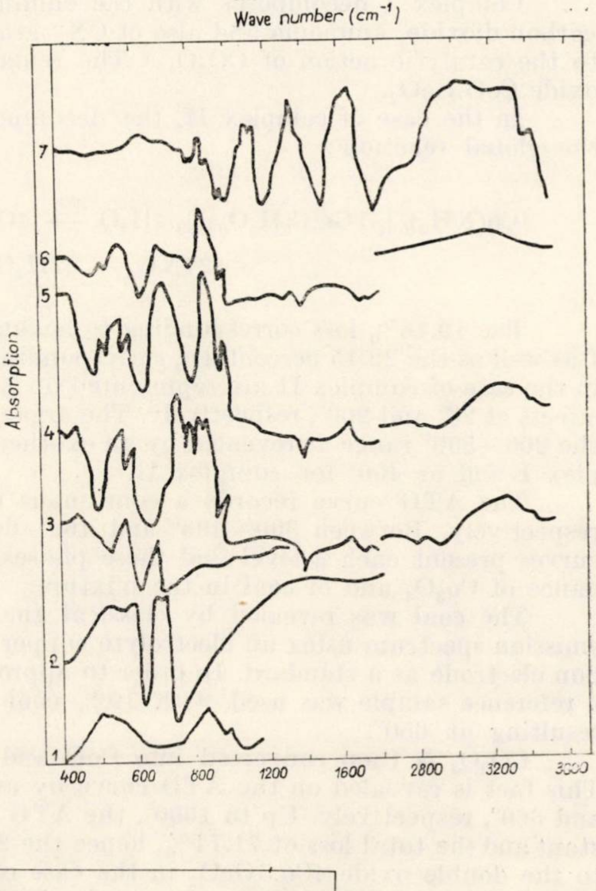
Fig. 4. — IR spectra of : 1) GeO_2 ; 2) CoO ; 3) Co_3O_4 ; 4) $4CoO \cdot 3GeO_2$; 5) complex II at 650° ; complex II at 450° ; 7) complex II.



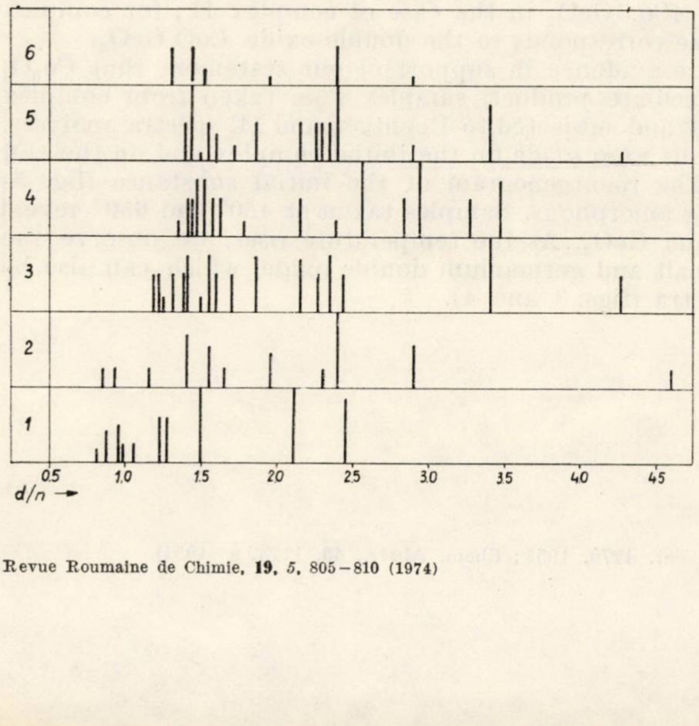


Fig. 5. — Roentgen diffraction spectra of : 1) CoO ; 2) Co_3O_4 ; 3) GeO_2 ; 4) $4CoO_3 \cdot$ $\cdot 3GeO_2$; 5) complex II at 650° ; 6) complex II at 450°.

Complex I decomposes with the elimination of hydrochloric acid, carbon dioxide, ammonia and also of CN^- groups which were formed due to the catalytic action of CO_3O_4.[5] The remaining residue is the double oxide $CoO.GeO_2$.

In the case of complex II, the decomposition occurs according to the global reaction:

$$[Co(NH_3)_6]_4.[Ge(C_6H_6O_8)_2]_3.4H_2O \xrightarrow{26O_2} 4CoO.3GeO_2 + 36CO_2 + \\ + 24NH_3 + 22H_2O$$

The 19.16% loss corresponding to hexamine in the case of complex I as well as the 22.15 percentage, corresponding to hexamine and to water in the case of complex II are represented on ATD curves by endothermic effects at 23° and 200°, respectively. The organic substance is burnt within the 200—500° range as revealed by an exothermic effect, at 350° for complex I and at 400° for complex II.

The ATG curve records a continuous decrease to 300° and 460°, respectively. Between 300—400° and 460—600°, respectively, the ATG curves present each a level and these phases correspond to the maintenance of Co_3O_4 and of coal in the mixture.

The coal was revealed by classical analysis and by means of the emission spectrum using an electrolyte copper electrode and a 100% carbon electrode as a standard. In order to approximate the coal percentage a reference sample was used with 10% coal in the mixture of oxides resulting at 650°.

CO_3O_4 is then converted into CoO and the coal is totally burnt. This fact is revealed on the ATD curve by an exothermic effect at 440° and 660°, respectively. Up to 1000°, the ATG curve remains almost constant and the total loss of 71.74%, hence the 28.31% residue, corresponds to the double oxide $4Co.3GeO_2$ in the case of complex II; for complex I, the 33.48% residue corresponds to the double oxide $CoO.GeO_2$.

To supply more evidence in support of our statement that Co_3O_4 results as an intermediate product, samples were taken from complex II at 450° and at 650° and subjected to Roentgen and IR spectra analyses. Similar determinations were made on the initial complex and on the end product at 1000°. The roentgenogram of the initial substance (fig. 5) shows no lines, being amorphous. Samples taken at 450° and 650° reveal the lines of Co_3O_4 and GeO_2. As the temperature rises, we observe the formation of the cobalt and germanium double oxide, which can also be seen in the IR spectra (figs. 3 and 4).

ON THE REDOX POTENTIALS IN THE TRANSITION-METAL COMPLEXES

C. I. LEPĂDATU and CRISTINA RUSU

Centre of Chemical Physics, Dumbrava Roşie 23, Bucharest, Romania

Received June 11, 1973

A molecular orbital treatment of the chemical bonding contribution to the redox potentials in the transition-metal complexes is presented. It has been shown that the ligand field interpretation of these contributions must be reformulated, because of the inconsistency of the baricenter conservation rule of the split *d*-levels. A correlation between the chemical bonding contribution to the redox potentials and the spectral behaviour of the complexes is also given.

It has been suggested that among other main factors determining the values of the redox potentials in the transition-metal complexes, [1] an important role would play the so-called ligand field stabilization energies (LFSE) of the two M^{+z}/M^{+z+1} ions in the field produced by the ligands directly bound to the central metal.

As has been recently shown,[2,3] the stabilization problem of the coordination clusters must be reformulated in terms of the MO theory which leads to a more realistic basic concept on the spatial stabilization of the complexes, quite different of that offered by the ligand field theory, exclusively based on the baricenter conservation rule of the split energy levels, valid only in the elctrostatic approach of the interactions in molecule.

This is the reason why the mentioned factor contributing to the redox potentials must be reconsidered in the framework of the LCAO MO theory. The aim of the present note is to give a MO treatment of the contribution due to the chemical bonds to the redox potentials in the *d*-complexes, and to see the possible correlation with the spectral and magnetic behaviour of the complexes. As may be seen in the following, the chemical bonding effects included into the redox potential values have nothing to do with the ligand field stabilization energy, and may be put, on the contrary, in connection with the destabilization of the

d-state, going from the d-levels to the antiboding molecular levels in which the d-states are involved.

Let us consider the following oxidation-reduction mechanism for the gaseous metal ion

$$d^n \rightleftarrows d^{n-1} + e^- \tag{1}$$

whose energy balance

$$\varepsilon(d^{n-1}) - \varepsilon(d^n) = V(d^n/d^{n-1}) \tag{2}$$

is the oxidation-reduction potential, equal to the difference with changed sign between the energies of the ground spectral terms of the metal having the electronic configurations d^{n-1} and d^n.

Because we are dealing with coordinate metal ions, the energies of their ground states in complexes will differ from those in the free metal ion, difference mainly produced by the chemical bond formation and by the possible rearrangements occurring in the electron population (high spin and low spin states).

If (1) and (2) are considered not for gaseous metal ions but for the free ions before coordination in their proper valence states in complexes, the differences

$$\begin{aligned} \varepsilon_c(d^{n-1}) - \varepsilon(d^{n-1}) &= \Sigma(d^{n-1}) \\ \varepsilon_c(d^n) - \varepsilon(d^n) &= \Sigma(d^n) \end{aligned} \tag{3}$$

will give the chemical bonding effects, where ε_c's are the ground state molecular energies in the complex molecules. Like (2), the oxidation-reduction potentials of the coordinate metal ion will be

$$V_c(d^n/d^{n-1}) = \varepsilon_c(d^{n-1}) - \varepsilon_c(d^n) = V(d^n/d^{n-1}) + [\Sigma(d^{n-1}) - \Sigma(d^n)] \tag{4}$$

where $V(d^n/d^{n-1})$ is the redox potential of the free metal ion before coordination but for its proper valence states in complexes, Σ's being the chemical bonding effects taken with changed sign. Expression (4) gives us a way to estimate the contribution of the chemical bond formation to the redox potential values (the last right-hand term).

We give below the energy expressions for the ground states in the free and coordinate metal ion in its two possible spin distributions (high spin and low spin states, the last one marked by an asterisk) for orthoaxial complexes, that is cluster molecules having six identical ligands located along the Cartesian axes of the central ion

$$\varepsilon(d^0) = \varepsilon_c(d^0) = \varepsilon^{\text{core}}(0)$$

$$\begin{cases} \varepsilon(d^1) = \varepsilon^{\text{core}}(1) \\ \varepsilon_c(t_2^1,\ {}^2T_{2g}) = \varepsilon^{\text{core}}(1) + 4e_\pi(1) \end{cases}$$

$$\begin{cases} \varepsilon(d^2) = \varepsilon^{\text{core}}(2) - 8B(2) \\ \varepsilon_c(t_2^2,\ {}^3T_{1g}) = \varepsilon^{\text{core}}(2) + 8e_\pi(2) - 5\alpha_\pi^4 B(2) \end{cases}$$

$$\begin{cases} \varepsilon(d^3) = \varepsilon^{\text{core}}(3) - 15B(3) \\ \varepsilon_c(t_2^3,\ {}^4A_{2g}) = \varepsilon^{\text{core}}(3) + 12e_\pi(3) - 15\alpha_\pi^4 B(3) \end{cases}$$

$$\begin{cases} \varepsilon(d^5) = \varepsilon^{\text{core}}(5) - 35B(5) \\ \varepsilon_c(t_2^3e^2, {}^6A_{1g}) = \varepsilon^{\text{core}}(5) + 6e_\sigma(5) + 12e_\pi(5) - [15\alpha_\pi^4 + 12\alpha_\sigma^2\alpha_\pi^2 + \\ \qquad + 8\alpha_\sigma^4]B(5) \\ \varepsilon_c^*(t_2^5,\ {}^2T_{2g}) = \varepsilon_c(t_2^3e^2) - 2[\,\Delta(5) - \Pi(d^5)] \end{cases}$$

$$\begin{cases} \varepsilon(d^6) = \varepsilon^{\text{core}}(6) - 35B(6) + 7C(6) \\ \varepsilon_c(t_2^4e^2,\ {}^5T_{2g}) = \varepsilon^{\text{core}}(6) + 6e_\sigma(6) + 16_\pi(6) - [15\alpha_\pi^4 + 12\alpha_\sigma^2\alpha_\pi^2 + \\ \qquad + 8\alpha_\sigma^4]B(6) + [5\alpha_\pi^4 + 2\alpha_\sigma^2\alpha_\pi^2]\,C(6) \\ \varepsilon_c^*(t_2^6,\ {}^1A_{1g}) = \varepsilon_c(t_2^4e^2) - 2[\,\Delta(6) - \Pi(d^6)] \end{cases}$$

$$\begin{cases} \varepsilon(d^7) = \varepsilon^{\text{core}}(7) - 43B(7) + 14C(7) \\ \varepsilon_c(t_2^5e^2,\ {}^4T_{1g}) = \varepsilon^{\text{core}}(7) + 6e_\sigma(7) + 20e_\pi(7) - [20\alpha_\pi^4 + 12\alpha_\sigma^2\alpha_\pi^2 + 8\alpha_\sigma^4]B(7) + \\ \qquad + [10\alpha_\pi^4 + 4\alpha_\sigma^2\alpha_\pi^2]\ C(7) \\ \varepsilon_c^*(t_2^6e^1,\ {}^2E_g) = \varepsilon_c(t_5^5e^2) - [\Delta(7) - \Pi(d^7)] \end{cases}$$

$$\begin{cases} \varepsilon(d^8) = \varepsilon^{\text{core}}(8) - 50B(8) + 21C(8) \\ \varepsilon_c(t_2^6e^2,\ {}^3A_{2g}) = \varepsilon^{\text{core}}(8) + 24e_\pi(8) + 6e_\sigma(8) - [38\alpha_\pi^4 + 12\alpha_\sigma^2\alpha_\pi^2]B(8) + \\ \qquad + [15\alpha_\pi^4 + 6\alpha_\sigma^2\alpha_\pi^2]C(8) \end{cases}$$

$$\begin{cases} \varepsilon(d^9) = \varepsilon^{\text{core}}(9) - 56B(9) + 28C(9) \\ \varepsilon_c(t_2^6e^3,\ {}^2E_g) = \varepsilon^{\text{core}}(9) + 24e_\pi(9) + 9e_\sigma(9) - [30\alpha_\pi^4 + 18\alpha_\sigma^2\alpha_\pi^2 + \\ \qquad + 8\alpha_\sigma^4]B(9) + [15\alpha_\pi^4 + 9\alpha_\sigma^2\alpha_\pi^2 + 4\alpha_\pi^4]C(9) \end{cases}$$

$$\varepsilon(d^{10}) = \varepsilon_c(d^{10}) = \varepsilon^{\text{core}}(10) - 70B(10) + 35C(10)$$

where $\varepsilon^{\text{core}}(n)$ is the core energy

$$\varepsilon^{\text{core}}(n) = nU + \frac{n(n-1)}{2}A \tag{5}$$

U being the one-electron energy summing up the kinetic and potential electron-SCF metal core energies, A, B, C the Racah interelectronic repulsion energies, $e_{\sigma(\pi)}$ the antibonding orbital energies, $\Delta(n) = 3e_\sigma(n) - 4e_\pi(n)$ the orbital parameter, $\Pi(d^n)$ the spin-pairing energies and $\alpha_{\sigma(\pi)}$ the mixing coefficients of the d-orbitals in the $\sigma(\pi)$ MO's (usually antibonding) practically located on the central metal ion. The above master formulas were obtained using truncated MO's in a strong-coupling scheme,[4] which reproduce in general lines the three parametric (Δ, B, C) ligand field energies in the strong field-coupling, [5] except the LFSE's coming from the baricenter rule which cannot be accepted in a MO approach. Concerning the spin-pairing energies, their master formulas expressed in terms of Racah energies and mixing coefficients may be found elsewhere. [4]

According to (3)—(4), the redox potentials of the coordinate transition-metal ions could be calculated if the ground state energies as written above, were known. These energies may be in principle estimated using *ab initio* or semiempirical MO approximations in order to find $e_{\sigma(\pi)}$ and $\alpha_{\sigma(\pi)}$ values. Unfortunately, this problem represents a difficult task, because there are not as yet reliable quantum-mechanical methods suitable to this purpose. For this reason, we shall try in the following to get different quantities involved in (3)—(4) from the spectral and the magnetic behaviour of the transition-metal complexes. We can obtain in this way all necessary Σ's, which according to (3)—(4), do contribute to the redox potentials.

The quantity

$$V(d^n/d^{n-1}) = \varepsilon^{\text{core}}(n-1) - \varepsilon^{\text{core}}(n) \tag{6}$$

which would represent the redox potential of the free metal ion in its proper valence state before coordination, remains thereby undetermined. Since the core energies are dependent on the formal charge on the SCF metal core, according to the electroneutrality principle generally valid for the majority of the transition-metal complexes, it results that $V(d^n/d^{n-1})$ may be roughly considered as being practically unchanged in the complexes of the pair $M(d^n)/M(d^{n-1})$ with different ligands.

If the electroneutrality principle holds, it follows that the dependence of the redox potential values on the ligand nature should be straightforwardly linked with the chemical bonding effects. One may therefore conclude that the changes occurring in the electrochemical redox potentials of the systems $M(d^n/)/M(d^{n-1})L_6$ and $M(d^n)/M(d^{n-1})L'_6$ will be, according to (4), equal to

$$V_{L,L}(d^n/d^{n-1}) = V_L(d^n/d^{n-1}) - V_L'(d^n/d^{n-1}) = \delta_L(n-1, n) - \delta_{L'}(n-1, n) \tag{7}$$

where

$$\delta(n-1,\ n) = \Sigma(d^{n-1}) - \Sigma(d^n)$$

---

[5] J. S. Griffith, "The Theory of Transition-Metal Ions", University Press, Cambridge, 1964.

Σ's being the chemical bonding effects taken with changed sign. We give below some of the known systems for which the spectral and the magnetic behaviour are well studied. Since it was not possible in each case, to have a collection of spectrally determined mixing coefficients, we adopted in the following the approximation of the isotropic covalency, in order to make use of ligand field data, at least as the mean energies Δ and B are concerned. Since the B values are less dependent on the oxidation state than the orbital energies, one may consider $B(d^{n-1}) \approx B(d^n)$. With these approximations in mind, the following $\delta(n-1, n)$ expressions may be obtained for $n = 3-7$:

d^3/d^4

$$\delta(3,\ 4) = 12e_\pi(3) - 16e_\pi(4) - \Delta(4)$$

$$\delta(3,\ 4^*) = 12e_\pi(3) - 16e_\pi(4) - \Pi(d^4)$$

where the asterisk shows the low spin ground state $d^4(t_2^4)$.

For the system $Cr^{3+/2+}(H_2O)_6$, both complexes have high spin ground states, [5,6] for which $\Delta(3) = 17.4$ kK, $\Delta(4) = 14$ kK, and $e_\pi(3) = 1.25$ kK independently calculated by Lever [7] and by one of us [8] With

$$\frac{e_\pi(n-1)}{e_\pi(n)} \approx \frac{\Delta(n-1)}{\Delta(n)} \text{ (see ref. }^{9}\text{)} \tag{8}$$

one obtains $\delta_{H_2O}(3, 4) \approx +1.85$ eV.

For the system $Cr^{2+/3+}(CN)_6$, the orbital energies e_π, arisen from the π ligand $\leftarrow$ metal bonds, may be ignored due to the fact that for strongly heteropolar chemical bonds the bonding effects are much smaller than the antibonding ones.

Considering the spin-pairing energy $\Pi(d^4, M^{2+}) \approx 17.5$ kK, as it results from magnetic and spectral studies, [10] and taking into account that $Cr(d^4)(CN)_6$ has a low spin electron distribution [6] we find $\delta(3, 4^*) \approx$ $\approx +2.169$ eV. According to (7), we have $V_{H_2O,\ CN}(Cr^{3+}/Cr^{2+}) \approx -$ -0.32 eV which may be compared with -0.87 eV experimentally found [1] ($\pi_{H_2O} = +0.41$ eV ; $\pi_{CN} = +1.28$ eV).

d^4/d^5

We find in the same way

$$\delta(4,\ 5) = \Delta(4) - 2\,\Delta(5) + 16e_\pi(4) - 20e_\pi(5)$$

$$\delta(4^*,\ 5^*) = \Pi(d^4) - 2\Pi(d^5) + 16e_\pi(4) - 20e_\pi(5)$$

---

[10] E. KÖNIG and S. KREMER, *Theor. Chim. Acta*, **23**, 12 (1971).

For the system $Mn^{3+/2+}(H_2O)_6$ we have the following spectral data [5,6] $\Delta(4) = 20$ kK (in oxalate), $\Delta(5) = 8.3$ kK, $e_\pi(5) = \chi_{Mn^{2+}} \times 1.25$ kK where $\chi_{Mn^{2+}} = 0.517$ is the spectrochemical ratio taking Cr(III)-ligand bonds as standard, [9] $e_\pi(4) = 1.53$ kK (eq.(8)). Hence, $\delta(4, 5) = -1.819$ eV.

For the system $Mn^{3+/2+}(CN)_6$, both complexes are low spin [6], $e_\pi \approx \approx 0$, $\Pi(d^4, M^{3+}) = 20.1$ kK and $\Pi(d^5, M^{2+}) = 10.1$ kK (see ref. [10]). Hence, $\delta(4^*, 5^*) = +0.26$ eV, and therefore $V_{H_2O,\,CN}(Mn^{3+}/Mn^{2+}) = -2.079$ eV which may be compared with -1.73 eV experimentally found [1]

d^5/d^6

$$\delta(5,\ 6) = 2[\Delta(5) - \Delta(6)] + 20e_\pi(5) - 24e_\pi(6)$$

$$\delta(5^*,\ 6^*) = 2[\Pi(d^5) - \Pi(d^6)] + 20e_\pi(5) - 24e_\pi(6)$$

System $Fe^{3+/2+}(H_2O)_6$; $\Delta(5) = 14.2$ kK, $\Delta(6) = 10.4$ kK (see ref [5]) and $e_\pi(6) = \chi_{Fe^{2+}} \times 1.25$, where [9] $\chi_{Fe^{2+}} = 0.597$, $e_\pi(5) = 1.01$ kK (eq.(8)). Therefore, $\delta(5, 6) = -1.15$ eV.

System $Fe^{3+/2+}(CN)_6$: $e_\pi \approx 0$, $\Pi(d^5, M^{3+}) = 19$ kK, $\Pi(d^6, M^{2+}) = = 12$ kK.

Both complexes are low spin [6] and, therefore, $\delta(5^*, 6^*) = -1.73$ eV, and hence $V_{H_2O,\,CN}(Fe^{3+}/Fe^{2+}) = +0.58$ eV (exp.[1] -0.42 eV).

As may be seen, there is an obvious disagreement between the predicted value and that experimentally found. One of the sources of errors could be found in the dependence of $V(d^n/d^{n-1})$ of the formal charge on the SCF metal core. It may happen that the formal charge on the metal core be very different going from high spin complexes to low spin complexes and this is undoubtedly the case in the systems $Fe^{3+/2+}L_6$, where $L = H_2O, CN^-$. A confirmation of this statement is supplied by the next systems whose $\delta(n-1, n)$ are evaluated using the same master formula.

d^6/d^7

$$\delta(6^*,\ 7) = 2[\Pi(d^6) - \Delta(7)] + 24e_\pi(6) - 28e_\pi(7) - 3B$$

System $Co^{3+/2+}(H_2O)_6$: $\Delta(6) = 18.5$ kK, $\Delta(7) = 9.3$ kK, $B = = 0.800$ kK (ref. [5]), $e_\pi(6) = \chi_{Co^{3+}} \times 1.25$, where $\chi_{Co^{3+}} = 1.051$ (ref, [9]), $e_\pi(7) = 0.66$ kK (eq. [8]), $\pi(d^6, M^{3+}) = 13.1$ kK (ref.[10]). Therefore $\delta(6^*, 7) = -2.12$ eV.

System $Co^{3+/2+}(NH_3)_6$: $\Delta(7) = 10.1$ kK, $B = 0.680$ kK (ref.[5]), $e_\pi = 0$ (ref. [8]), $\pi(d^6, M^{3+}) = 13.1$ kK (ref.[10]). Therefore, $\delta(6^*, 7) = - - 0.49$ eV.

Consequently, $V_{H_2O,\,NH_3}(Co^{3+}/Co^{2+}) = -1.63$ eV, which agrees with the experimentally found change in the electrochemical redox potentials [10], equal to -1.70 eV.

Ni(II) CHELATES SYNTHETIZED WITH 1-METHYL-2-CARBETHOXY-GLYOXALANIL-(1)-TOLYLHYDRAZONES-(2)

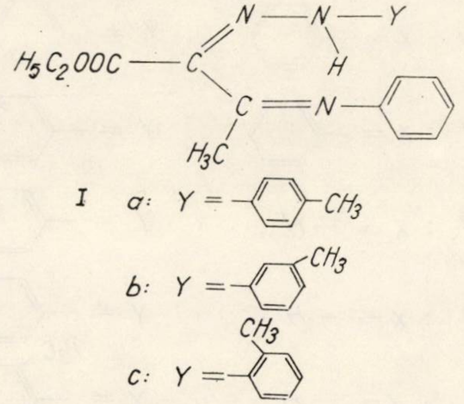
A. C. BANCIU and P. SPACU

Center of Physical Chemistry, Str. Dumbrava Roşie, 23, Bucharest, Romania

Received November 21, 1973

Using the three 1-methyl-2-carbethoxy-glyoxalanil-(1)-tolylhydrazones-(2) as ligands, depending on the preparation conditions, two types of Ni(II) complexes were obtained, some of them containing the mentioned ligands and other having the anil group in the molecule substituted by an imino group. The elemental analysis data, IR and electronic spectra as well as the magnetic measurements show that all the prepared complexes are tetracoordinate chelates with a low-spin square-planar arrangement of the coordination Ni-(II)-N bonds. The intense colour of the chelates is due to the CT metal → ligand bands, occurring in the visible range.

In a previous paper, [1] two complexes formed by the Ni(II) ion with 1-methyl-2-carbethoxy-glyoxalanil-(1)-phenylhydrazone-(2), the simplest ligand from the class of these substituted aryl-hydrazones, were described. In a subsequent paper, [2] there were studied the ligands, the complexing way and the coordination compounds of Co(II) with the 1-methyl-2-carbethoxy-glyoxalanil-(1)-tolylhydrazones-(2), (Ia-c).



---

The present note deals with five Ni(II) complexes prepared with the organic compounds Ia-c, the preparation of the last ones being already described elsewhere. [2]

EXPERIMENTAL

Reagents. Acetylacetic ester (Merck, reagent for synthesis, minimal content 98 %), aniline (tri-distilled), *p*-toluidine (Carlo Erba, minimal content 99 %), *m*-toluidine (Schuchardt, p.*a.*), *o*-toluidine (Loba-Chemie, *p.a.*), anhydrous $NaCH_3COO$ (Austranal, *p.a.*), $NiCl_2 \cdot 6H_2O$ (Reactivul, Bucharest, *p.a.*), NH_3 25 % solution (Reactivul, Bucharest, *p.a.*).

Preparation of the Ni(II) chelates. The Ni(II) chelates were synthetized using a known method, [3] refluxing alcoholic solutions, containing amounts of 1/100 m ligand and 1/200 m $NiCl_2 \cdot 6H_2O$, plus a slight excess of 15 % from this theoretical quantity in the case of the last reagent, in order to assure the completeness of the reaction. The chelates IIa-1 and IIb-1 were obtained in the presence of a small amount of triethylamine (*ca.* 1 cc). The attempts to prepare the corresponding Ni(II) chelate with the compound Ic have invariably failed as the previous attempts to get the corresponding Co(II) chelate. [2] Using the same conditions and amounts of reagents as shown above, in the absence of triethylamine, but in the presence of a quantity of about 20 cc of 25 % solution NH_3, the chelates IIa-2, IIb-2 and IIc were obtained using the compounds Ia-c. Under the catalytic influence of the Ni(II) salt, NH_3

[3] B. HIRSCH and A. BASSL, *Z. Chem.*, **2**, 115 (1962).

generates the anil group splitting and its substitution by the imino group, NH, in the ligand molecule. [4]

The obtained products were repeatedly washed with 3% acetic acid, warmed at 40°, until the washing solutions did not contain Ni(II) ions. The chelates IIa-2, IIb-2 and IIc, which are less soluble, were afterwards repeatedly washed with warmed absolute ethanol, and the chelates IIa-1, IIb-1, which are more soluble, were recrystallized from absolute ethanol in the presence of active charcoal. After washings and recrystallizations, respectively, the compounds were dried under vacuum on di-P_2O_5.

The elemental analyses of C, H and N were made by microcombustion. For the Ni(II) dosing the chelates were disintegrated with H_2SO_4 and H_2O_2 and the Ni(II) ions dosed with dimethylglyoxime.

The absorption spectra of compounds were recorded with a VSU-2 Carl Zeiss (Jena) spectrophotometer on acetonic solutions of $0.25\times10^{-4}-2.5\times10^{-4}$ m/l (complexes IIa-2, IIb-2 and IIc) and $0.5\times10^{-4}-5\times10^{-4}$ m/l (complexes IIa-1 and IIb-1) concentrations.

The reflectance spectra of the chelates were recorded with a VSU-1 Carl Zeiss (Jena) spectrophotometer, using MgO as standard.

The IR spectra of the compounds were recorded within 400–4000 cm^{-1} range by means of a UR-10 Carl Zeiss (Jena) spectrophotometer, using KBr pellets.

The magnetic susceptibilities were measured at the room temperature, according to the Faraday method, using $Hg[Co(NCS)_4]$ as standard.

RESULTS AND DISCUSSIONS

The analytical data of all Ni(II) chelates are summarized in table 1. On these results and IR data, the chelatic structural fromulas of IIa-c complexes have been thereby established.

The IR spectra of one of the ligands used, namely the 1-methyl-2-carbethoxy-glyoxalanil-(1)-*p*-tolylhydrazone-(2), (Ia), and of the chelates IIa-1 and IIa-2, synthetized with this ligand, are systematized in table 2.

Table 1

Analytical data of the Ni(II) chelates

Chelate	Ni %		C %		H %		N %		m.p. °C
	Calcd.	*Found*	*Calcd.*	*Found*	*Calcd.*	*Found*	*Calcd.*	*Found*	
IIa–1	8.34	8.07	64.88	65.03	5.73	5.90	11.95	12.12	158–160.5
IIb–1	8.34	8.12	64.88	64.32	5.73	6.04	11.95	12.32	138–141
IIa–2	10.65	10.20	56.65	56.89	5.85	6.12	15.24	16.00	200
IIb–2	10.65	10.51	56.65	56.54	5.85	6.21	15.24	15.91	179–181
IIc	10.65	10.15	56.65	56.16	5.85	6.28	15.24	15.87	198–199.5

One may observes that the spectra of both Ni(II) chelates are in general lines similar but they markedly differ in what the very intense band at 3305 cm^{-1} is concerned, this band occurring only in the spectrum

of the chelate IIa-2 being due to a vibration frequency proper to the imino group, NH, in agreement with the analytical data and the structural formula ascribed by us to the chelate IIa-2.

The strongest differences in the IR spectra of the ligand and chelates are those within 1270—1360 cm^{-1}. For the free ligand there is a band of mean intensity within 1270—1340 cm^{-1}, with maxima at 1280, 1310 and 1330 cm^{-1}. In the case of the chelate IIa-1, as a consequence of the coordination, the above band occurs as broadened and very intense within 1290—1360 cm^{-1}, with a shoulder at 1290 cm^{-1} and maxima, at 1330 and 1350 cm^{-1}, and in the case of the chelate IIa-2 the same band appears as very intense within 1280—1340 cm^{-1}, with two maxima at 1300 and 1320 cm^{-1}. It is known that in the case of the secondary aromatic amines (C_6H_5-NH-) an absorption band occurs in the region between 1280—1350 cm^{-1} and in almost the same range (1310—1360 cm^{-1}) there is an intense band for the tertiary aromatic amines (C_6H_5-N=), both bands being due to the C-N stretching vibration inside of this group.[5] As a consequence of the coordination of the nitrogen atom from the hydrazonic group directly bound to the aryl radical, structural modifications will be therefore expected to occur, reflected in the IR spectra as shown above. It may be, therefore, concluded that the changes observed with the IR spectra of the compounds going from the free ligand to irrespective of the two chelates, and namely the slight shifts and the strong enhancements of the vibration bands in the 1270—1360 cm^{-1} range tell us that the coordination *via* nitrogen atom took place.

It should be important to mention that in the 1690—1710 cm^{-1} range no changes have taken place, compared with the free ligand spectrum. The intense band with a maximum in this domain, occurring in the spectra of all mentioned compounds, has been assigned [5] to the esteric group ($COOC_2H_5$). Its appearance in the spectra of the two chelates (for the chelate IIa-2 slightly moved, at 1690 cm^{-1}) would indicate that this group does not participate to coordination, a possibility which could not be *a priori* avoided. If the esteric group participated to coordination, a strong shift of its band [5] was expected to occur at approximately 1635—1665 cm^{-1}, which is not, obviously, the case.

It may be, therefore, concluded that the strong modifications in the 1280 — 1360 cm^{-1} range and the lack of any modification in the 1690—1720 cm^{-1} domain in the spectra of the chelates compared with that of the free ligand, show that the coordination has taken place only *via* the nitrogen atoms, the esteric group being not involved into coordination, in agreement with the structural formulas IIa-c of all the chelates.

ELECTRONIC SPECTRA AND MAGNETIC PROPERTIES

The magnetic susceptibility measurements performed on the chelates IIa-1 and IIa-2 have shown that both the compounds are diamagnetic.

---

[5] L. J. Bellamy, "The Infrared Spectra of Complex Molecules", Methuen, London, 1962.

The absorption spectra in the visible range of all five Ni(II) complexes, recorded on acetonic solutions, are plotted in figure 1.

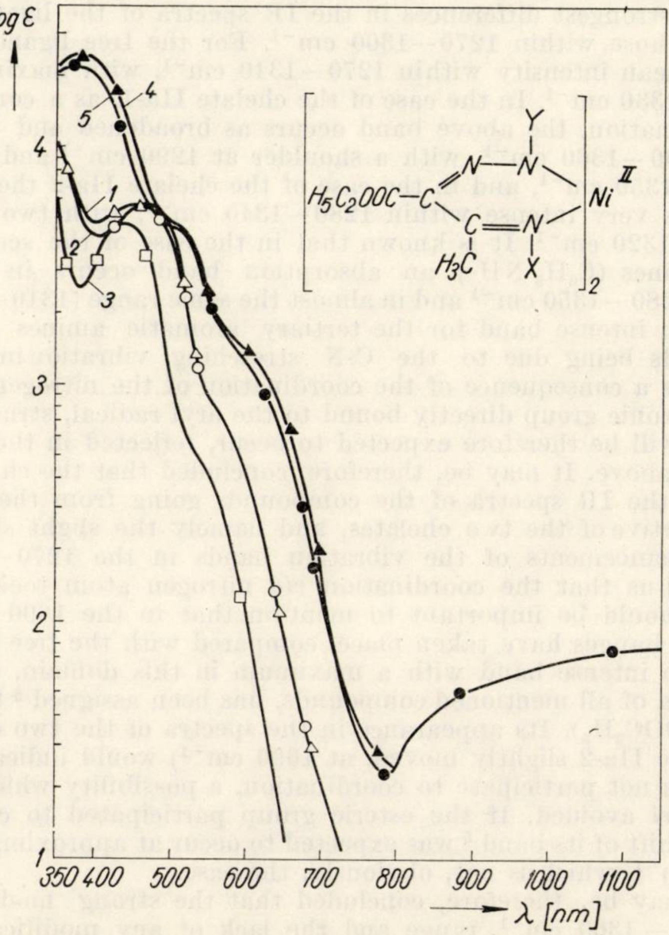

Fig. 1. – The electronic spectra of the Ni(II) chelates.

1, Chelate IIa-2: X=H, Y=$p-CH_3-C_6H_4$; *2*, Chelate IIb-2: X=H, Y=$m-CH_3-C_6H_4$: *3*, Cnelate IIc: X=H, Y=$o-CH_3-C_6H_4$; *4*, Chelate IIa-1: X=C_6H_5; Y=$p-CH_3-C_6H_4$; *5*, Chelate IIb-1: X=C_6H_5, Y=$m-CH_3-C_6H_4$.

One may observe that the spectra of the chelates IIa-1, IIb-1 and IIa-2, IIb-2 and IIc are strikely similar respectively, which allow us to ascribe the diamagnetic properties to the other chelates for which the magnetic susceptibilities were not determined. It may be, therefore, concluded that the diamagnetism is a general feature of the five synthetized chelates, indicating the low spin $Ni^{2+}(3\ d^8)$ electronic configuration in a square-planar coordination geometry.

The spectra of the chelates IIa-2, IIb-2 and IIc. As may be seen in figure 1, the spectra of the chelates IIa-2 and IIb-2 are very similar in the 350–500 nm range, being practically the same at wavelengths higher than 500 nm. The spectrum of the chelate IIc, though similar to the spectrum of the first two chelates is hypsochromically moved with about 40 nm on the whole visible range. The very high intensity ($\varepsilon \approx$ ≈ 6000) of the bands occurring approximately at 470 nm, for the chelates IIa-2 and IIb-2, and at 430 nm for the chelate IIc, shows the fact that these bands are of CT nature.

Taking into account the Jørgensen's formula [6,7]

$$\nu_{\mathrm{CT}} = 30{,}000\ (x_{\mathrm{N}} - x_{\mathrm{Ni}})\ \mathrm{cm}^{-1}$$

where [6] $x_{\mathrm{Ni(square\text{-}planar)}} = 2.2$ and [7] $x_{\mathrm{N}} = 3.2$ are the corresponding optical electronegativities, it results that the CT bands ligand → metal should occur at approximately 330 nm (30,000 cm^{-1}) which, of course, is not the case. The single remained alternative is to assign the absorption band to a CT metal → ligand transition, namely, from the filled MO placed on the metal to the empty antibonding MO's of the organic ligand.

The other less intense bands ($\varepsilon \approx 650$ for the IIa-2 and IIb-2 chelates and $\varepsilon \approx 400$ for the IIc chelate) occurring at higher wavelengths, as shoulders of the previously mentioned CT bands, may indoubtedly be ascribed to the spin-allowed $d-d$ transition.

The energetical expressions for the spin-allowed $d-d$ transitions for the low spin square-planar d^8 configuration obtained in the strong field are

$$^1A_{1g}(e_g^4\ b_{2g}^2\ a_{1g}^2) \rightarrow {}^1B_{1g}(e_g^4\ b_{2g}^2\ a_{1g}^1\ b_{1g}^1);\ \Delta_1 - C$$

$$^1A_{1g}(e_g^4\ b_{2g}^2\ a_{1g}^2) \rightarrow {}^1E_g(e_g^3\ b_{2g}^2\ a_{1g}^2\ b_{1g}^1);\ \Delta_1 + \Delta_2 + \Delta_3 - 3B - C$$

$$^1A_{1g}(e_g^4\ b_{2g}^2\ a_{1g}^2) \rightarrow {}^1A_{2g}(e_g^4\ b_{2g}^1\ a_{1g}^2\ b_{1g}^1);\ \Delta_1 + \Delta_2 - C$$

where B and C are the Racah parameters for the interelectronic repulsion energies, and Δ_1, Δ_2 and Δ_3 the orbital energies in the most probable MO energy diagram for the mentioned chelates. If one takes into account that the "π" metal-nitrogen bonds, if they occur, are too much weak to bring down the d_{z^2} orbital under d_{xy} one, such that the D_{4h}-strong distortion orbital scheme to be valid, it remains as the most probable energy diagram for the studied chelates that of D_{4h}-weak distortion with the following orbital sequence: $e_g(d_{xz},\ d_{yz}) < b_{2g}(d_{xy}) < a_{1g}(d_{z^2}) < b_{1g}(d_{x^2-y^2})$. In this diagram, the orbital energies Δ_3, Δ_2 and Δ_1 from the above expressions, would represent the energy distances between e_g and b_{2g}; b_{2g} and a_{1g}; and a_{1g} and b_{1g}, respectively.

The most like assignment of these d-d bands would correspond to a transition up to the double degenerate excited spectral term ^1E_g, i.e.

$$^1A_{1g}(e_g^4\ b_{2g}^2\ a_{1g}^2) \rightarrow {}^1E_g(e_g^3\ b_{2g}^2\ a_{1g}^2\ b_{1g}^1)$$

---

[6] A. B. P. Lever, "Inorganic Electronic Spectroscopy", Chap. 8–9, Elsevier Publishing Company, Amsterdam-London-New York, 1968.

[7] C. K. Jorgensen, "Electron Transfer Spectra", in "Progress in Inorganic Chemistry", vol. 12, Interscience Publishers, New York–London–Sydney–Toronto, 1970, p. 101–158.

This assignment which involves a transition from the most stable "π" antibonding e_g level to the highest "σ" antibonding level is in agreement with the relative high intensity of these bands ($\varepsilon \approx 400-650$) for a centrosymmetric arrangement. It should be, however, emphasized that the above assignment represents only an attempt. If one takes into consideration the fact that the shoulders in the spectra of the chelates IIa-2, IIb-2 and IIc are broad enough, these absorption bands could be constituted from many (at least two) unresolved *d-d* transitions. In this way similar absorption bands (extinctions, positions and their widths) were interpreted by Coussmaker, Venanzi *et al.*[8] for diamagnetic Ni(II)phosphine chelates.

The hypsochromic shift of about 40 nm of the *d-d* band occurring as a shoulder at approximately 530 nm in the spectrum of the chelate IIc, compared with the corresponding bands of the chelates IIa-2 and IIb-2, is difficult to be interpreted only through the inductive, electron repeller effect, of the CH_3 substituent, stronger if it is attached on the *ortho* position of the hydrazonic phenyl, than the same CH_3 group placed on the *meta* or *para* positions. Most probably, the hypsochromic shift of this band of the chelate IIc should be caused by the shift in the same direction and with the same amount of the very intense CT metal → ligand band, to the shoulder of which it belongs. In any way, the hypsochromic shift of the whole visible spectrum of the chelate IIc shows that in this case the steric hindrances due to the aromatic groups (*o*-tolyl) directly attached to the two donor nitrogen atoms involved in the Ni(II) coordination cannot overpass the inductive, electron repeller effect of the CH_3 group attached to the phenyl radical, which is very relevant for the *ortho* position[9] (*o*-tolyl group).

The electronic spectra of the chelates IIa-1 and IIb-1 are very similar and practically coincide in some domains of wavelengths. Even though they are similar to the already discussed spectra of the chelates IIa-2 and IIb-2, some differences nevertheless appear. For instance, the intense bands ($\varepsilon \approx 5000$) which may be in the same manner, as above, regarded as CT metal → ligand transitions, occurring as shoulders of the more intense bands ($\varepsilon \approx 23{,}000$), placed in the UV range.

The position of these shoulders, approximately at 500 nm, shows a bathochromic shift of about 30 nm of these CT bands compared with those of the former chelates. The other very broad shoulders at 600 nm show a bathochromic shift of about 40 nm compared with those assigned as $d-d$ transitions in the aforementioned chelates. More relevant than their widths is the enhancement in the intensity of the bands occurring as shoulders at approximately 600 nm. It may be mentioned that their molar extinction coefficient values $\varepsilon > 1200$ unobserved even for the $d-d$ transitions in the majority of the tetrahedral chelates, make the assignment as *d-d* bands for a centrosymmetric arrangement less probable.

---

[8] C.R.C. Coussmaker, M. H. Hutchinson, J. R. Mellor, L. E. Sutton and L. M. Venanzi, *J. Chem. Soc.*, **1961**, 2705.

[9] H. Becker, "Einführung in die Elektronen-theorie organish-chemischer Reaktionen", Deutscher Verlag der Wissenschaften Berlin, 1965, p. 362.

For this reason, the best assignment of these bands should be of CT metal → ligand nature, occurring, as has been earlier emphasized, in the visible range. These bands obscure the possible less intense *d-d* transitions, which may be expected to appear in this region, taking into consideration the bathochromic shift of the whole visible spectra of the chelates IIa-1 and IIb-1, compared with the already discussed complexes, where the *d-d* transitions were placed at approximately 560 nm.

The authors thank the lecturer V. Mincu of University of Bucharest for the magnetic susceptibility measurements and Mrs. M. Popa for the C, H and N elemental analyses.

HETEROPOLYTUNGSTATES WITH U(IV) AS CENTRAL ATOM

SYNTHESIS AND PHYSICO-CHEMICAL STUDY OF THE UL_2 COMPLEX WHERE $L=P_2W_{17}O_{61}^{10-}$

GH. MARCU*, MARIANA RUSU** and A. V. BOTAR**

* Chemistry Laboratory of Radioactive Elements,
University of Cluj, Str. Arany János 11, Romania
**Institute of Chemistry of the Ministry of Education,
str. Donath 65, Cluj, Romania

Received May 21, 1973

The U(IV) ion has a rapid reaction with the unsaturated heteropolyanions, forming UL_2 complexes where $L = PW_{11}O_{39}^{7-}$ and $P_2W_{17}O_{61}^{10-}$. The potassium salt of the $U(P_2W_{17}O_{61})_2^{16-}$ heteropolyanion has been isolated. The chemical analysis, the photocolorimetric study of the reaction between U(IV) and $P_2W_{17}O_{61}^{10-}$, as well as the basicity determinations of the heteropolyacid show that the U/W combination is 1/17.

GENERAL CONSIDERATIONS

The heteropolyanions of $X_2'ZW_{17}O_{62}^{x-}$ type are obtained from the $X_2'W_{18}O_{62}^{p-}$ anion by substituting a tungsten atom with a Z metalic atom. [1] These heteropolyanions are obtained after the partial degradation of the $X_2'W_{18}O_{62}^{p-}$ type anions under the influence of the potassium acetate up to pH 6–7, in the presence of the Z metalic atom in different oxidation states.[2–6] In every 18-tungsten heteropolyanion the Z atom substitutes a single tungsten atom octahedronically coordinated. It is well known that these "unsaturated" heteropolyanions react with a whole series of bi-, tri- and tetravalent atoms, forming a series of heteropolyanions.[3-11]

It has been found that the U(IV) ion forms UL_2 type complexes where $L = PW_{11}O_{39}^{7-}$ and $P_2W_{17}O_{61}^{10-}$.

In the present paper we study only the type complex where $L = P_2W_{17}O_{61}^{10-}$

EXPERIMENTAL

The potassium salt of the $U(P_2W_{17}O_{61})_2^{16-}$ type heteropolyanion has been obtained by applying a largely used procedure for the synthesis of this kind of heteropolyanions, with small differences. To a $K_{10}P_2W_{17}O_{61}.22\ H_2O$ solution heated at 70–80° a U(IV) solution was added, stepwise and stirring continuously.

The U(IV) salt has been obtained from a U(IV) salt by reduction through a Zn-amalgamated column. [12]

After cooling at 5°, 1,4-dioxan was added in order to extract the synthesized heteropolycombination which was separated under the form of an oily mass.

The purification of the synthesized heteropolycombination has been made by dissolving it in water and repeated extractions with 1,4-dioxan. The product was reduced to dryness at 40–50° and ground.

WORKING METHOD AND CHEMICAL ANALYSIS

The chemical analysis of the synthesized U(IV) heteropolytungstate has been made using the general method. [13] The uranium was photocolorimetrically recognized with Arsenazo III. [14] The tungsten was recognized by precipitation with cinchonine and calcination at WO_3.[15] The phosphorus was recognized by precipitation as magnesium and ammonium

[16] A. I. Vogel, "Quantitative Inorganic Analysis", 3rd ed., London, 1961, p. 575.
[17] G. H. Glass, *Chemist Analyst*, 42, 50 (1953).

The photocolorimetric study of the reaction between the $P_2W_{17}O_{61}{}^{10-}$ heteropolyanion and the U(IV) ion has been performed by measuring the extinction of the solution containing the $K_{16}U(P_2W_{17}O_{61})_2 \cdot 39\ H_2O$ compound by means of a FEK-M type photocolorimeter. Titration curve is in figure 3.

RESULTS AND DISCUSSION

The conditions of formation, of the $U(P_2W_{17}O_{61})_2^{16-}$ heteropolyanion in the solution have been followed, depending on concentration, pH and time, by using the photocolorimetric titration method.

In order to find the optimum pH for the formation of the respective heteropolyanion, in solution 10^{-2}M mixtures of solutions were prepared from U(IV) and $K_{10}P_2W_{17}O_{61} \cdot 22\ H_2O$ with a 1 : 2 ratio, at the following pH : 2,3, 4, 5, 6, 7 and it has been found that stability of these solutions is maximum at pH=3—4, which is confirmed also by the pH value of the final solution obtained after the synthesis process.

The variation of the extinction has been followed, measurements being carried out 20 minutes after the preparation of test-proofs, 1, 6, 24, 48, 72 and 96 hours later.

A red colour appears from the very beginning of the mixing of the solutions, which remains stable even 3—4 days later but the intensity decreases as time goes on.

Titration has been made in solutions with different concentrations; it has been notified that the optimum concentration in order to determine the extinction is 10^{-2} M—$5 \cdot 10^{-3}$ M.

From the equivalence point which is at 0.87 ml of U(IV) solution, the $U : P_2W_{17}O_{61}^{10-}$ combination ratio has been calculated, it has been found that the ratio is 1 : 2, a value which has been also found by chemical analysis of the $K_{16}U(P_2W_{17}O_{61})_2 \cdot 39\ H_2O$ salt.

These results are in good agreement with the calculated data for the respective salt, as seen in table 1.

The transformations of the salt in the 40°—1000° temperature range have been studied by thermogravimetric analysis.

The thermogram permits a direct determination of the water contained in the complex and of the modality of its elimination depending on temperature. The aspect of thermogram shows that the maximum speed of water removal is between 80°—200° and this process is concluded between 500°—600°, the substance coming to a constant weight at 800°.

By conductometric titration of the $K_{16}U(P_2W_{17}O_{61})_2 \cdot 39\ H_2O$ salt with thalium acetate, total basicity has been found to be 16. Two points of inflexion have been obtained for this titration, one of them corresponding to the substitution of 6 potassium ions, and the other one to the substitution of 16. The same results have been obtained by titration of the acid in aqueous solution by means of ion exchangers (Amberlite IR 120 H^+ form).

The basicity of the $U(P_2W_{17}O_{61})_2^{16-}$ anion, very easily to be predicted theoretically (the degree of oxidation of the complex generator being precisely known), is in good agreement with that one determined by conductometric titration.

CONCLUSIONS

1. The $U(P_2W_{17}O_{61})_2^{16-}$ type heteropolyanion was synthesized for the first time, extending the class of the heteropolycombinations that have a U(IV) central atom. The $K_{10}U(PW_{11}O_{39})_2 \cdot x\ H_2O$ compound was isolated, the results being the subject of another scientific paper.

2. The photocolorimetric study of the reaction between $P_2W_{17}O_{61}^{10-}$ and the U(IV) ion, as well as the analysis of the isolated potassium salt $K_{16}U(P_2W_{17}O_{61})_2 \cdot 39\ H_2O$ show that the U/W combination ratio is 1/17.

3. The study by paper electrophoresis, the obtaining of the corresponding acid using the ion exchangers, as well as the photocolorimetric study of the formation and stability of the $U(P_2W_{17}O_{61})_2^{16-}$ heteropolyanion show that it is not a mixture of combinations we deal with, but a unitary product which is stable.

4. Magnetic measurements being carried out on the $K_{16}U(P_2W_{17}O_{61})_2 \cdot 39\ H_2O$ complex show that uranium is in a 4+ oxidation state.

SYNTHESIS AND THERMAL ANALYSIS OF TITANIUM OXYHYDRATE ULTRAFINE POWDERS

A. BĂRBULESCU

Polytechnic Institute of Bucharest, Str. Polizu N⁰ 1, Bucharest, Romania

Received March 24, 1973

Ultrafine non-crystalline titanium oxyhydrate separated by freezing from hydrogel was examined by various thermal methods of analysis. The thermal behaviour of the powdering product was pointed out. A large dehydration process up to 400°, coalescence phenomena at 305° and anatase to rutile polymorphic transformation at the range of 680° have been found out. High purity active TiO_2 powder may be obtained, for calcination temperatures ranging between 300 and 600°.

1. INTRODUCTION

Obtainment of oxydic products by the sol-gel procedure [1] or by ion coprecipitation [2] is of great interest today in connection with the development of certain materials for electronics, the nuclear technique or the catalyst industry. In this way, ultrafine powdery products, solid phases homogenized at ionic scale, as well as synthesis at low temperatures of refractory compounds, etc., may be obtained. The features of the products thus obtained depend to a large extent on the synthesis and thermal treatment conditions, and a control of these factors is decisive for obtaining the desired quality.[3] Thus, the synthesis and thermal behaviour of non-crystalline titanium oxyhydrate ultrafine powders were studied, when obtained by the sol-gel procedure. The results are discussed by the present paper.

2. EXPERIMENTAL

2.1. SYNTHESIS OF TITANIUM OXYHYDRATE POWDERS

Titanium tetrachloride was turned into aqueous solution without its hydrolysis, after the method described by Clabaugh and collaborators.[4] Titanium hydrogel was obtained through ammonia neutralization by spraying the aqueous solution in a precipitation bath heated up to 80°, at pH $\simeq 7$ maintained as a result of continually adding NH_4OH. The precipitate was washed through decantation and separated in a Buchner funnel. In this state, titanium hydrogel is consistent and has an about 95 p.c. water content. The separation of water from hydrogel was achieved by the freezing procedure .[5] In this way a powdery product was directly obtained and it was further decanted and dried at 50°.

2.2. CHARACTERIZATION METHOD

The powder obtained was examined from a morphological and structural point of view, then it was subjected to thermal analysis. The thermal behaviour was studied through differential thermal analysis (DTA), thermogravimetric analysis (TGA), dilatometric analysis (DA) and thermal analysis of the electric resistance (TAER). The thermal analysis was completed with structure, specific area and colour determinations.

The JEM 7 A electronic microscope was used in the microscopic examination and electronic diffraction, the TUR M 61 equipment in X-ray analysis, and a STRÖHLEIN apparatus in measuring the specific area after the BET method. In the thermal analysis the NETZSCH installation with electronic recorder was used, as well as Stanton thermobalance and an absolute dilatometer of own design. In TAER the working technique is described in a published paper .[6]

3. RESULTS

3.1. *The morphology of the powder.* The powdery products are made up of agglomerated granules, each consisting of particles of about 10 nm or smaller. The specific area of the powder is of 300 sq.m/g and it confirms the microscope examination. Under the influence of the electronic beam, agglomeration phenomena of the powder were noticed with each intensity growth.

When the product was checked up by means of X-rays and electronic difraction, non diffraction lines were visible, hence the powder obtained was practically amorphous.

3.2. *The differential thermal analysis* evidenced a large endothermal effect within the interval up to 400°, which was interupted at 305° by a strong sharp exothermic peak. At over 400° a range of exothermic effects appear, which are manifest up to about 850°. The DTA curve rising up to 1300° at a speed of 10°/min was recorded to have the sensitivity of ± 0.5 mV up to 400° and of ± 0.1 mV at over 400° (fig. 1).

3.3 *The thermogravimetric analysis* showed a total mass loss of about 34 p.c. manifest up to about 400°. The mass loss curve function of temperature (fig. 2) is drawn for a heating speed of 5°/min.

3.4. *The dilatometric analysis* of a sample obtained by isostatic compacting at 1500 at evidenced the anomaly of contraction when the temperature reaches about 700° (fig. 3). At this temperature the process

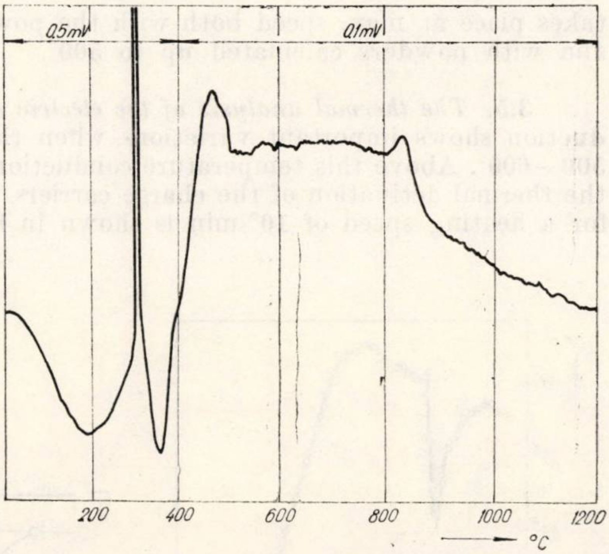

Fig. 1. – The DTA curve of titanium oxyhydrate ultrafine powder. Sensitivity ±0.5 mV up to 400° and ± 0.1 mV over 400°.

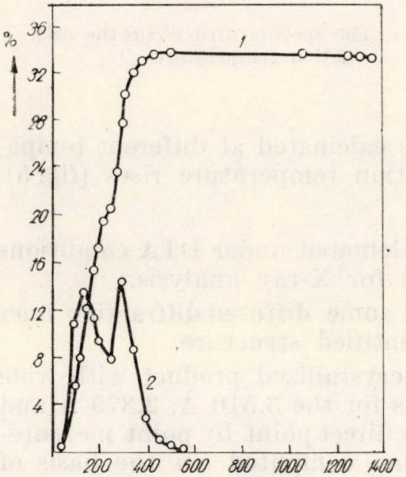

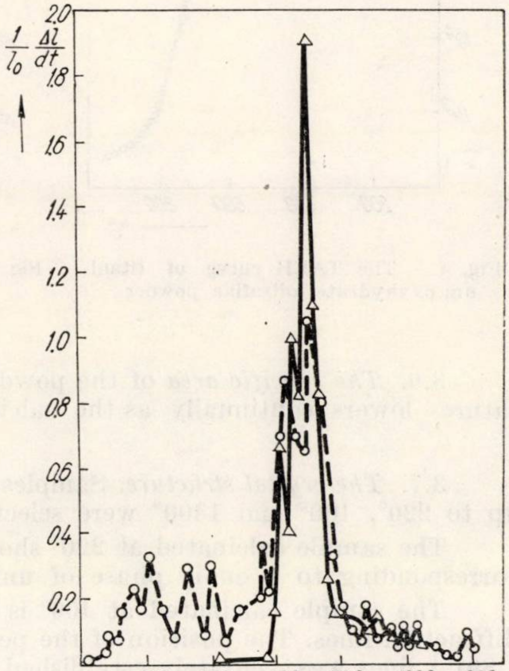

Fig. 2. – The mass loss (*1*) and its derivative (*2*) as a function of temperature for titanium oxyhydrate ultrafine powder.

Fig. 3. – The contraction derivative relative to temperature.

Revue Roumaine de Chimie, **19**, *5*, 833–838 (1974)

takes place at max. speed both with the powders calcinated under 200° and with powders calcinated up to 500°.

3.5. *The thermal analysis of the electric resistance.* The electric conduction shows important variations when the powder is heated up to 500—600°. Above this temperature conduction rises as a consequence of the thermal activation of the charge carriers. The TAER curve obtained for a heating speed of 10°/min is shown in fig. 4.

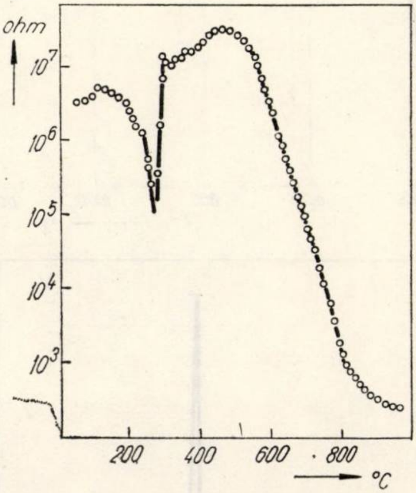

Fig. 4. — The TAER curve of titanium oxyhydrate ultrafine powder.

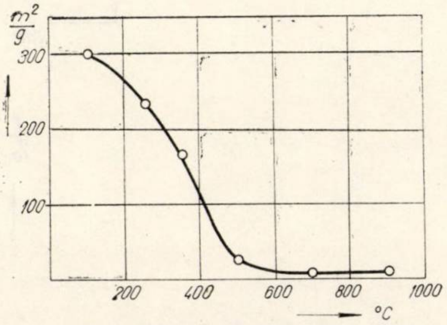

Fig. 5. — The specific area *versus* the calcination temperature.

3.6. *The specific area* of the powders calcinated at different temperatures lowers continually as the calcination temperature rises (fig. 5).

3.7. *The crystal structure.* Samples calcinated under DTA conditions up to 220°, 400° and 1300° were selected for X-ray analysis.

The sample calcinated at 220° shows some diffused diffraction lines corresponding to a cubic phase of unidentified structure.

The sample calcinated at 400° is a crystallized product with wide diffraction lines. The position of the peaks for the 3.510 Å, 2.379 Å and 1.891 Å lines was accurately established by direct point by point measurements. The following lattice parameters computed on the basis of the data obtained:

$$a = 3.783 \pm 0.05 \text{ p.c. and } b = 9.51 \pm 0.05 \text{ p.c.}$$

correspond to TiO_2 under the form of anatase.

The sample calcinated at 1300° is TiO_2 under the form of rutile. The following lattice parameters were computed on the basis of the value of the 18.03 Å and 27.15 Å lines :

$$a = 4.594 \pm 0.01 \text{ p.c. and } b = 2.958 \pm 0.01 \text{ p.c.}$$

4. DISCUSSION

Titanium hydrogel is liable to contain solid phase in both max. dispersion and min. crystalline ordering stages.[7,8]

The morphology of the powdery product obtained, its specific area and the state of the structure reveal the formation of an ultrafine non-crystalline powder as a consequence of the freezing procedure which brought about the destruction of the gel structure and the separation of water. The avoidance of heating allows for the conservation of the advanced dispersion and of the low structural ordering level, corresponding to the solid phase within hydrogel. At the same time, direct formation of the powder, i.e. with no physical mechanical loosening or grinding, eliminates any chance of contamination.

Thus, it is possible to obtain high purity active TiO_2 powders depending on the heat treatment conditions.

When titanium oxyhydrate is heated, dehydration processes as well as the formation of titanium dioxide under the form of anatase and the turning of anatase into rutile [9] take place.

The endothermal effect shown by the DTA curve and the mass loss recorded by the TGA curve are caused by the dehydration process. The mass loss becomes insignificant at over 360° and it ceases completely at about 500°. TiO_2 and the total water quantity released are in a ratio corresponding to a titanium oxyhydrate of the $TiO_2.2H_2O$ form. The dehydration can be shown by the following reactions :

$$TiO_2 \cdot 2H_2O \xrightarrow{150} TiO_2 \cdot H_2O \xrightarrow{300} TiO_2$$

The attempts to evidence the way in which water is connected into the structure, through nuclear magnetic resonance and infrared absorption, did not yield conclusive results.

The exothermal effect at 305° is caused by a process similar to that noticed when zirconia [10] gels are calcinated. The process is due to a coalescence phenomenon[11] whose physical significance is not yet clarified. The

[11] R. C. MACKENZIE, "Differential Thermal Analysis", vol. I, Academic Press, London, 1970, p. 277.

TAER curve contains an important discontinuity at the coalescence temperature. Up to this temperature a significant temperature growth of the charge carriers is perceptible, then their sudden reduction and the growth of the electric resistance by a number of largeness levels.

In accordance with Towe and Bradley [12] who consider that the continuous release of water leads to the formation of a residue which nucleates in oxydic phase, the TAER result is explainable if we admit that water is released according to reaction:

$$2OH^- \rightarrow H_2O + O^{2-}$$

and that the negative charges of the oxygen ions participate in the mechanism of the electric conduction, up to the moment in which the ions are rearranged and the bonds are re-established.

By releasing water from titanium oxyhydrate, TiO_2 under the form of anatase is obtained. The dimensions of the lattice parameters for the anatase obtained through calcination at 400°, greater than the usual ones, are the consequence of the presence of the hydroxyl ions, as well as of the conservation of an extraquantity of energy within the recently formed lattice. The crystalo-chemical features and the high ratio between area and mass confer to the anatase thus formed a great reactivity. The growth of the temperature causes a rapid diminution of the specific surface and of reactivity up to about 600°.

At a temperature above 600° anatase turns into rutile. This process, shown by the contraction-temperature curve, takes place between 600° and 800° and reaches its peak at about 680°.

5. CONCLUSIONS

Freshly prepared titanium hydrogel can be directly turned into a ultrafine, non-crystalline powdery product through the freezing procedure.

The powdery product is titanium oxyhydrate under the form of $TiO_2.2H_2O$ which is dehydrated through heating according to the following reactions:

$$TiO_2 \cdot 2H_2O \xrightarrow{150^\circ} TiO_2 \cdot H_2O \xrightarrow{300^\circ} TiO_2$$

When ultrafine non-crystalline powders of titanium oxyhydrate are heated a coalescence phenomenon appears at 305°, accompanied by an important modification in the electric conduction.

The release of water from the oxyhydrate leads to the formation of TiO_2 under the form of anatase. Anatase turns into rutile through heating between 600° and 800°, the turning speed being maximum at about 680°.

The suitable conditions for the obtaining of TiO_2 powders of increased reactivity correspond to the calcination temperatures ranging between 300 and 600°.

THE HYDROXYMERCURATION OF NOR-BORNENE

HAROLD KREHM and GEORGE F. WRIGHT
Lash Miller Chemical Laboratories, 80 St. George St., Toronto, Canada

Received July 23, 1973

We have found that treatment of [2,2,1]-bicycloheptene with mercuric perchlorate or mercuric nitrate forms two *exo*-hydroxymercurials and two *bis*-(2-chloromercuri-bicycloheptyl-3) ethers.

INTRODUCTION

The question of configuration of the oxymercurials formed by addition of mercuric salts to the carbon-carbon double bond seems now to have been decided by several workers.[1] Therefore, this report does not involve configuration, but instead involves the formation of two isomeric hydroxymercurials and at least two isomeric bis-ethers when [2, 2, 1]-bicycloheptene-2 is hydroxymercurated by means of aqueous mercuric perchlorate or mercuric nitrate.

We have found that this hydroxymercuration, by contrast with the more complex reaction involving mercuric acetate ,[2] results not only in the predominant yield of the diastereomer previously reported, the structure of which has been designated[1] as 2-*exo*-chloromercuri-3-exo-hydroxy [2, 2, 1]bicycloheptane but also in a small yield of a second diastereomer. We shall designate this second diastereomer as α in conformity with earlier nomenclature [3] and the more prevalent isomer as β because it is the one with the higher dipole moment. The dipole moment of the α-3-hydroxy-2-chloromercuri-bicyclo-heptane in benzene at 20° is found to be 3.63 D in contrast to the more prevalent β diastereomer of moment 4.9 D in benzene at 20°.

Earlier observations have shown that when cyclopentene, cyclohexene or other alkenes have been oxymercurated only one diastereomer is formed ; it has always been the one more rapidly deoxymercurated by use of strong (molecular) hydrochloric acid than the other diastereomer derived by radical-induced isomerization. The single products of these oxymercurations (not acid catalyzed) have lower dipole moments than the β diastereomers derived from them by radical-induced isomerization. By contrast the preponderant product from the present (acid catalyzed) oxymercuration of [2, 2, 1]-bicycloheptene has a higher dipole moment than the other diastereomer formed concomitantly in smaller amounts. But the diastereomer of higher dipole moment (by our convention the β isomer) is in the present instance more readily deoxymercurated than is the α isomer of lower dipole moment. In short the ease of deoxymercuration is now shown not to be directly related to the dipole moment.

[2] M. G. Abercrombie, Alan Rodgman, K. R. Bharucha and G. F. Wright, *Canad. J. Chem.*, **37**, 1328 (1959).

[3] G. F. Wright, *Ann. New York Acad. Sci.*, **65**, 436 (1957).

Both these α and β diastereomers upon reduction with sodium borohydride yield *exo*-2-hydroxy-[2, 2, 1]-bicycloheptane. Therefore, according to present configurational designation[1] the α-isomer must be 2-*endo*-chloromercuri-2-*exo*-hydroxy [2, 2, 1]bicycloheptane.

Hydroxymercuration of [2, 2, 1]-bicycloheptene yields, besides the hydroxy diastereomers, also a mixture of *bis*-(3-chloromercuri-[2, 2, 1]-bicycloheptyl-2) ethers. Formation of *bis*-ethers concomitant with hydroxymercurials is not unprecedented[4] but some of the conditions for their formation are now discernible. In aqueous solution with 3.4 equivalents of free acid per equivalent of mercury salt the yield of ethers is about 3–4%. But this can be increased to about 20% (at the expense of the hydroxy compound) by carrying out the reaction in *tert*-butyl alcohol. It may be observed that in this medium precipitation of products by addition of sodium chloride is slower than in water.

Clearly if the ethers were derived from two diastereomeric alcohols then 6 ethers could be expected — two *meso* isomers and two chiral pairs. In point of fact when the ether mixture, of wide melting point range, is reduced by sodium borohydride a single *bis*-[2, 2, 1]-bicycloheptyl ether is obtained. This latter compound has the same melting point as one obtained, along with *exo*-hydroxy-[2, 2, 1]-bicycloheptane, by Bruson[5] and Schmerling.[6]

By laborious crystallization we have been able to isolate two isomeric ethers but have not established their configurations. It is of interest that these two ethers can be obtained in small (10%) yield if β-*exo*-3-hydroxy-[2, 2, 1]-bicycloheptyl-2-mercuric chloride is converted to the analogous organomercuric nitrate and then is treated with [2, 2, 1]-bicycloheptene.

The authors are grateful to the National Research Council of Canada from whom a grant in-aid made this investigation possible.

[2,2,1]-bicycloheptyl-2-mercuric chloride showed $\Delta E/\Delta\omega$, 8.22, and $\Delta V/\Delta\omega$, -0.744 which may be calculated to $\mu = 4.94$ D from an electronic polarization of 48 cc based on atom, or bond refraction values. On the same basis the α-3-*exo*-hydroxy-[2,2,1]-bicycloheptylmercuric chloride showed $\Delta E/\Delta\omega$ of 4.76 and $\Delta V/\Delta\omega$ of -0.77 which may be calculated to $\mu = 3.63$ D. From the determinations of dielectric constant of the solid substances [8] the distortion polarization of the β-form is found to be 61 cc and that of the α-form to be 63 cc, which would alter the dipole moments only slightly from those calculated according to electronic alone.

Reagents. The [2,2,1]-bicycloheptene (100 g) was skaken twice at 50° with 200 ml of 5% aqueous ferrous sulphate under nitrogen, then twice with 50 ml of water. It was dried under nitrogen with magnesium sulphate and distilled under nitrogen, b.p. 94—96°. The distillate, m.p. 46.3—46.8, was peroxide-free by test with potassium iodide.

The *tert*-butyl alcohol was partially frozen and the remainder was decanted. The melted residue was twice treated with sodium and once with lithium aluminum hydride under nitrogen, b.p. 82—82.5°, peroxide-free.

Both Merck and Fisher Reagent grade mercuric nitrate or its monohydrate were used as received. The yellow mercuric oxide was used as received from Mallinckrodt.

β-3-*EXO*-HYDROXY-[2,2,1]-BICYCLOHEPTYL-2-MERCURIC CHLORIDE

To 3.06 g (0.009 mole) of mercuric nitrate monohydrate in 18 ml water plus 2 ml *conc* nitric acid was added a solution of 0.9 g (0.01 mole) of [2,2,1]-bicycloheptene in 8 ml of tert-butyl alcohol. After 7 hours the system was decanted (from 0.037 g (2%) of metallic mercury) into 6 ml of 10% aqueous sodium chloride chilled 50 —10°. The precipitate was filtered (filtrate being reserved) after 6 hours at 20°, wt 2.9 g m.p. 95—102°. Extraction with ethanol gave a 70% yield of crude β-isomer (m.p. 123—126°) leaving a residue extractable with hot benzene to separate the *bis* ethers, in 5% yield, from mercurous chloride (10% of total mercury). Three crystallizations from 85% ethanol (2.5 ml per gram) raised the mp of the β-isomer to 130—131.5°.

The long reaction time mentioned above is not necessary for initial consumption of the inorganic mercury. This is evident because treatment of an aliquot with aqueous sodium hydroxide after a reaction time of 1 minute does not cause any precipitate of mercuric oxide. Also when the reaction is worked up after one minute of reaction time any oxidation is avoided, with a consequent higher crude yield (90%) of the β-isomer with m.p. 126—8°. However, only traces of the ethers are formed and none of the α isomer can be found. Essentially the same results are obtained when the reaction system is made up with mercuric oxide and perchloric acid instead of mercuric nitrate and nitric acid, but the extent of mercurous salt formation is greater with perchloric acid.

The infrared spectrum of the β-isomer, m.p. 131°, in chloroform, (2%) showed absorptions in cm^{-1} with extinctions (E) as follows: 3600 (133), 3450 (7), 2950 (22), 2450 (62), 1750 (77), 1460 (120), 1370 (115), 1335 (185), 1170 (172), 1145 (161), 1115 (142), 1030 (244), 945 (134), 920 (142), 888 (107), 878 (107), 860 (125).

α-3-*EXO*-HYDROXY-[2,2,1]-BICYCLOHEPTYL-2-MERCURIC CHLORIDE

The reserved filtrate from which the crude product was filtered in the previous experiment was extracted 4 times with a total of 100 ml of chloroform. The combined extracts, vacuum-evaporated to a volume of 5 ml precipitated 0.199 g (6%) of crude α-isomer upon dilution with 5 ml of petroleum ether. This material, m.p. 118−19°, may be crystallized from chloroform, m.p. 119−20°. Anal. *Calcd.* for $C_7H_{11}ClHgO$: C, 24.2 ; Hg, 3.20. *Found*: C, 24.0 ; 3.39. The infrared spectrum of a 1.6% solution in chloroform in cm^{-1} with extinction (E) is as follows: 3600 (130), 3450 (86), 2950 (246), 2450 (76), 1490 (123), 1460 (153), 1400 (130), 1340 (155), 1308 (191), 1170 (191), 1120 (189), 1114 (191), 1050 (216), 1000 (408), 950 (153), 940 (147), 925 (143), 845 (155).

---

3-*EXO*-HYDROXY-[2,2,1]-BICYCLOHEPTANE

To a stirred solution at 0° of 3.5 g (0.01 mole) of the α-isomer described above with 0.40 g (0.01 mole) of sodium hydroxide in 45 ml of methanol and 3 ml of water was added 0.46 g (0.012 mole) of sodium borohydride during 25 minutes. After 8 hours subsequently at 20° metallic mercury (2.05 g, 102%) was filtered off. The filtrate was diluted with 300 ml of water and brought to pH 7.2−7.5 by cautious addition of diluted hydrochloric acid. This solution was extracted 5 times with 50 ml portions of diethyl ether. Evaporation of the combined extracts left 0.74 g (66%) of the exo-alcohol m.p. 124−6.5°. A mixture melting point with an authentic sample was not depressed.

To 0.10 g (9×10^{-4} mole) of this product in 3 ml of dry petroleum ether (b.p. 60−70°) was added 0.1 ml of phenylisocyanate. After 8 hours 0.16 g (62%) of the urethane m.p. 143−6° was obtained. After crystallization from benzene the melting point was 145−6° and it was not depressed by admixture with the authentic phenylurethane.

An identical experiment with the β−isomer gave identical results. Admixture of products and derivatives gave no depression in melting point.

BIS-(EXO-3-HYDROXY-[2,2,1]-BICYCLOHEPTYL-2)-MERCURY

A solution of 1.4 g (0.0004) of the β-isomer and 0.32 (0.008 mole) of sodium hydroxide in 1 ml of water and 18 ml of methanol was treated with 0.4 ml (0.0008 mole) of 100% hydrazine hydrate and the whole was refluxed for 6 hours. The hot system was then filtered to remove 0.55 g (69%) of metallic mercury. When the filtrate was cooled it yielded 0.25 g (60%) of colourless needles, m.p. 162−3°. Anal : *Calcd.* for $C_{14}H_{22}O_2Hg$: C, 39.8 ; H, 5.20. *Found* : C), 40.1 ; H, 5.32.

A solution of 100 mg of the *bis*-organomercury and 75.6 mg of mercuric acetate in 3 ml methanol was heated to 50° for 15 minutes. Dilution with 6 ml of water and 0.2 ml of 10% aqueous sodium hydroxide was followed by addition of 0.3 ml of 5% aqueous sodium chloride and then carbon dioxide. The product, 100 mg, m.p. 129 − 29.5 was shown to be the β-diastereomer by mixture melting point.

3-*EXO*-HYDROXY-[2,2,1]-BICYCLOHEPTYL-2-MERCURIC CHLORIDE HYDRAZINATE

To a solution of 1.75 g (0.005 mole) of the β-isomer m.p. 131°, in 7 ml of absolute ethanol was added 0.25 ml (0.005 mole) of 100% hydrazine hydrate with stirring. The white precipitate, which formed at once, weighed 1.60 g (90% m.p. 143−6°, decomp.). Five crystallizations from acetonitrile raised this m.p. to 154.5 − 6° (decomp.). The compound releases gas and deposits mercury upon treatment with mercuric acetate in methanol. It slowly decomposes spontaneously. Anal. *Calcd.* for $C_7H_{15}ON_2HgCl$: C, 22.2 ; H, 3.97 ; N, 7.4. *Found* : C, 22.5 ; H, 3.99 ; N, 6.6.

ACID HYDROLYSIS OF THE α AND β ISOMER MIXTURE

To a solution of 0.19 g each of the β and α isomer in 3 ml of 95 % ethanol was added 1 ml of *conc.* hydrochloric acid. After one minute the system was poured into 2 ml of 20 % aqueous sodium hydroxide. Filtration removed 0.10 g (80 %) of mercuric oxide which was washed with ether. The ether washings and extract of the filtrate yielded [2,2,1]-bicycloheptene in 30 % yield. The aqueous phase was treated with 0.5 ml of 10 % aqueous sodium chloride and gaseous carbon dioxide. Vacuum evaporation of the ethanol left 42 mg (20 %) of the α-isomer, m.p. 119 – 120°, authenticated by mixture melting point.

CIS-CYCLOPENTANE-1,3-DICARBOXYLIC ACID

To a solution of 3.47 g (0.01 mole) of the β chloromercurial in 16 ml of 10 % aqueous sodium hydroxide and 75 ml of water was added during 150 minutes 4.74 g (0. 03 mole) of potassium permanganate with stirring. After addition of a few ml of methanol the system was stirred for 27 hours longer then was filtered and the filtrate was evaporated to a small volume. After acidification the hydrated manganic oxide was filtered off. Further evaporation of the filtrate and three-fold extraction of the residue with 60 ml portions of absolute ethanol left 1.33 g, m.p. 110 – 120° (83 %) after evaporation of the solvent. This product, containing no mercury, was crystallized from 2.5 ml of hot water, m.p. 118 – 19°. [9]

A repetition of the experiment except for use of the α instead of the β-isomer gave a 70 % crude yield mp 100–109°. Crystallization from water raised this m.p. to 118–9° and it was not depressed by admixture with the product of the previous reaction. A 4 mg sample in 400 mg of potassium bromide gave the following infrared spectrum (cm^{-1}) : 3600–2300 (s), 1725–1600 (s), 1470 (m), 1410 (s), 1340 (m), 1320–1220 (s), 1210 (s), 1170 (s), 1090 (m), 1065 (w), 100–880 (s), 740 (m), 720–690 (m), 665 (m).

BIS-(2-CHLOROMERCURI-[2,2,1]-BICYCLOHEPTYL-3)ETHERS

Formation. To a solution of 94 g (1 mole) of [2,2,1]-bicycloheptene in 900 ml of tert-butyl alcohol was added a solution of 304 g (0.89 mole) of mercuric nitrate monohydrate and 144 ml (2.27 mole) of *conc* nitric acid (d 1.42) in 2320 ml of water. After 7 hours the clear solution did not test positively for presence of mercurous salt. To the stirred system was added during 2 hours 1052 ml of 5 % aqueous sodium chloride. The system was chilled and filtered, 283 g m.p. 118–28°. The aqueous filtrate was exhaustively extracted with chloroform. Evaporation of the extract left a residue which was crystallized from absolute ethanol to yield 8.0 g, m.p. 119–120°, of the α-isomeric hydroxymercuric chloride, authenticated by mixture melting point.

---

[9] J. F. Birch, W. H. Oldman and E. A. Johnson, *J. Chem. Soc.*, **1947**, 818.

The crude yield of 283 g was extracted with 1200 ml of hot 95% ethanol to leave an insoluble residue of 93.5 g of crude ethers, m.p. 145—56°. The cooled ethanol solution yielded 173 g (50%) of the β-isomer, m.p. 131°. Crystallization of the crude ethers from hot 3 : 2 chloroform-absolute ethanol yielded 68 g m.p. 200—203. This amount may be considered to comprise the actual yield of the mixture of ethers (20%) because of the elemental analysis (% C, 25.0; % H, 3.31) and because the infrared spectrum in potassium chloride shows no hydroxyl absorption.

Benzene (35 ml per g) may be used instead of chloroform-ethanol to raise the melting point of the crude ethers from 140° to 200°. Another useful method, especially when small amounts are involved, is dependent upon the marked difference in stability between the β-isomer and the ethers toward molecular hydrogen chloride. When 2 g crude product (m.p. 145—50°) was shaken with a solution of 5 ml *conc.* hydrochloric and 5 ml of methanol for one minute and then filtered the melting point of the solid which survived was 190—200°. About 5% of the ethers originally present are deoxymercurated together with all of the β-isomer. When 2.4 g (0.026 mole) of [2,2,1]-bicycloheptene, in 16 ml of *tert*-butyl alcohol was treated with a solution of 4.32 g of mercuric oxide in 6.5 ml (0.075 mole) of perchloric acid and 36 ml of water during 7 hours followed by subsequent treatment with aqueous sodium chloride the crystalline product contained mercurous salt (5% of total mercury), a 14% yield of the ethers, 200—203°, 60% of the β and 4% of the α-isomer, all calculated on the mole percent yield basis.

The mixtures of ethers (m.p. 200—203°, approximately in equal amounts according to rough thermal analysis) may be obtained also from the β-isomer and bicycloheptene in acid. To a warm solution of 1.3 g (3.76 mmole) of the β-isomer, m.p. 131°, in 5 ml of *tert*-butyl alcohol was added 3.6 ml of a molar solution of silver nitrate in water. After 30 minutes on the steam bath the system was filtered. The precipitate, washed with 7 ml of hot water and dried, weighed 0.69 (110% as silver chloride). To the filtrate was added 0.15 g (1.6 mmole) of [2,2,1]-bicycloheptene and 0.8 ml (13 mmole) of *conc.* nitric acid (d, 1.42). After 7 hours the system was then shaken with 2.3 ml (0.5 equiv.) of 5% aqueous sodium chloride. When the precipitated oil had coagulated another 2.3 ml of the aqueous sodium chloride was added and the thoroughly mixed system was chilled at 4° for 5 hours. The crude product, 1.0 g m.p. 115—135°, was then filtered off. This crude material was extracted with 10 ml of hot 85% ethanol to remove the β-isomer (m.p. 128—9, 60% recovery upon cooling) and to leave 0.21 g m.p. 164—176°. Multiple crystallization from benzene raised this m.p. to 200—203°, 0.18 g (10%). No attempt was made to isolate the α-isomer from the system.

The high melting ether. The mixture of ethers was fractionally crystallized from nitrobenzene (33 ml per gram) to give half the original weight m.p. 232°. Sometimes this m.p. was 242° but it reverted to 232° on subsequent crystallization and both melting points were definite, indicating polymorphism. Anal. *Calcd.* for $C_{14}H_{20}Cl_2Hg_2O$: C, 24.9; H, 3.00. *Found*: C, 24.9; H, 3.33. The infrared spectrum of 3 mg in 400 mg of potassium chloride (cm^{-1}) is 2950 (s), 2700 (s), 1450 (shoulder, m) 1380 (w), 1345 (m), 1315 (shoulder, m), 1927 (w), 1880 (w), 1220 (s), 1200 (w), 1178 (m), 1165 (m), 1140 (m), 1110 (m), 1050 (s), 1030 (s), 1015 (s), 955 (w), 940 (w), 925 (m), 890 (m), 860 (m), 780 (w), 765 (m).

The low melting ether. The mother liqours from the fractional crystallization out of nitrobenzene were vacuum-evaporated to dryness. Four or five crystallizations from benzene (35 ml per g) yielded the other ether, m.p. 215—16° in quantity about half of the original weight. Anal. *Found* for $C_{14}H_{20}Cl_2Hg_2O$: C, 24.9; H, 3.33. The infrared spectrum of 3 mg in 400 mg of potassium chloride (cm^{-1}) is 2950 (s), 2865 (s), 1460 (m), 1360 (m), 1325 (s), 1314 (s), 1297 (d), 1250 (s), 1218 (w), 1210 (w), 1185 (w), 1155 (shoulder, s) 1140 (m), 1025 (very broad, s), 988 (s), 955 (w), 926 (shoulder, m), 878 (w), 858 (m), 800 (w), 776 (s), 758 (w), where intensities are indicated as strong, medium and weak.

BIS-[2,2,1]-BICYCLOHEPTYL-3-ETHER

To a shaken slurry of 2.89 (4.1 mole) of high-melting ether in 60 ml of tetrahydrofuran with 0.22 g (8 mole) of sodium hydroxide in 3 ml of water was added 8.2 mole of sodium borohydride at 0° during 30 minutes. After 6 hours subsequently at 20° the system was filtered to remove 1.75 g (105 % of metallic mercury). The clear filtrate was diluted with 150 ml of water, neutralized with 1.3 ml of *conc.* hydrochloric acid and extracted three times with a total of 100 ml of petroleum ether (b.p. 35–56°). Evaporation of the extracts left 0.64 g (77 %) m.p. 60–62°. Crystallization from 1.5 ml of hot methanol raised this m.p. to 65–66°. Anal. *Calcd.* for $C_{14}H_{22}O$: C, 81.4 ; H, 10.75. *Found* : C, 80.6 ; H, 10.71. The infrared spectrum (cm^{-1}) of a 10 % solution in carbon tetrachloride was 2950 (v.s.), 1484 (m), 1450 (s), 1315 (m), 1285 (w), 1250 (w), 1215 (w), 1170 (s), 1148 (s), 1113 (s), 1089 (v.s.), 1036 (s), 1022 (v.s.), 980 (m), 945 (s), 917 (w), 880 (w), 855 (w), 833 (w).

The exepriment was repeated except that low-melting ether was reduced. The yield of mercury was 93 % and that of the ether, m.p. 62–64, was 67 %. After crystallization from methanol (m.p. 65–66°) the product was shown by mixture melting point and infrared spectra to be identical with the ether obtained from the high-melting diastereomer.

THE ACTIVATION OF PALLADIUM CATALYSTS BY RARE EARTH AND OTHER OXIDES FOR THE HYDROGENATION OF CYCLOHEXENE

S. M. ISMAIL, M. A. ALEEM and ASHRAF ALI

Pakistan Council of Scientific and Industrial Research, Karachi, Pakistan

Received May 14, 1973

It has been found that small quantities of metallic oxides, mainly of the rare earth type and including, thoria, zirconia, chromia, titania, vanadium pentoxide, ceria, lanthanum oxide, praseodymium oxide, thallium oxide and samarium oxide, act as strong promoters in the hydrogenation of cyclohexene by reduced palladium at 30° and at normal atmospheric pressure. In general the activity of a constant amount of palladium on varying amounts of promoters first rises to a peak (true promoter action) and subsequently falls as the ratio of promoters to palladium is further increased. The order of activities of these promoters follows the sequence : $\mathrm{ThO_2} > \mathrm{ZrO_2} > \mathrm{Cr_2O_3}$ $\mathrm{CeO_2} > \mathrm{TiO_2} > \mathrm{V_2O_5} > \mathrm{La_2O_3} > \mathrm{Pr_2O_{11}} > \mathrm{Tl_2O_3} > \mathrm{Sm_2O_3}$. The degree of activation is considerable being almost five times the unpromoted value for thoria and zirconia at the peak point in the activity curves. The apparent activation energies of hydrogenation of cyclohexene in alcoholic solution have been determined at 30°. Hydrogen adsorbed by these promoted catalysts have been determined by a chemical dehydrogenation method. Activation energies observed were higher for the promoted catalysts than for reduced palladium. A variation in the palladium : promoter ratio affected both the apparent activation energy and the total volume of hydrogen adsorbed per gram of palladium. A strict logarithmic dependence of the activation energy results in the disappearence of the promoter action of the supports at low temperatures. There was no dependence of catalytic activity on the hydrogen content of these catalysts, as has been found in the case of Raney nickel [1] except that the adsorbed hydrogen per gram of supported palladium was more than that on reduced palladium.

The only approach to a complete understanding of catalytic process is through an analysis of all factors involved, investigating each variable as completely separated from all other variables as possible. In molecular reactions the reactants must often be adsorbed to yield the product. The rate determining steps in such reactions may be the rate of adsorption or desorption of the reactants on the surface. By definition, catalysts reduce the energy of activation of a reaction and thus an equilibrium is achieved through the formation of an activated adsorption complex with the catalyst. For supported catalysts in particular, it is of interest to determine the separate contributions of the temperature independent factor and of the activation energy to the total activity, to know whether a support increases the activity by virtue of a decrease in the activation energy, by an increase in the frequency factor, or by both. Supported catalysts have been used to hydrogenate cyclohexene in alcoholic solutions at temperatures considerably below the inversion, in the region in which the reaction is strictly of the first order with respect to the concentration. The classical methods of rate determining steps have shown that the catalysts were employed under conditions in which mass transfer did not control the reaction rates. The first order reaction having, $k = (1/t)\ [1\mathrm{n}a/(a - x)]$, giving a linear graph on plotting $\log\ [a/(a - x)]$ against time t, and a slope of 0.0648 per min was obtained. The value of the constant k obtained was 1.492×10^{-1} per min. The measure of activity taken was the volume in ml of hydrogen adsorbed in the first four minutes of the reaction which does not affect the concentrations, and can thus be regarded as preliminary rates.

---

[1] H. Gautt and G. Mason, *Compt. rend.*, **1947**, 224, 281.

The independence of the hydrogenation rates on the concentrations can be attributed to a saturation of the catalyst surface with the olefin, and the first order dependence on near atmospheric pressures suggest that the reaction occurs through a Rideal-Eley type of mechanism. [2] There are many variations of this mechanism, the simplest of which involves adsorption of the olefin and its collision with free hydrogen. Various reaction mechanisms can, however, result in a first order dependence on the hydrogen pressure. The capacity of the catalyst to adsorb hydrogen under conditions similar to those prevailing during the reaction is of interest. A correlation between the hydrogen content of Raney nickel and its activity has been reported by many authors. [3] The adsorption of hydrogen from the liquid phase on to the supported palladium has been measured by Sokolskii, [4] but its catalytic activity has not been determined.

EXPERIMENTAL

All the reagents used were of ordinary laboratory grade and were used as purchased Ceric ammonium sulphate, being a primary standard, analytical reagent grade was used Cyclohexene and ethyl alcohol were distilled twice under vacuum.

Preparation of the catalyst. The catalysts were deposited on the supports by precipitation in situ. This method has been used with excellent results by Maxted *et al.* Finely divided palladium were prepared by the reduction of palladous chloride with aqueous formaldehyde. By this method, the tendency of the palladium to form a colloid was avoided, and the catalysts could then be readily separated by centrifuging.

[5] E. B. Maxted and S. Akhtar, *J. Chem. Soc.*, **1960** 405, 1995; E. B. Maxted and S. I. Ali, *Ibid.*, **1961**, 4137; E. B. Maxted and S. M. Ismail, *Ibid.*, **1962**, 447.

Amount of catalysts. 9.976 mg of reduced palladium was deposited on a varying amount, 0.1 g to 2.0 g of the oxide supports. The charge in the reaction pipette consisted of 0.1 mole of cyclohexene and 9 ml of absolute alcohol. The rate of hydrogenation was taken as the ml of hydrogen adsorbed in the first four minutes. Hydrogenation data are shown in figures 1 and 2, having been separated in two figures to avoid excessive overcrowding.

Weight of the catalyst. With all considerations standardized at a constant, the dependence of the rate of hydrogenation upon the weight of the catalyst used was determined. Typical data are shown in figure 3.

The nature of the catalyst. Under the same experimental conditions and with the same amount of catalyst, the rate of hydrogenation of palladium over various metallic oxides follow the sequence: $ThO_2 > ZrO_2 > Cr_2O_3 > CeO_2 > TiO_2 > V_2O_5 > La_2O_3 > Pr_6O_{11} > Tl_2O_3 >$ Sm_2O_3. The results indicate that the solvent composition does not affect the reaction-order in any way.

Occlusion of hydrogen. A small amount of hydrogen occluded by palladium in the presence of 9 ml of alcohol at 30° was also measured by the same method as that for hydrogenation. It was found that 9.976 mg of unsupported palladium occluded 0.2 ml of hydrogen in 4 min and that supported palladium occluded 1.4 ml of hydrogen in the same period of time. Any correction for occlusion was however not made, as in a comparative study such as this, the amount occluded was the same for all the catalysts and this in any case being a very small percentage of the total volume of hydrogen adsorbed.

Agitation frequency. In a static system such as the present work, in which the mixing of hydrogen and the liquid is carried out by shaking, it is important to ensure that the reaction rate is independent of the rate of shaking. The influence of the mode of frequency of agitation upon the rate of hydrogenation was determined for several different lots of catalysts using a magnetic stirrer at 920 RPM in comparison with the mechanical shaker operating at a frequency of 200 oscillations/min. The resulting data showed that the use of a mechanical shaker gave increased rates of hydrogenation for all weights of catalysts, and that this effect is more pronounced for some supports than for others. However, it was established after repeated experiments that the activity of 9.976 mg of palladium on 1.0 g thoria at 30° became independent of the shaking speed when this exceeded 450 oscillations per minute. As such, the shaking rates for all subsequent activity measurements were adopted at 550 oscillations per minute, to take account of any variations due for instance to the belt slip.

Carriers and promoters. When a carrier increases the rate of a reaction, it is no longer a carrier, but becomes a promoter. It is often hard to make a distinction between the promoter, the active catalyst component and the carrier, in that definitions are somewhat arbitrary, synonyms such as support and activator are also cited in the literature. For our purposes, a promoter can be defined as a substance, added in small amounts to the catalyst, which in itself has little activity but which imparts a higher activity, stability or selectivity. Its amount is just economic, but optimal amounts show sharp maxima. Whereas carriers give quantitative mechanical extension to the catalyst, the function of a promoter is a specific one, in that it interacts with the adsorption complex fo form intermediate compounds

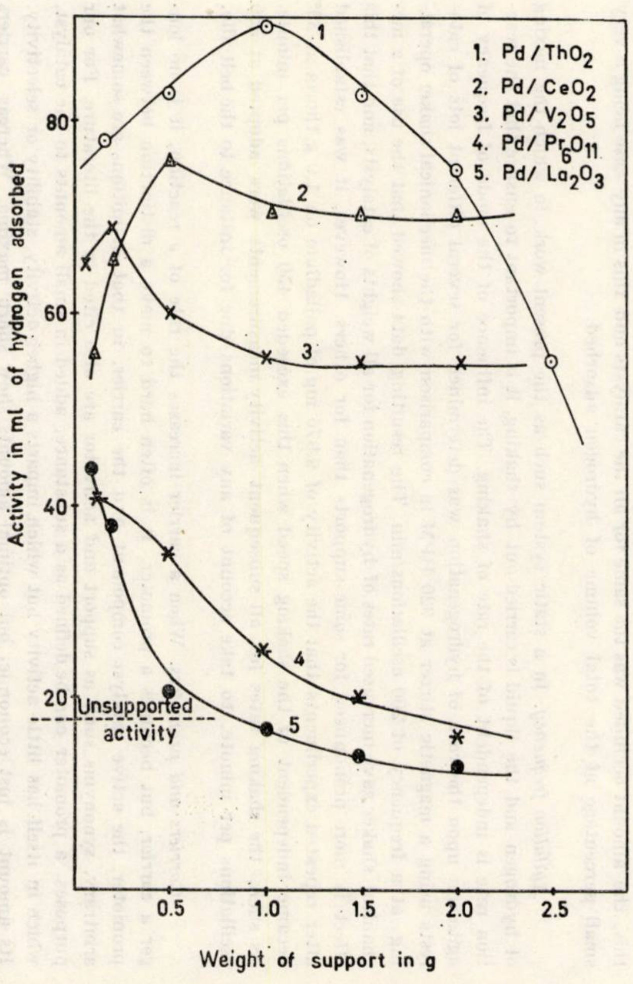

Fig. 1. — Activity/Support isotherm.

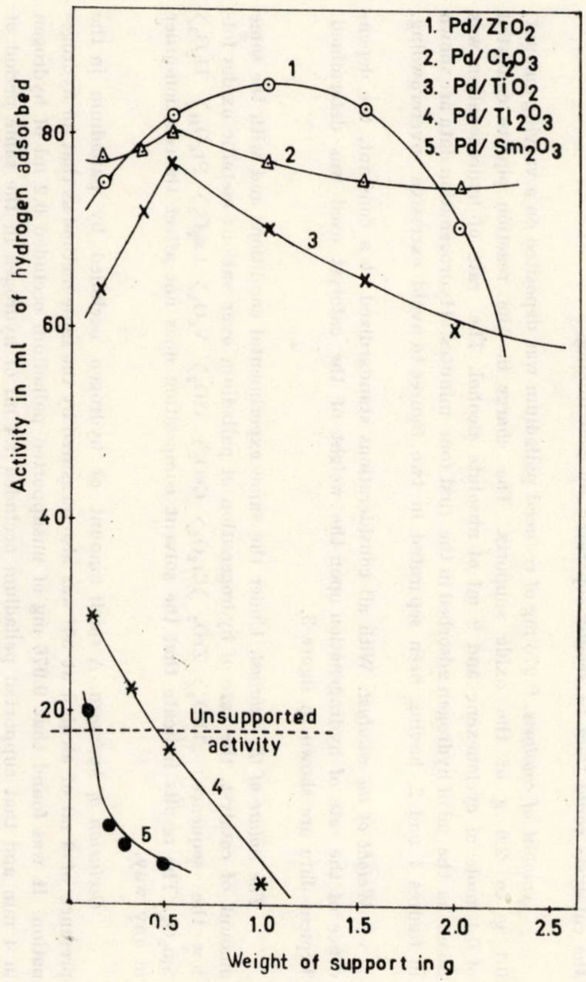

Fig. 2. — Activity/Support isotherm.

between the catalyst and the components of the reaction. Since there is no *a priori* difference between structural promotion and pure carrier action, ambiguity can be avoided by confining the term promoter action to cases in which the specific activity of a two or more component catalyst is greater than the sum of the specific activities of the separate components.

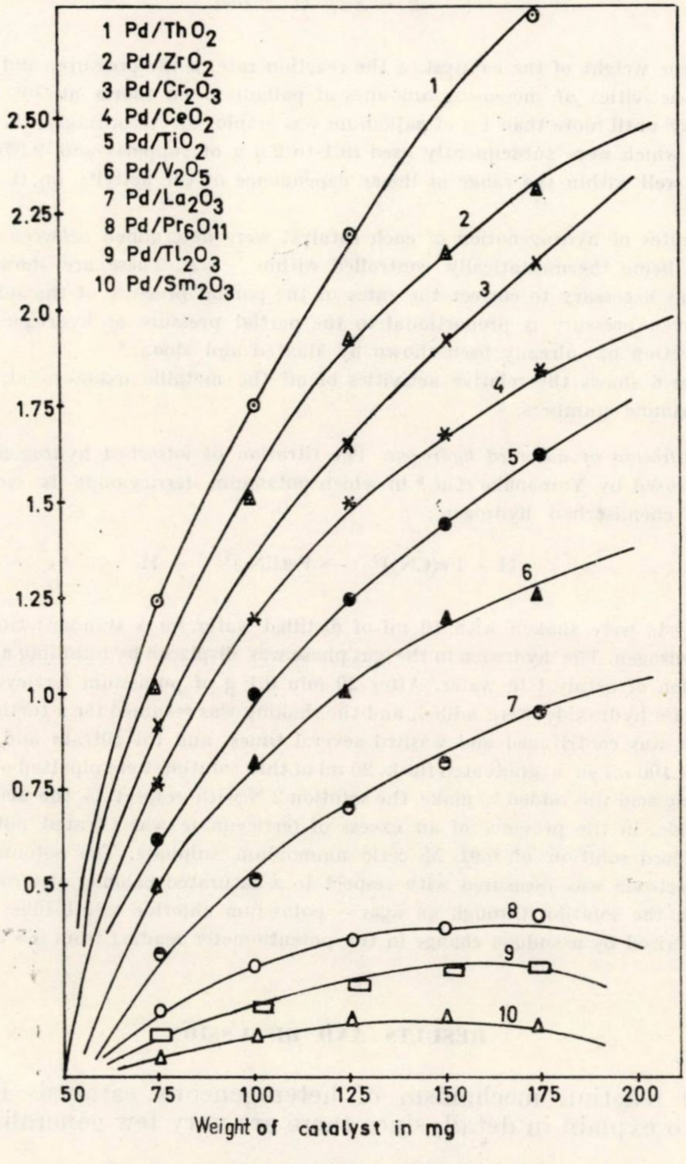

Fig. 3. — Activity/Weight of the catalysts.

Kinetic factors of the reaction. The first order dependence of the reaction rate on the weight of the catalyst is a necessary condition for the absence of mass transfer effects. As the amount of the catalyst is increased, the reaction rate increases linearly at first, but subsequently becomes independent of the weight of the catalyst. Watt and Walling [6] represented this limiting value by an empirical formula :

$$k = Awp \ (1 + Bw)$$

where w is the weight of the catalyst, k the reaction rate, p the pressure, and A, B are constants. The activities of increasing amounts of palladium on thoria at 30° do not deviate from linearity until more than 1 g of palladium was employed. Accordingly, the small amounts of catalysts which were subsequently used (0.1 to 2.0 g of supports and 9.976 mg of palladium) were well within the range of linear dependence of the activity on the weight of the catalyst.

The rates of hydrogenation of each catalyst were determined between 0° and 40°, the temperature being thermostatically controlled within $\pm 0.2°$. These are shown in figures 4 and 5. It was necessary to correct the rates of the partial pressure of the solvent, since the rate at a given pressure is proportional to the partial pressure of hydrogen. [7] The validity of this correction has already been shown by Maxted and Moon. [8]

Figure 6 shows the relative activities of all the metallic oxides used, arranged with increasing atomic numbers.

The titration of adsorbed hydrogen. The titration of adsorbed hydrogen was based on the method used by Yamanaka *et al.* [9] in which potassium ferricyanide is reduced to ferrocyanide by chemisorbed hydrogen :

$$\mathrm{H} + \mathrm{Fe(CN_6)^{3-}} \rightarrow \mathrm{Fe(CN_6)^{4-}} + \mathrm{H^+}$$

Catalysts were shaken with 10 ml of distilled water for a standard time in an atmosphere of hydrogen. The hydrogen in the gas phase was displaced by bubbling nitrogen through the suspension of catalyst in water. After 20 min 0.1 g of potassium ferricyanide and 2 ml of N – sodium hydroxide were added, and the shaking was resumed for a further known time. The catalyst was centrifuged and washed several times, and the filtrate and washings were made up to 100 ml in a graduated flask. 20 ml of this solution were pipetted out in a beaker, and sulphuric acid was added to make the solution 2 N with respect to the acid. This solution of ferricyanide, in the presence of an excess of ferricyanide was titrated potentiometrically with a standard solution of 0.01 M ceric ammonium sulphate. The potential of a bright platinum electrode was measured with respect to a saturated calomel electrode which made contact with the solution through an agar – potassium chloride salt bridge. The end point was characterized by a sudden change in the potentiometer reading from 0.5 to 1 volt.

RESULTS AND DISCUSSION

The reaction mechanism of heterogeneous catalysis is extremely difficult to explain in detail, since there are very few generalizations. One

feature, which is characteristic of heterogeneous catalysis in general and of hydrogenation in particular, is the participation of adsorbed molecules or atoms in an activated complex. The effective result of this is the reduction of the overall activation energy of the uncatalysed reaction. The reaction can be summarized in five important steps, namely :

(i) The transport of the reactant to the surface of the catalyst.
(ii) The adsorption on the surface of at least one of the reactants.

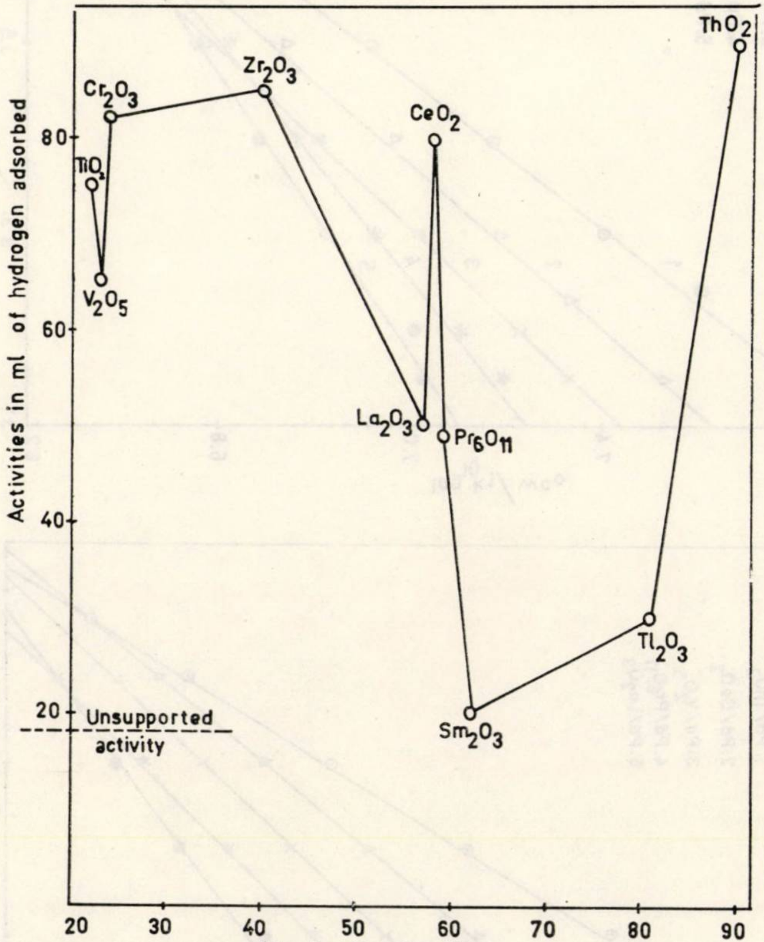

Fig. 6. — Activity/Atomic number isotherm of metallic oxides.

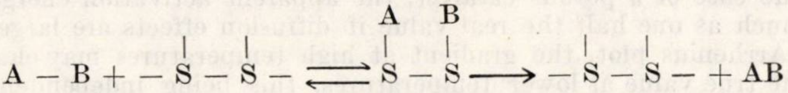
(iii) The reaction on the surface giving the product.
(iv) The desorption of the product.
(v) The transport of the products away from the surface.

The first and the last of these steps are in general fast reactions and only the remaining three are of main interest, except in the case of reactions involving highly porous catalysts such as kieselguhr or diatomaceous earth.

In hydrogenations two molecular species are involved in the reaction in that the second of the above steps will have either one or both reactants chemisorbed on the catalytic surface. These two possibilities will lead to two different reaction mechanisms, namely :

(i)



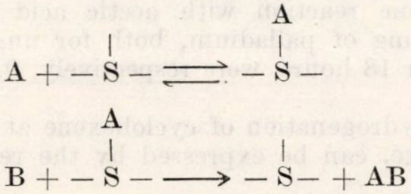
$$A - B + -\overset{|}{S} - \overset{|}{S} - \rightleftharpoons \overset{A}{\overset{|}{S}} - \overset{B}{\overset{|}{S}} \longrightarrow -\overset{|}{S} - \overset{|}{S} - + AB$$

Let A and B represent the two molecules involved in the reaction and S represent the surface atoms. The rate of reaction in this mechanism will be dependent on the probability of A and B being adsorbed on neighbouring sites. If θ_A and θ_B are the fractions of surface covered by reactants A and B respectively, the following expression can be deduced from the Langmuir[10] adsorption isotherm :

$$\frac{Kp}{1 + Kp}$$

where K is the ratio of the rate of adsorption and desorption and p the pressure of the gas in equilibrium with the surface.

(ii)



$$A + -\overset{|}{S} - \rightleftharpoons -\overset{A}{\overset{|}{S}} -$$

$$B + -\overset{A}{\overset{|}{S}} - \longrightarrow -\overset{|}{S} - + AB$$

This mechanism involves an adsorbed reactant A and a non-adsorbed reactant B. The effect of adsorbed but non-reacting molecules of B should also be considered.

These kinetic mechanisms have been derived on the assumption that the adsorption is localized, that each adsorption site is occupied by only one atom or molecule and that the heat of adsorption is independent of the coverage.

The influence of temperature on the observed activity is a useful guide in the determination of the rate controlling step, since the activation energies of diffusion processes are generally much smaller than those of adsorption or reaction. The activation energy of the transfer of hydrogen into water has been calculated to be 2.7 kcal mole^{-1} on the basis of diffusion coefficients. Since activation energies as low as this were not obtained, the activities were of the first order with respect to the weight of the catalyst and were independent of the rate of shaking. The transfer of hydrogen across the gas liquid boundary, or of products from the catalyst surface, cannot control the overall reaction rates.

---

[10] I. Langmuir, *J. Amer. Chem. Soc.*, **38**, 2221 (1916) ; **40**, 1361 (1918).

The quantitative effect of diffusion in lowering the true activation energy of gas reaction on solids has been described by Weiss and Prater .[11] The same would apply in principle to the liquid phase catalytic reactions. In the case of a porous catalyst, the apparent activation energy can be as much as one half the real value if diffusion effects are large; and in the Arrhenius plot, the gradient at high temperatures may change over to the true value at lower temperatures, this being independent of the relative rates of the chemical and diffusion processes.

The standard time allowed for the saturation of the catalysts with hydrogen was 30 min, although preliminary experiments showed that the adsorption of hydrogen was virtually complete after only 15 min. The reduction of ferricyanide took longer. Titres obtained with reduced palladium, after 10,45 and 960 min were, respectively, 9.15, 10.55 and 10.53 mls of hydrogen per gram. A similar variation of the hydrogen titre with time was found for supported catalysts.

If a decrease in the amounts of catalyst did not alter the apparent activation energies, it can be assumed that diffusion effects did not control the activities. Quantitative transference of reduced palladium to the reaction vessel was found to be inaccurate with amounts less than 0.02 g, so the hydrogenation rate was substantially reduced by sintering. The activation energy did not change on sintering, as has been previously reported for the same reaction with acetic acid as the solvent. [8] The activities of 9.976 mg of palladium, both for unsintered and sintered at 300° and at 400° for 18 hours, were respectively, 9.6, 4.8 and 0.9 ml. per min at 30°.

The rate of hydrogenation of cyclohexene at unit pressure, i.e. the specific reaction rate, can be expressed by the relationship;

$$k_1 = wSk_s$$

Where w is the weight of palladium, S its specific surface area, and k_s the activity per unit area. The activity is related to a frequency factor A, and the apparent energy of activation, E_A, by the usual Arrhenius expression $k_s = A_{\text{exp}}(-E_A/RT)$. Although absolute values of S are not known, they can be assumed to be proportional to the reciprocals of the poisoning coefficients per gram of palladium. The appropriate values of $C_0/0.00625$ are given by Maxted. [7] The value of C_0 for reduced palladium used in this work is 7.2×10^{-5} mole g^{-1}. Plots of $\log (k_1/wc_0)$ against $1/T$ are given in figures 4 and 5 for different ratios of palladium on the supports containing the optimum ratio of platinum to support activity at maximum.

If k is the true velocity constant, K_H the adsorption coefficient of hydrogen in the Langmuir adsorption isotherm, and p_H the partial pressure of hydrogen, the reaction rate is given by $v = kK_H p_H$ and the true first order velocity constant $k_1 = k K_H$. It can readily be shown that, whenever the apparent first order constant is given by the product of an adsorption equilibrium constant and the true velocity constant, the apparent activation energy is lower than the true activation energy by the value of the heat of adsorption of hydrogen, irrespective of the reaction mechanism. The apparent activation energies should therefore be corrected by the addition of 16—18 kcal $mole^{-1}$ in order to obtain the true values.

---

[11] P. W. Weiss and C. D. Prater, *Adv. Catalysis*, **6**, 143 (1954).

Another factor which can affect the activation energy observed, for a series of related catalysts, is a compensation effect between the activation energy and the frequency factor. The absence of a strict logarithmic relation between E_A and A is apparent in figures 4 and 5, since a necessary condition for this is that the Arrhenius plots should intersect at a common point, i.e. a temperature exists at which all the reaction rates are equal. Nevertheless, it is evident that the relative activities at a given temperature also depend on the activation energy.

At room temperatures, promoter action of the supports become active, since the specific activities of the supported catalysts are greater than the corresponding activity of unsupported palladium. Owing to a compensation effect, the degree of this promoter action becomes smaller as the temperature decreases. At sufficiently low temperatures, the increase in the temperature independence factor for the supported catalysts becomes inadequate to overcome the effect of a larger activation energy, and promotion does not occur. For supported palladium catalysts, these temperatures lie in the experimental region from 3° to 15°.

The temperature coefficient of hydrogenation processes is also of considerable importance. By virtue of the dependence of the reaction velocity on the adsorbed concentration, a decrease in the hydrogenation velocity as the temperature is increased, may occur at high temperatures. A change in the kinetic form with increasing temperature has been observed in liquid-phase hydrogenation by Maxted and Moon. [8] For this reason, the hydrogenation temperature was kept as low as possible, an optimum value being found to be at 30°.

ELECTRONIC STRUCTURE OF CYCLOBUTADIENE FUSED WITH HETEROCYCLIC RING. I. HETEROBENZOCYCLOBUTADIENES

M. D. GHEORGHIU and P. FILIP

Institute of Organic Chemistry, Spl. Independenţei 202–B, Bucharest 15, Romania

Received August 3, 1973

The electronic structure of nine unknown heterobenzocyclobutadiene (HBCB) is discussed in comparison with benzocyclobutadiene (BCB). The investigated HBCB are, according to our findings, more reactive than BCB.

Cyclobutadiene is an elusive compound, [1] challenging a large number of experimental efforts. Partly, these efforts were directed towards the synthesis of more stable derivatives of cyclobutadiene classified as using (i) electronic, (ii) steric and (iii) stereoelectronic factors. While (ii) would leave the electronic π system of cyclobutadiene unchanged, (iii) and especially (i) could alter the π system substantially, making some examples hardly recognizable as cyclobutadienes.

Among the numerous reported works on cyclobutadiene and derivatives, few have succeeded to isolate stable compounds; to our best knowledge, nowadays there are known: push-pull cyclobutadienes (**1**) [2] e.g. electronic stabilized cyclobutadiene, having a symmetric structure with C–C average bond distances equal to 1.455 Å [3] and a second example as a sterically hindered cyclobutadiene (**2**). [4] Recently, the isolation of cyclobutadienes (substituted and unsubstituted in solid matrix) was reported. [5]

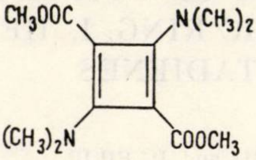
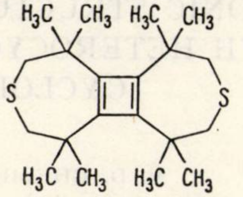
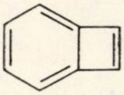
The interest in this field, from a theoretical point of view is focused on the electronic structure. As the system is very unstable, one must search models in which the π system becomes more stable. As we already mentioned above, one way to stabilize the π system of the cyclobutadiene is to add on the ring donor (s) and accepter (s) substituents in such a way, that they can exert their push-pull effects.[6] Another way would be to fuse aromatic ring[7] on one side of the cyclobutadiene leading to compounds such as BCB (**3**), naphto [b] cyclobutadiene (**4**), anthra [b] cyclobutadiene (**5**), phenanthro [l]cyclobutadiene (**6**), etc.



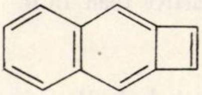
1



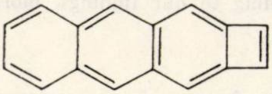
2



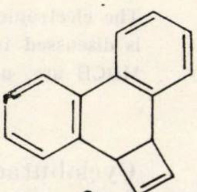
3



4



5



6

However, **4** and **5** were reported as transient reaction intermediates; the fusion of an aromatic ring seems to confer probably only a relative stability of the above mentioned systems with respect to the parent cyclobutadiene. Substituents such as Br— and C_6H_5— on the side of the double bond to the cyclobutadiene ring in **4**, were reported to confer stability to these compounds.[8]

We would like to confine our theoretical interest to the area of BCB and some heterobenzocyclobutadienes (HBCB), the latter being formally considered as obtained by fusing to the double bond of the cyclobutadiene either a six-membered heteroaromatic ring or a five-membered heteroaromatic ring.

The present paper deals only with the six-membered heteroaromatic cyclobutadienes while in a forthcoming paper we would like to present our results regarding the five-membered heteroaromatic cyclobutadienes.

No heterobenzocyclobutadiene (HBCB) was reported until now. Benzocyclobutadiene (BCB) is a highly reactive species, never isolated, but inferred from trapping experiments, especially with dienes.[9] One

[9] see reference la, chap. 6, 1b p. 231.

of the most important questions to be answered is whether HBCB systems are more or less stable than BCB.

METHODS OF COMPUTATION

The calculations were carried out within the framework of a standard ω-Hückel Molecular Orbital (HMO) method.[10,11] The diagonal matrix element H_{ii} is calculated according to the following expression:

$$H_{ii} = H^0_{ii} + \omega \times (N - Q_{ii}) \qquad (1)$$

where H^0_{ii} is the initial coulomb integral (see table 1); $\omega = 1.4$; N is the number of electrons contributing to the π-system, Q_{ii} is the computed atomic charge density.

The off-diagonal matrix elements, H^0_{ij} were not modified during the iterative step calculation. The heteroatoms were treated in the usual manner[12]:

$$\alpha_X = \alpha_C + k_X \cdot \beta_{C-C} \qquad (2)$$

$$\beta_{X-Y} = r_{X-Y} \cdot \beta_{C-C} \qquad (3)$$

Values chosen for k_X and r_{X-Y} are presented in table 1.

Table 1

Parameters of heteroatoms

Atom	k_X	Bond	X−Y
N	0.5	C−N	1.0
		N−N	1.0

To speed up the convergence, a procedure for averaging consecutive iterated values of charge densities was used[13], especially in the first stages of calculations (av-average, iter-represents an iterative index):

$$Q^{av}_{ii} = 0.5 \times (Q^{iter-1}_{ii} + Q^{iter}_{ii}) \qquad (4)$$

DISCUSSION OF THE RESULTS

Let us summarize briefly the main features of the cyclobutadiene π system. One can visualize this molecule as resulting from two ethylene units approaching each other in parallel planes :

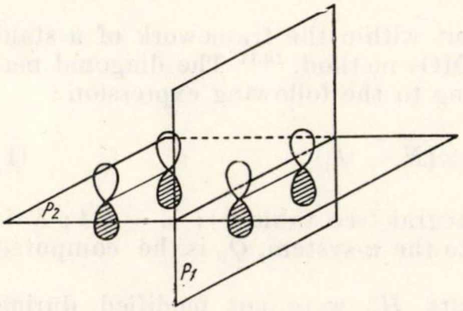

Fig. 1. — Definition of symmetry planes for two ethylenic units side-approach.

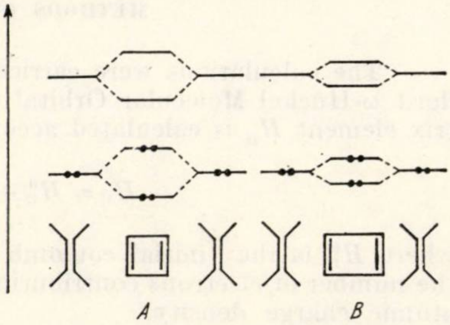

Fig. 2. — Perturbation diagram for two ethylene-side approach. (A) strong interaction, (B) weak interaction.

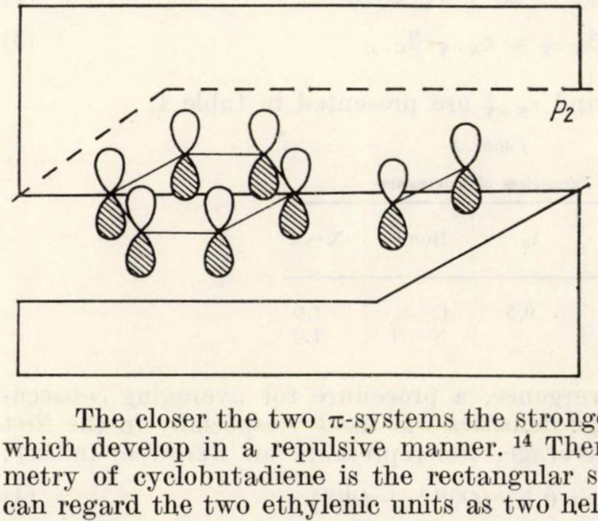

Fig. 3. — Definition of symmetry planes for the ethylene + + benzene system.

The closer the two π-systems the stronger their mutual interactions, which develop in a repulsive manner.[14] Therefore, the most stable geometry of cyclobutadiene is the rectangular structure. Alternatively, one can regard the two ethylenic units as two helium atoms, which approach each other without presenting any again in stabilization, on the contrary the system becomes less stable.[15] Indeed elaborate calculations predict for cyclobutadiene a rectangular structure which keeps the two double bonds further appart having single C—C bonds equal to 1.51 Å, and double bonds equal to 1.338 Å.[16]

---

[14] M. D. Gheorghiu and R. Hoffmann, *Rev. Roumaine Chim.*, **14**, 781 (1969).

[15] For an excelent discussion of the above arguments based upon interaction diagrams see : M. J. Goldstein and R. Hoffmann, *J. Amer. Chem. Soc.*, **93**, 6193 (1971).

[16] M. J. S. Dewar and G. J. Gleicher, *J. Amer. Chem. Soc.*, 87 (1965) ; M. J. S. Dewar, M. C. Kohn and N. Trinajstic, *ibid.*, **93**, 3437 (1971).

The BCB-π system could be conceived, in a similar manner, as resulting from the benzene π system perturbated by an ethylene unit. The approach is achieved so that the whole system preserves continuously the plane of symmetry P_1.

In respect to this plane the wave functions of benzene, ethylene and benzocyclobutadiene are either S (symmetric) or A (antisymmetric). The levels with like symmetry will interact. The consequences are that half of them become stabilized while the other half are destabilized. The interaction diagram of pertinent levels is depicted in fig. 4, where index B means benzene, while E is related to the ethylene unit.

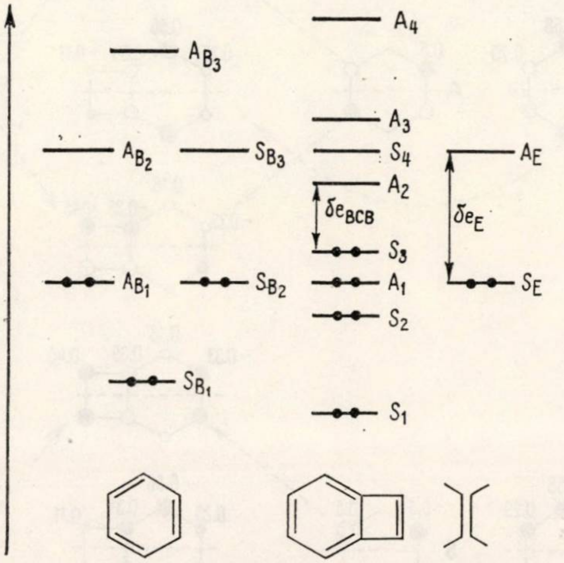

Fig. 4. — Energetic scheme for the benzene — ethylene interaction.

An inspection of wave function diagram (fig. 5) reveals for the highest occupied molecular orbital (HOMO), S_3, as being mainly a double bond located in the outer part of the four-membered ring of BCB, so is the next level, the lowest unoccupied molecular orbital (LUMO), A_2. Both levels are, therefore, in fact a very reactive double bond, not only due to their high energy content, but also to the very low value of the splitting. Thus, S_3 is higher than S_E with 0.5 β, while $\Delta e_{BDB} \simeq 0.5\ \Delta e_E$.

The very reactive nature of BCB is therefore the consequence of the fact that it has a destabilized double bond in respect to an isolated ethylene system. The available experimental[17] and theoretical[18] data support these conclusions.

Continuing our examination beyond the topmost occupied orbitals, one should note the position of S_1 level as being lower than the S_{BI} level

Fig. 5. — Molecular π-wave functions of benzene (left), benzocyclobutadiene (middle) and ethylene (right).

of benzene, as a result of secondary interactions, especially with the S_2 level of BCB, which is pushed upwards.

Next, we turn our attention on the molecular wave functions corresponding to the energetic scheme of BCB presented in fig. 5. Here the figures represent the coefficients of the atomic orbitals belonging to the atom above which they are written. The shaded circles represent an atomic orbital participating with a minus sign in the wave function. The horizontal dotted line corresponds to the plane of symmetry according to which the molecular wave functions are classified.

Since benzocyclobutadinee is a highly reactive olefin, one can ask whether a bicyclo [4.2.0] octatetraene system can be stabilized in some way. Therefore, we decided to examine derivatives of BCB in which the benzene ring is replaced by a heteroaromatic ring such as pyridine, 1,2-diazine, 1,2,3-triazine, 1,2,4-triazine and 1,2,3,4-tetrazine. Unfortunately, none of these compounds are known, to our knowledge there were never mentioned any synthetic or trapping attempts. We would like to provide, however, some prognosis concerning their reactivity relatively to that of BCB. Two criteria are used to indicate the stability.

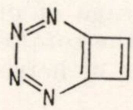
12



15

(1) There are many reasons to believe that both HOMO and LUMO play a crucial role in determining the chemical stability of a molecule. [19] The energy gap δe between HOMO and LUMO is related to the chemical reactivity. Examining the energy of all HBCB's, it is interesting to note that they are more destabilized relatively to BCB.

Table 2

Significant energetic figures of HBCB (in beta units)

Compound	Total energy of HBCB E_{HBCB}	Total energy of the Aromatic + ethylene (2β) E	$\Delta = E_{HBCB} - E$	Energy of HMO	$\delta e = E_{HOMO} - E_{LUMO}$

---

[19] K. Fukui, *Accounts Chem. Res.*, **4**, 57, (1971).

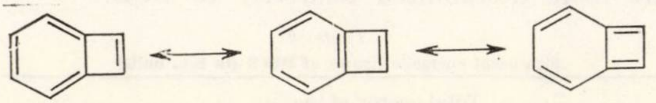
Additionaly, we note also that δe, the splitting of HOMO-LUMO, is approximately half of the corresponding value of BCB. We mentioned above that the high reactivity of BCB is related to the low value of its δe; but now we figure that our HBCB models have even lower values, which are situated approximatively at $0.5\,\delta e_{BCB}$, in other words one fourth from the δe value of an isolated olefine bond. Based on this result, we tentatively consider that the HBCB's studied will display an even higher reactivity than BCB, due to the presence in the four-membered ring of a very reactive double bond.

(2) Our second criterium of stability relies on the energetic scheme related to the perturbation diagram discussed for cyclobutadiene and BCB. If there is any interaction developing between the cyclobutadiene unshared double bond and the aromatic system, it should be reflected in the energy gain or loss calculated as energy difference between the HBCB and the sum total energy of the heteroatomic nucleus (E_{HAr}) plus an isolated double bond (2β). This difference is presented as Δ in table 2. As expected, Δ values are relatively small, less than $0.5\ \beta$, indicating a slight interaction between the heteroaromatic ring and the double bond. Again, our models present a Δ_{HBCB} smaller than Δ_{BCB}. Thus Δ parallels the δ values, leading to conclusions that both indexes suggest a relative instability of HBCB compared to an already unstable BCB.

At this stage of discussion we draw attention that the accidental coincidence of the total energy of those HBCB's which differ only by the relative position of heteroatom (s), is an artifact of our method of computation.

BOND ORDER DIAGRAMS

BCB is a hybrid of three neutral resonating structures **3A**, **3B** and **3C**:



3A **3B** **3C**

while structure **3C** could be neglected, since it is in fact an orthoquinodimethane, the remaining structures **3A** and **3B**, which should have a significant contribution to the structure of BCB, posses antagonistic features. In **3A**, the cyclobutadiene system is "avoided", the system consisting of a dimethylenecyclobutene; this is an example of what we called in the introduction of this paper as a hardly recognizable cyclobutadiene. Structure **3B** contains a cyclobutadiene unit. Double bond diagram shows for BCB a preference for structure **3A**, in which the cyclobutadiene structure does not in fact exist. Moreover this is true also for all our HBCB models. In table 3 the bond orders for the pertinent bonds are presented.

The original bond order of the same bond is also presented for comparison. As a general feature, it has a lower value in the HBCB than in

Table 3

Bond order diagram*)

Compound	1–2	2–3	3–4	Same bond in the isolated aromatic compounds	3–5	1–4	4–6
3	0.949	0.151	0.544	0.667	0.75	0.151	0.75

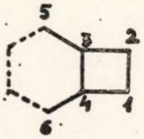
14	0.889	0.226	0.541	0.658	0.730	0.223	0.729
15	0.887	0.226	0.541	0.655	0.722	0.226	0.722

*) The numbering scheme for the entries of the first column of table 3 results from the superposition of the corresponding formula on the skeleton



parent aromatic systems, since in the former an electronic density shift occurs, favoured by a **3A** type resonance structure.

CONCLUDING REMARKS

Our analysis suggests that a heteroaromatic system does not improve the stability of HBCB's derived from it. They are destabilized in respect of the already very reactive BCB.

This work was inspired from the experimental chemistry started and directed in our laboratory by the late Prof. C. D. Nenitzescu in collaboration with Prof. M. Avram.

A generous allotment of computer time made available by Computer Center of the Polytechnic Institute is gratefully acknowledged.

RECHERCHES DANS LA SÉRIE DES TRICYCLO [7.3.1.$0^{2,7}$] TRIDÉCANES. III*

HYDRAZONES DE LA 2-HYDROXY-8-R-TRICYCLO[7.3.1.$0^{2,7}$]TRIDÉCAN-ONE-13

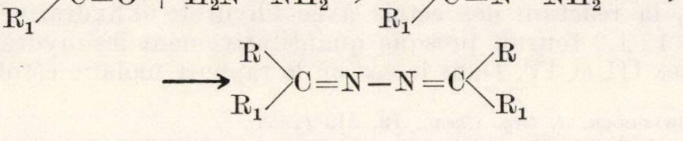
N. BĂRBULESCU et ANCA NICOLAE
Université de Bucarest, Faculté de Chimie, Splaiul Independenţei

Reçu 18 juillet 1973

Dans le présent mémoire on a étudié la réaction de l'hydrazine avec des dérivés de 2-hydroxy-8-R-tricyclo[7.3.1.0 ^{2,7}]tridécan-one-13 où R=H et CH_3. Suivant les conditions, la réaction fournit les hydrazones ou les azines symétriques respectives. On a établi que le cours de la réaction est déterminé par le rapport molaire cétol : hydrate d'hydrazine et aussi par la présence des quantités catalytiques d'acide. Les hydrazones ont été caractérisées par voie chimique (formation de dérivés acétylés). Les hydrazones et les azines obtenues ont été également analysées par des méthodes physico-chimiques.

Dans le présent mémoire on a abordé l'étude de la réaction de l'hydrazine avec la 2-hydroxy-8-R-tricyclo [7.3.1.$0^{2,7}$]tridécan-one-13 où R=H et CH_3. Suivant les conditions de réaction on a obtenu les hydrazones ou les azines correspondantes.

Vu les réactions secondaires qui l'accompagne, la synthèse des hydrazones non substituées à l'atome d'azote est généralement assez difficile. Les hydrazones obtenues lors de la réaction de condensation des composés carbonyliques avec l'hydrazine peuvent réagir par la suite avec le composé carbonylique en obtenant les azines symétriques respectives [1-5]



$$\overset{R}{\underset{R_1}{>}}C=O + H_2N-NH_2 \rightarrow \overset{R}{\underset{R_1}{>}}C=N-NH_2 \xrightarrow{\overset{R}{\underset{R_1}{>}}C=O} \overset{R}{\underset{R_1}{>}}C=N-N=C\overset{R}{\underset{R_1}{<}}$$

La formation des azines avec les aldehydes est plus facile qu'avec les cétones. La tendance de formation des azines diminue dans l'ordre suivant :

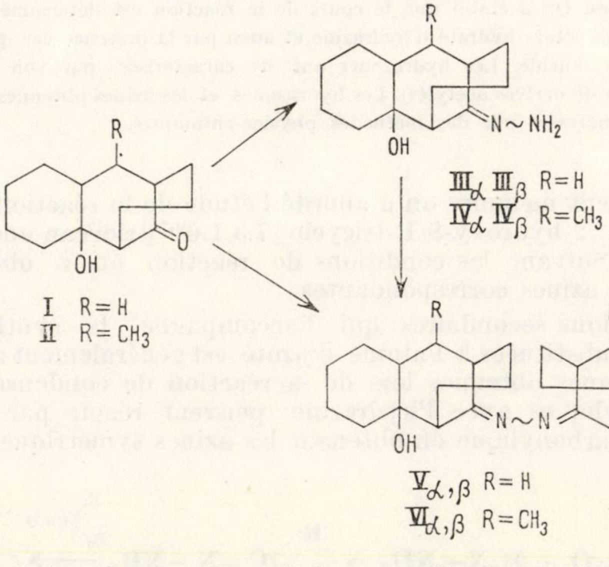
aldehyde > dialkylcétone > alkylarylcétone > diarylcétone.

L'emploi de l'hydrazine en excès permet d'éviter la formation des azines. Parfois sont utilisés des agents de condensation tels la triéthylamine, l'oxyde de baryum ou l'hydroxyde de sodium. [6,7]

D'autres produits secondaires formés lors de la synthèse des hydrazones non substituées proviennent des réactions de cyclisation, d'élimination, etc.. [8-11]

La séparation de l'hydrazone n'a plus lieu dans le cas de certains composés carbonyliques. [12,13]

En fonction du rapport molaire cétol : hydrazine, les cétols de la série de 2-hydroxy-8-R-tricyclo[$7.3.1.0^{2,7}$]tridécan-one-13 (I $R=H$; II $R=CH_3$) fournissent des paires d'hydrazone (III_α, III_β $R = H$; IV_α, IV_β $R=CH_3$) ou bien les azines correspondantes (V_α, V_β $R=H$; VI_α, VI_β $R=CH_3$) conformément au schéma 1 :



Ainsi, la réaction des cétols avec l'hydrate d'hydrazine de 100% en rapport 1 : 1,2 fournit presque quantitativement les hydrazones correspondantes III et IV. Dans le cas où le rapport molaire cétol : hydrate

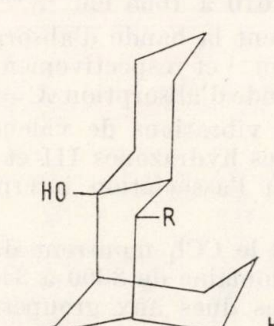
d'hydrazine est 2 : 1 en présence de quantités catalytiques d'acide acétique la réaction conduit à la formation des azines symétriques correspondantes V et VI. On admet [3] que la présence de l'acide chlorhydrique ou de l'acide acétique favorise la formation de l'azine. En effet, si l'on conduit la réaction dans le même rapport molaire, mais en l'absence de l'acide acétique, les rendements en azine symétrique V ou VI sont très faibles. Les azines symétriques des cétols mentionnés peuvent être obtenues également à partir des hydrazones correspondantes en présence d'acide. Dans le tableau 1 sont présentées les hydrazones III, IV et les azines V et VI.

Tableau 1

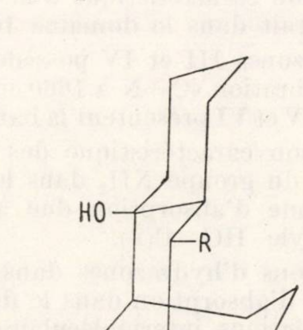
Les constantes caractéristiques des hydrazones et des azines

Cétol	Hydrazone III, IV				Azine V, VI		
	η%	p.f^o·brut	Solvant	p.f^o·isomère	η%	Solvant	p.f^o·isomère
I	99	95–98	$CHCl_3$-éther de pétrole	77–81 90–92	96	MeOH	133–134 174–176
II	99	105–107	Et_2O	63–65 109–110	91	MeOH	112–113 173–174

Étant donné l'asymétrie de ces systèmes et l'existence de la liaison C=N–, les hydrazones III et IV peuvent présenter deux isomères notés conventionnellement par α et β et qui peuvent avoir les configurations suivantes :



III$_\alpha$ R=H
IV$_\alpha$ R=CH$_3$



III$_\beta$ R=H
IV$_\beta$ R=CH$_3$

Dans les deux configurations on n'observe pas de liaison hydrogène intramoléculaire, car la distance des atomes qui pourraient être impliqués est trop grande. La séparation des hydrazones et aussi des azines isomères est difficile due à la facilité de transformation d'un isomère dans l'autre.

La séparation complète des hydrazones isomères III et IV par cristallisation fractionnée n'a pas été possible ; on a réussi seulement à obtenir une fraction enrichie d'un des isomères.

L'instabilité des hydrazones III et IV et leur tendance de transformation en azine pendant les opérations de recristallisation rendent encore plus difficile la séparation des isomères.

La présence de l'azine a été vérifiée par chromatographie sur couche mince. L'hydrazone de départ ne présente pas le spot caractéristique pour l'azine ; cependant il apparaît après la recristallisation. Par la suite on a essayé la séparation des isomères de l'azine. Ainsi, l'azine V par cristallisation fractionnée dans le méthanol fournit deux isomères de p.f. 133 – 134° et respectivement p.f. 174–176°. La plupart de l'azine V fournit par cristallisation fractionnée un produit de p.f. 152 – 153°.

Par cristallisation fractionnée dans le méthanol l'azine VI conduit à deux isomères de p.f. 173–174° et respectivement p.f. 112–113°.

Les isomères de bas point de fusion sont instables en se convertissant en isomères de haut point de fusion.

Dans les spectres I.R. des hydrazones et des azines de 2-hydroxy-8-R-tricyclo$[7.3.1.0^{2,7}]$tridécane-one-13 on peut observer l'apparition des vibrations caractéristiques du groupement hydrazone, respectivement azine. Ainsi, les spectres des hydrazones présentent la vibration $\nu C{=}N$ dans le domaine 1570 à 1650 cm^{-1} [14,15] et les vibrations symétrique et asymétrique du groupe NH_2 dans le domaine 3200 à 3400 cm^{-1}. [15–19]

L'absorption caractéristique à la vibration de valence $\nu C{=}N$ dans les azines apparaît dans le domaine 1610 à 1665 cm^{-1}. [15,20,21]

Les hydrazones III et IV possèdent la bande d'absorption caractéristique de la vibration $\nu C{=}N$ à 1660 cm^{-1} et respectivement à 1665 cm^{-1}. Les deux azines V et VI présentent la bande d'absorption $\nu C{=}N$ à 1655 cm^{-1}.

L'absorption caractéristique des vibrations de valence symétrique et asymétrique du groupe NH_2 dans les hydrazones III et IV est superposée à la bande d'absorption due à l'association intermoléculaire du groupe hydroxyle HO–C(2).

Les solutions d'hydrazones dans le CCl_4 montrent dans le spectre I.R. une bande d'absorption dans le domaine de 3300 à 3400 cm^{-1} attribuée aux associations intermoléculaires dues aux groupes NH_2 et OH. Dans les spectres I.R. des solutions diluées ($< 10^{-1}$M) des hydrazones dans le CCl_4 apparaissent les bandes caractéristiques aux vibrations

ν NH_2 non associées à 3350 à 3400 cm^{-1} et ν OH non associé à 3600 à 3610 cm^{-1}.

La présence de l'hydrazone a été mise en évidence également par l'étude des spectres de R.M.N.

Ainsi, les spectres R.M.N. des hydrazones en solution dans le DMSO-d_6 montrent le signal des protons du groupe $=N-NH_2$ dans le domaine $\delta = 5{,}3-5{,}4$ ppm.

Les données de la littérature indiquent pour ces protons le domaine $\delta = 4{,}3-5{,}8$ ppm [18,22].

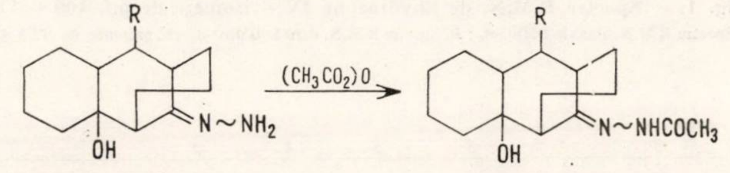
En solution dans le DMSO-d_6 en présence de T.F.A.-d_1, la résonance des protons du groupe $=N-NH_2$ est déplacée à $\delta = 6{,}2$ à 7,1 ppm (voir fig. 1) en accord avec la mobilité des deux protons.

La comparaison des spectres R.M.N. des hydrazones en solution dans le DMSO-d_6 et dans le DMSO-d_3 + T.F.A-d_1 permet de constater le déplacement de la résonance du proton HO—C(2).

Ainsi, son signal apparaît à $\delta = 3{,}6-3{,}64$ ppm en solution dans le DMSO-d_6 et se déplace à $\delta = 6{,}1-7{,}1$ ppm en solution dans le DMSO-d_6 + T.F.A-d_1 (voir fig. 1).

Les spectres R.M.N. des azines ne présentent plus le signal caractéristique des protons $=N-NH_2$ (voir fig. 2).

Les hydrazones III et IV ont été caractérisées également par leurs dérivés acétylés VII et VIII :



III_β R=H
IV_β $R=CH_3$

VII_β R=H
VIII_β $R=CH_3$

Après l'acétylation, les isomères III_β et IV_β fournissent les dérivés monoacétylés VII_β et VIII_β dont les caractéristiques sont présentées dans le tableau 2.

Tableau 2

Les constantes caractéristiques des dérivés acétylés

Hydrazone	Dérivé acétylé					
	M	p.f.°	ν $NHCOCH_3$ cm^{-1}			
III	264	213—214	1558	1680	3065	3250
IV	278	203—204,5	1562	1670	3058	3230

[22] B. A. Arbuzov, Yu. Yu. Samitov et P. Yu. Kitaev, *Izvest. Akad. Nauk S.S.S.R., Otdel. khim. Nauk.*, 1, 55 (1966).

Comparés aux spectres I.R. des hydrazones les spectres I.R. des dérivés acétylés montrent l'apparition de quelques bandes supplémentaires dues aux vibrations du groupement $NHCOCH_3$. Leurs valeurs sont présentées dans le tableau 2.

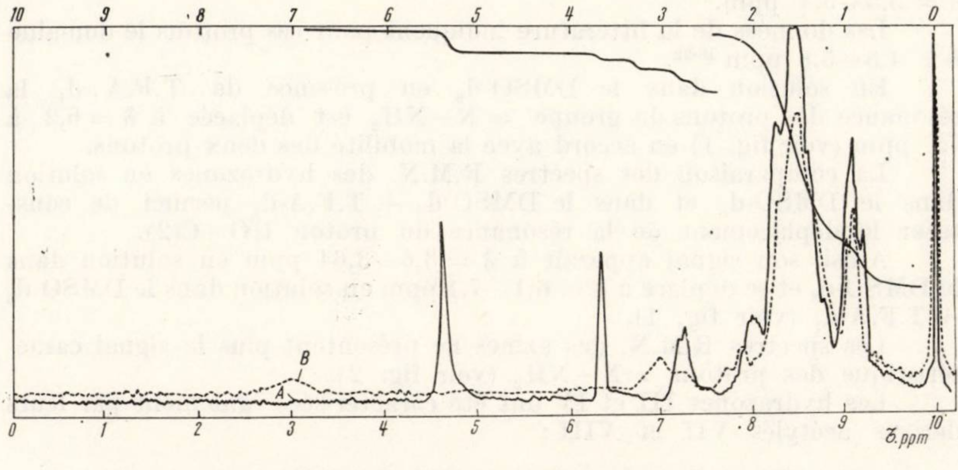

Fig. 1. — Spectre R.M.N. de l'hydrazone IV — isomère de p.f. 109 — 110°.
A, Spectre R.M.N. dans le DMSO-d_6 ; *B*, Spectre R.M.N. dans le DMSO-d_6 en présence de TFA-d_1

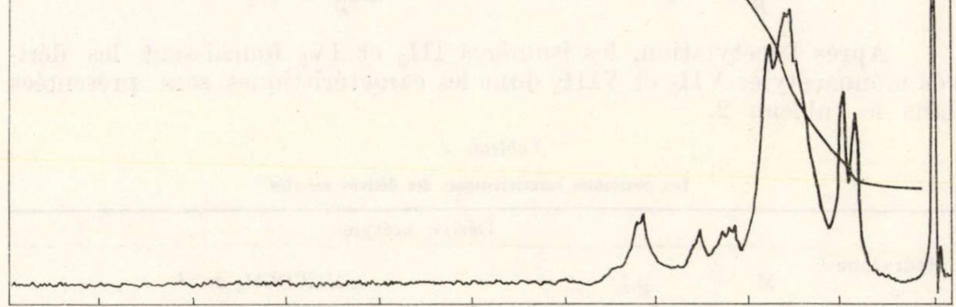

Fig. 2. — Spectre R.M.N. de l'azine VI dans le $CDCl_3$.

La réaction d'acétylation des hydrazones présente un intérêt particulier car elle permet la séparation de l'hydrazone à partir d'un mélange hydrazone-azine.

PARTIE EXPÉRIMENTAL

Les spectres I.R. ont été enregistrés avec un appareil U.R.—20 en utilisant la méthode en pastille de KBr ou les solutions dans le CCl_4.

Les spectres de R.M.N. ont été enregistrés avec un appareil Perkin-Elmer R—12 à 60 MHz avec le tétraméthylsilane comme étalon interne.

SYNTHÈSE DES HYDRAZONES III ET IV

Une solution de 0,022 moles de cétol (I ou II) dans 8 ml d'éthanol est traitée graduellement à une solution de 0,025 moles d'hydrate d'hydrazine de 100% dans 12 ml d'éthanol. Le mélange réactionnel est porté à l'ébullition au reflux pendant une heure et ensuite le solvant est distillé sous vide. On reprend le résidu par de l'éther de pétrole et après 24h de séjour à la température ambiante l'hydrazone cristallisée est filtrée.

On obtient avec un rendement de 99% des cristaux d'hydrazone III de p.f. 90—94°. Le produit est purifié par dissolution dans du chloroforme à froid et précipitation avec de l'éther de pétrole, en obtenant les hydrazones de p.f. 77—81°, et respectivement p.f. 90—92°.

$C_{13}H_{22}ON_2$ p.f. 77—81° *Calculé* N = 12,61% *Trouvé* N = 12,33%

$C_{13}H_{22}ON_2$ p.f. 90—92° *Calculé* N = 12,61% *Trouvé* N = 12,40%

L'hydrazone IV a été obtenue selon la méthode décrite plus haut. Le produit brut (Rd. 99%) de p.f. 105—107° fournit par cristallisation fractionnée dans l'éther les deux hydrazones de p.f. 63—65° et respectivement p.f. 109—110°.

$C_{14}H_{24}ON_2$ p.f. 63—65° *Calculé* N = 11,86% *Trouvé* N = 11,94%

$C_{14}H_{24}ON_2$ p.f. 109—110° *Calculé* N = 11,86% *Trouvé* N = 11,98%

SYNTHÈSE DES AZINES V ET VI

0,022 moles de cétol (I ou II) dans 8 ml d'éthanol sont traités par une solution de 0,011 moles d'hydrate d'hydrazine de 100% dans 20 ml d'éthanol. On introduit ensuite 1—2 gouttes d'acide acétique et le mélange réactionnel est porté à l'ébullition au reflux pendant 2h. Après l'élimination du solvant sous vide le résidu est repris à l'éther de pétrole. Les cristaux formés au bout de quelques heures sont filtrés. Dans le cas de l'azine V on a obtenu un produit brut de p.f. 124—128° (Rd. 96%). Par cristallisation fractionnée dans le méthanol on a réussi la séparation des deux isomères de p.f. 133—134° et respectivement p.f. 174—176°, mais en petites quantités. La plupart de l'azine est retrouvée sous forme d'un produit de p.f. 152—153°.

$C_{26}H_{40}O_2N_2$ p.f. 133—134° *Calculé* N = 6,79% *Trouvé* N = 7,17%

$C_{26}H_{40}O_2N_2$ p.f. 174—176° *Calculé* N = 6,79% *Trouvé* N = 7,10%

L'azine VI a été obtenue selon la même méthode (Rd. 91%). Par cristallisation fractionnée dans le méthanol il en résulte deux isomères de p.f. 112 — 113° et respectivement p.f. 173 — 174°.

$C_{28}H_{44}O_2N_2$ p.f. 112—113°; *Calculé* N = 6,36% *Trouvé* N = 6,59%

$C_{28}H_{44}O_2N_2$ p.f. 173—174°; *Calculé* N = 6,36% *Trouvé* N = 6,63%

SYNTHÈSE DES DÉRIVÉS ACÉTYLÉS VII ET VIII

Une solution de 0,009 moles d'hydrazone (III ou IV) dans 15 ml d'éthanol à chaud est traitée par 0,01 moles d'anhydride acétique. Le mélange réactionnel est chauffé à 80° pendant 15 mn et ensuite laissé pendant une heure à la température ambiante. Les cristaux du dérivé acétylé sont filtrés et lavés à l'eau. La synthèse donne des rendements quantitatifs dans le cas des deux hydrazones. L'hydrazone III donne un dérivé acétylé brut de p.f. 198—204° dont la recristallisation dans l'éthanol fournit des cristaux de p.f. 213—214°

$C_{15}H_{24}O_2N_2$ *Calculé* N = 10,60 % *Trouvé* N = 10,84 %

Le dérivé acétylé VIII brut de p.f. 198 à 199°, par recristallisation dans l'éthanol, fournit des cristaux de p.f. 203—204°.

$C_{16}H_{26}O_2N_2$ *Calculé* N = 10,07 % *Trouvé* N = 10,30 %

ON THE CONFORMATIONAL MOBILITY OF BICYCLO[3.3.1]NONANE-2-ONES AND BICYCLO[3.2.1]OCTANE-2-ONES

M. MORARU* and G. M. BENEDIKT**

*Department of Organic Chemistry of University, Splaiul Independenţei 89, Bucharest, Romania

**Institute of Organic Chemistry, Splaiul Independenţei 202B, Bucharest, Romania

Received June 15, 1973

The NMR study of the title ketones substituted with phenyl groups, using $Eu(DPM)_3$* as paramagnetic shift reagent is reported. Marked differences between the conformational mobilities of the two skeletons are revealed.**

Studies concerning the conformation of byciclo[3.3.1] nonanes have dealt either with qualitative correlations between conformation and spectral properties, [1] or with the evaluation of the position of equilibrium between chair-chair and chair-boat forms of substituted derivatives. [2,3] Much less attention has been given to bicyclo[3.2.1] octanes, except some considerations related to the reflex effect. [4] Presently, no comparison between the conformational mobilities of these systems is available, although recent "force field" calculations seem to indicate marked differences. [4,5] Thus, in agreement with the experimental values, the potential energy difference between chair-chair and chair-boat forms of bicyclo [3.3.1] nonane is 3.5–3.7 kcal/mole, much less than the calculated chair-boat difference of 5.8–6.2 kcal/mole for bicyclo [3.2.1] octane.

*** Europium(III)-tris(dipivaloylmethanato)

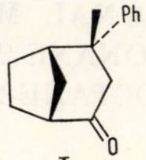
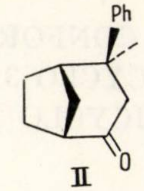
[5] E. N. Marvell, G. J. Gleicher, D. Sturmer and K. Salisbury, *J. Org. Chem.*, **33**, 3393 (1968).

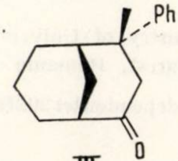
In the present paper we wish to report an experimental evidence supporting the above considerations, the NMR study of bicyclic ketones I—IV.



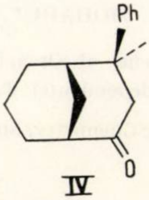
I



II



III



IV

The synthesis of these ketones is described in literature [6,7] and their configuration at C_4 is undoubtedly.

EXPERIMENTAL

The NMR study consisted in the gradual addition of weighed amounts of freshly sublimed $Eu(DPM)_3$ complex in the NMR tube containing a weighed amount (40—60 mg) of ketone, in CCl_4, each time waiting till the complex solved or helping it by gentle warming the tube in a water bath, and recording the spectrum (on a 60 Mc. VARIAN A 60-A NMR Spectrometer).

At the molar ratio (r_m), shift reagent per substrate, of 0.6 the main coupling constants and chemical shifts became readable.

RESULTS AND DISCUSSION

The vicinal coupling constants for compounds I and II show the normal trend for an essentially chair conformation of the six-membered ring (see table 1).

On the other side, $J_{3\alpha,4}$ and $J_{3\beta,4}$ for compounds III and IV are not consistent with a double chair conformation.

In the case of compound IV with an exo-phenyl group, the vicinal coupling constants are abnormally high for a chair conformation and they could be explained only by assuming a boat conformation or an equilibrium in which the boat is preferred. The epimeric ketone III exhibits vicinal coupling constants whose magnitudes do not correspond to axial-axial and axial-equatorial normal couplings. In this case it must be assumed either a distorted chair, in which the C_3 and C_7 atoms are spread apart more than in the parent hydrocarbon, or a conformational equilibrium in which the double chair form predominates.

---

[6] N. Bărbulescu and M. Moraru, *Rev. Chim. (Bucharest)*, **43**, 447 (1972).

[7] W. Dressler and K. Bodendorf, *Liebigs Ann. Chem.*, **720**, 71 (1968).

Table 1

Coupling constants: a) estimated from the normal spectrum, b) from the Eu(DPM)$_3$ shifted spectrum (at r_m = 0.6) (Hz.)

	$J_{3\alpha 4}$		$J_{3\beta,4}$		$J_{3\alpha,3\beta}$		$J_{4,5}$	
	a	b	a	b	a	b	a	b
I	11.7	12.4	6.6	6.0	15.2	16.0	2.4	—
II	6.0	8.8	3.4	1.3	16.0	16.8	—	4
III	10.3	—	9.1	—	16.8	—	3.3	—
IV	6.8	6.9	9.0	8.8	16.0	16.1	9.5	—

Further data on the conformation are given by the study of Eu (DPM)$_3$ induced shifts. The dependence of pseudocontact shifts with the lanthanide-proton distance and the proton-lanthanide-complexating heteroatom angle is well established, but any attempt to calculate molecular geometries from experimental data fails without a precise positioning of the lanthanide. [8] Attempts to optimize this position in some particular cases, using computer programs, have been made. [9] The above mentioned difficulty can be avoided by comparing the relative induced shifts of a given proton in structurally similar compounds such as I—IV.

The plots of δ (induced shift, in ppm) *versus* r_m were linear in the range of r_m 0—0.6 for all the compounds, that meaning that the conformation is not changed by complexation [10,11] (there is in fact a little change of the coupling constants as shown in table 1). The slopes of these plots (table 2) show some interesting points :

Table 2

Slopes $\Delta\delta/r_m$ in ppm

	I	II	III	IV	V
H_1	14.7	14.5	14.4	14.3	14.9
$H_{3\alpha}$	12.4	12.8	12.5	13.4	12.2
$H_{3\beta}$	13.1	14.7	12.5	12.2	—
H_4	6.0	4.6	5.3	5.5	—
H_0	2.1	5.9	2.7	2.7	6.6
$H_{m,p}$	0.7	0.7	0.5	0.8	0.4

a) All the compounds exhibit comparable values for the protons α as to carbonyl.

b) The slopes of *ortho*-aromatic protons in compounds I and II are in agreement with a chair conformation in both compounds, showing a marked difference between the axial and equatorial phenyl group.

---

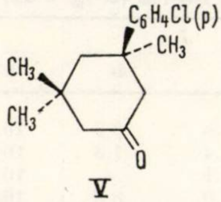
[8] C. C. Hinckley, *J. Amer. Chem. Soc.*, **91**, 5160 (1969); J. K. Sanders and D. H Williams, *Chem. Comm.*, **1970**, 422; R. Von Ammon and D. Fischer *Angew. Chem.*, **84**, 737 (1972).

[9] F. A. Hart, J. Briggs, G. H. Frost, G. P. Moss, M. L. Staniforth, *Chem. Comm.*, **1970**, 1506; S. Farid, A. Ateya and M. Maggio, *Chem. Comm.*, **1971**, 1285; M. R. Willcot III, R. E. Lenkinski and R. E. Davis, *J. Amer. Chem. Soc.*, **94**, 1742 (1972).

[10] I. Fleming, S. W. Hanson and J. K. M. Sanders, *Tetrahedron Letters*, **1971**, 3733.

[11] M. R. Vegar and R. J. Wells, *Tetrahedron Letters*, **1971**, 2847.

Moreover, the values for II compare well with those reported for ketone V,[12] with an axial phenyl group.



V

c) The compounds III and IV have identical slopes for ortho-aromatic protons, comparable with that of compound I and very different of that of compound II. This is in agreement only with a boat conformation of the substituted six-membered ring of compound IV, the keto and the phenyl group having a similar relative position as in compounds I and III.

d) The slopes for H_4 protons also indicate that the substituted ring adopts a chair conformation in compounds I, II, III and a boat conformation in compound IV, but the differences are not so marked as shown above.

All the above considerations lead to the following conformations of compounds I–IV (denoted by I'–IV'):

Concluding, all the data presented above suggest that the bicyclo [3.2.1] octane-2-one skeleton remains unaffected by bulky substituents (such as phenyl group) having a chair conformation of the six-membered ring, while the same substituents change dramatically the chair-boat equilibrium of the corresponding six-membered ring of bicyclo [3.3.1] nonane-2-one (some of its derivatives preferring a boat conformation). One can consider that the latter system has a greater conformational mobility than the former.

TRIS-ÉTHERS. II[1]

CONDENSATION DU BIS(CHLOROMÉTHYL)ÉTHER AVEC DES CYCLOHEXYLPHÉNOXYDES, MÉTHYLCYCLOHEXYLPHÉNOXYDES ET CHLOROCYCLOHEXYLPHÉNOXYDES DE SODIUM

M. IOVU, G. CÎMPEANU et N. MICLOVICI

Faculté de Chimie, Université de Bucarest
89, Splaiul Independenţei, Bucarest

Reçu le 7 decembre 1972

Dans un article précédent on a montré la possibilité de condensation du bis(chlorométhyl) éther avec les phénoxydes alcalins anhydres dans les conditions dans lesquelles on a obtenu antérieurement une série de biséthers par la condensation des dérivés dichlorométhylés aromatiques avec des phénoxydes alcalins. La condensation du bis(chlorométhyl)éther avec du phénoxyde, des crésoxydes et xylénoxydes de sodium ayant lieu aisément en milieu anhydre d'alcool et benzène, on a passé à la condensation de certains cyclohexylphénoxydes des sodium avec du bis(chlorométhyl)éther. Il en résulte, travaillant dans les mêmes conditions, des tris-éthers dont la formule générale est $Ar-O-CH_2-O-CH_2-O-Ar$ où le noyau Ar est substitué par un radical cyclohexyle et en certains cas aussi par un radical méthyle ou chlore.

La méthode qui permet d'obtenir les phénoxydes alcalins anhydres par distillation azéotropique de l'eau résultée de la réaction des phénols avec les hydroxydes alcalins, utilisée pour obtenir des phénoxydes alcalins nécessaires à la condensation avec des dérivés dichlorométhylés aromatiques [2-5] a servi aussi à l'obtention de tris-éthers par la condensation des phénoxydes alcalins avec le bis(chlorométhyl)éther. [1]

Comme nous venons de démontrer dans un article antérieur [1] les phénoxydes alcalins anhydres résultent par la réaction du phénol avec les hydroxydes alcalins en milieu d'alcool et de benzène (proportion 1 : 1

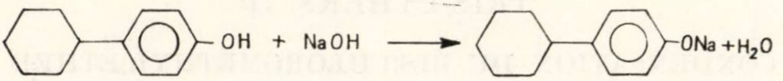
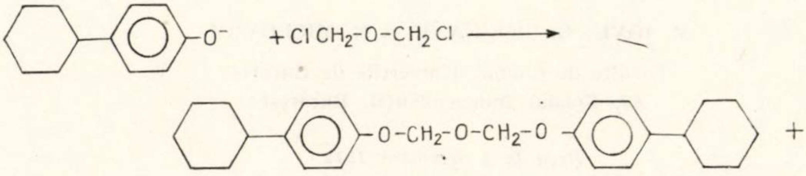
en volumes) et l'élimination de l'eau par distillation azéotropique d'un mélange eau-alcool-benzène. Par exemple :



Au phénoxyde de sodium se trouvant dans le mélange benzène-alcool pas encore distillé, on ajoute du bis(chlorométhyl)éther



Le tris-éther et le chlorure de sodium qui en résultent précipitent. Le précipité est séparé du solvant, qui contient aussi de petites quantités de matières premières et de produits intermédiaires, par filtrage sous vide.

Le chlorure de sodium est éliminé du mélange de précipités par lavage à l'eau sur un filtre. Le tris-éther resté sur le filtre est séché et recristallisé toujours du mélange d'alcool et de benzène.

Dans les conditions mentionnées, le bis(chlorométhyl) éther a été condensé avec les sels de sodium du 2-cyclohexylphénol, 4-cyclohexylphénol, 2-cyclohexyl-4-méthylphénol, 4-cyclohexyl-2-méthylphénol, 2-cyclohexyl-4-chlorophénol et 2-chloro-4-cyclohexylphénol en obtenant 6 nouveaux tris-éthers ayant la formule générale : $Ar-O-CH_2-O-CH_2-O-Ar$ où le noyau Ar est substitué par un radical cyclohexyle ou par un radical cyclohexyle et un radical méthyle ou chlore.

RÉSULTATS ET DISCUSSIONS

Le tableau 1 comprend les formules des tris-éthers synthétisés, les résultats de l'analyse élémentaire de carbone, d'hydrogène et de chlore, les températures de fusion, les valeurs des longueurs d'onde et des coefficients molaires d'extinction obtenus lors de l'analyse en UV (en cyclohexane) aussi bien que les rendements.

Tous les tris-éthers sont solides et cristallins. Les températures de fusion des produits ayant le radical cyclohexyle en position *para* sont inférieures à leurs isomères correspondants ayant le radical cyclohexyle en position *ortho*.

Les spectres électroniques sont ressemblants à ceux des tris-éthers synthétisés antérieurement.[5] La substitution d'un radical méthyl par un radical cyclohexyle sur le noyau aromatique ne favorise pas des déplacements importants des maximums d'absorption. Mais la présence en même temps d'un radical cyclohexyle et d'un radical méthyle sur le même

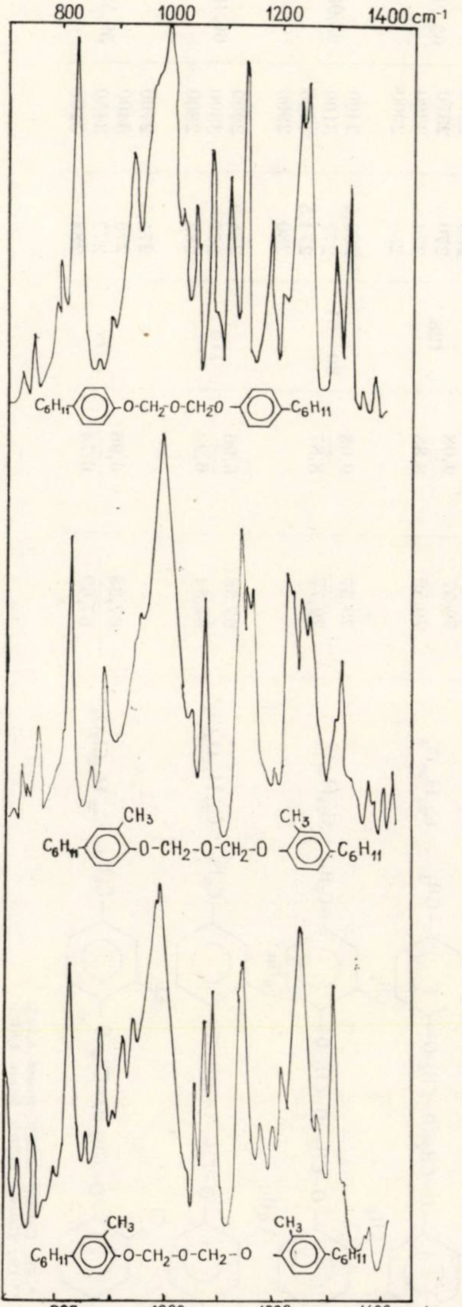

Fig. 1. — Les spectres IR du bis(4-cyclohexylphénoxyméthyl)éther, bis(2-méthyl, 4-cyclohexylphénoxyméthyl)éther et du bis (2-chloro, 4-cyclohexylphénoxyméthyl)éther.

noyau aromatique détermine un déplacement des maximums d'absorption vers des longueurs d'onde de 2 à 4 mμ plus grandes. La substitution du noyau aromatique par un atome de chlore cause un déplacement des maximums d'absorption vers des longueurs d'onde de 7,5 à 8 mμ plus grandes.

Les spectres IR mettent en évidence la présence des fonctions éther aliphatique $-CH_2-O-CH_2-$ et mixte $Ar-O-CH_2-$. Sur la figure 1 on peut suivre les spectres de certains composés synthétisés. Les bandes dues au ν_{asym} $C-O-C$ se trouvent entre 1240 et 1215 cm^{-1}. Tous les éthers synthétisés présentent une absorption très intense de 1240 à 1220 cm^{-1} due à la fréquence asymétrique de $C-O-C$ correspondant à l'éther mixte. De même, une absorption intense se manifeste de 1140 à 1130 cm^{-1}, due à la fréquence asymétrique d'éther aliphatique. Les bandes dues à la fréquence symétrique ν_{sym} $C-O-C$ d'éther mixte sont plus difficiles à identifier car dans cette région d'absorption a lieu aussi l'absorption due à la vibration de balancement en plan du groupe $-CH_2-$ (γCH_2r) de l'anneau cyclohexanique. Par conséquent tous les éthers synthétisés présentent une large bande d'absorption de haute intensité à 990 ± 30 cm^{-1}. Les bandes dues à la fréquence symétrique d'éther aliphatique présentent des absorptions de faible intensité à 940 à 920 cm^{-1}.

Les spectres IR des tris-éthers synthétisés sont bien caractérisés par la présence des vibrations de valence symétriques des groupes méthylène du cyclohexane ayant une fréquence de 2934 à 2853 cm^{-1} et de la vibration de valence asymétrique ayant une fréquence de 2930 à 2926 cm^{-1} (des bandes qui ne sont pas présentées sur la figure 1).

L'analyse thermogravimétrique indique une bonne stabilité des tris-éthers étudiés jusqu'à leur température d'ébullition. Dans le cas des produits sans chlore la perte de poids commence à 250 à 260° et se produit à grande vitesse au-dessus de 300°. Dans le cas des produits contenant du chlore, la perte commence à 300° et se produit rapidement au-dessus de 350°.

PARTIE EXPÉRIMENTALE

Le bis(chlorométhyl)éther a été obtenu en passant un courant d'acide chlorhydrique à travers une suspension de paraformaldéhyde en acide sulfurique concentré .[6]

Le 2-cyclohexylphénol, le 4-cyclohéxylphénol, le 4-méthyl-2-cyclohexylphénol et le 2-méthyl 4-cyclohexylphénol ont été obtenus par la cyclohexylation du phénol respectif, des crésols avec le cyclohexène en présence de $ZnCl_2$ anhydre et de l'HCl comme catalyseurs. [7]

Le 2-chloro 4-cyclohexylphénol a été obtenu par chloruration du 4-cyclohexylphénol avec le chlorure de sulfuryle .[7]

Le 4-chloro 2-cyclohexylphénol a été obtenu par la cyclohexylation du 4-chlorophénol avec le cyclohexène en présence de $ZnCl_2$ et HCl. [7]

Le cyclohexène a été obtenu par déshydratation du cyclohexanole en présence du H_3PO_4, la pureté étant contrôlée par chromatographie.

Le phénol, les crésols et le 4-chlorophénol ont été des produits commerciaux.

Les spectres IR ont été obtenus en tablettes de KBr en utilisant un appareil Karl Zeiss-Jéna.

Les spectres UV ont été obtenus en cyclohexane en utilisant un appareil CF-Optica Milano.

L'analyse thermogravimétrique a été effectuée à l'acide d'un dérivatographe de type Pauli.

LA SYNTHÈSE DU BIS(2-CYCLOHEXYL-PHÉNOXYMÉTHYL) ÉTHER

Dans un ballon de 50 ml, ayant deux cols et muni d'un réfrigérant ascendant et d'un thermomètre, on a introduit 3,524 g de 2-cyclohexyl-phénol (1/50 moles), 0,808 g NaOH (1/50 moles) avec un excès de 1/5000 moles et 30 ml de mélange d'alcool-benzène (1 : 1 en volumes) et on a chauffé jusqu'à l'ébullition et à la totale réaction du cychlohexyl-phénol avec l'hydroxyde de sodium (2 heures). On a remplacé ensuite le réfrigérant ascendant par un réfrigérant descendant et on a distillé 15 ml de mélange d'alcool-benzène-eau afin d'éliminer l'eau. On a ajouté 1,650 g (1/100 moles) de bis(chlorométhyl)éther et on a monté un réfrigérant ascendant. On a chauffé à reflux pendant 3 heures afin d'assurer la formation complète du tris-éther. (Tout d'abord la réaction a été violente). Ensuite on a laissé refroidir le contenu du ballon à la température ambiante, on l'a filtré sur un filtre G—2 et on a lavé le précipité constitué par le tris-éther et le NaCl avec 1 ml éthanol, puis plusieurs fois par de l'eau, pour éliminer le NaCl. Pour le séchage on a lavé le précipité sur le filtre avec 2 à 3 ml d'éthanol. Après le séchage ont résulté 2,800 g de bis(2-cyclohexylphénoxyméthyle) éther. Le rendement est de 79,45%. Après deux recristallisations du mélange d'alcool-benzène (50% en volumes) le produit a eu la température de fusion de 125°.

Les autres éthers, mentionnés dans le tableau 1, ont été synthétisés de façon identique.

ÜBER DEN EINFLUSS DER ELEKTROLYTEN AUF DIE ZÄHIGKEIT DER POLYVINYL-ALKOHOL-LÖSUNGEN

C. HÖLSZKY*, COSTELA SUCIU**, D. SĂNDULESCU***

* Institut für Erdöl, Ploieşti
** D. Bolintineanu-Schule, Bukarest
*** Institut für Erdöl, Gas und Geologie, Bukarest, str. T. Vuia nr. 6

Eingegangen am 23. Juni 1973

Es wurden Löslichkeitsmessungen von Polyvinylalkohol (PVA) in elektrolytischen Lösungen von LiCl, NaCl, KCl, NH_4Cl, $MgCl_2$ $CaCl_2$ durchgeführt und die negativen Setchenow-Aussalzungskoeffizienten bei 20° bestimmt. Die Viskositätsbestimmungen dieser Lösungen führten zur B-Koeffizientbestimmung der Jones-Dole Gleichung und gleichsam zur Bestimmung der Veränderung dieser Größe in Abhängigkeit der PVA-Konzentration. Die bemerkte Senkung durch die Struktur der Elektrolytlösungen und der PVA-Elektrolytlösungen im Wasser ist erläutert. Die Grenzviskositätsberechnung $[\eta]$ zeigt eine anionische Ausdehnung der PVA-Ketten in $CaCl_2$-Lösungen, im Verhältnis von NaCl-Lösung an.

In letzter Zeit wurden zahlreiche experimentale und theoretische Studien betreffend den „Verflüssigungseffekt“ („drag reduction“) bekannt. Diese Studien befassen sich demnach mit dem hervorgerufenen Wachsen der volumetrischen Durchflußmenge einer wässerigen Lösung bei gleichem Druckunterschied, die durch Zugabe von kleinen Mengen von makromolekularen Verbindungem mit großem Molekulargewicht wie Polyäthylenglykol, Carboximethylzellulose, Separan (teilweise hydrolisiertes Polyakrylamid) verursacht wird.[1–3]

Die eventuelle Verwendung des Polyvinylalkohols (P.V.A.) zur Verbesserung der rheologischen Eigenschaften der Bohrschlämme hat uns zu einem Studium betreffend den Einfluß der Elektrolyten auf die Zähigkeit der P.V.A.-Lösungen sowie auf den Aussalzungseffekt angeleitet.

Die Angaben betreffend den Einfluß der Elektrolyten auf die Zähigkeit der wässerigen P.V.A.-Lösungen sind sehr beschränkt, obwohl diese Effekte allgemein ein bedeutendes Forschungsgebiet in der Flüssigkeitslehre darstellen; diese Effekte entsprechen den in wässerigen Lösungen eintretenden Strukturveränderungen sowohl der aufgelösten Stoffe als auch des Wassers, und kann somit über das Wesen und die

gegenseitige Wirkungsstärke Lösungsmittel-aufgelöster Stoff Auskunft geben.

Von diesem Standpunkt ist das Wasser eine einzigartige Flüssigkeit da es die Fähigkeit besitzt mittels Wasserstoffbindungen quasikristallartige Raumgitter zu bilden. Obwohl über das Wasser und die wässerigen Lösungen sehr viel geschrieben wurde, bildet die sichere Struktur des reinen flüssigen Wassers und der wässerigen Lösungen den Gegenstand vieler Widersprüche.[4-6]

Im allgemeinen sind die wässerigen Lösungen von Nichtelektrolyten durch Bildung von Klatraten oder durch die Verstärkung der Struktur des normalen Wassers[7,8] dem Effekt der hydrofoben Hydratation zu Folge, zu erklären.[9]

Sicherlich ist das Erscheinen rings um die Kettenteile der Makromoleküle von in einer anderen als die bei reinem Wasser normalen lokalen Anordnung geliederten Wassermolekülschichten möglich, mittels einer vielleicht vollkommen unbekannten Strukturinduktion[10,11] unter fortdauerndem Zerreissen, Entformung und Wiederherstellung.[12,13]

Es is bekannt, daß der P.V.A. sowohl im festen Zustand als auch in wässerigen Lösungen eine Gitterstruktur aus Inter- und intramolekulären Bindungen bestehend, aufweist.[14-17] Demzufolge ist es umso interessanter den Einfluß der Elektrolyte auf die Zähigkeit der wässerigen Lösungen und im Vergleich mit polymerlosen wässerigen Lösungen welche niedrige Alkohole, Dioxan, Dimethylsulphoxyd, Harnstoff u.s.w. enthalten, festzustellen.

EXPERIMENTALTEIL

Polyvnylalkohol (P.V.A.) durch K-Wert (Fikentscher) $=75$ gekennzeichnet (mittlere Molmasse $\overline{M}_\eta \approx 85000$)

Destilliertes Wasser.

Elektrolyten : $LiCl.2H_2O$, $NaCl$, KCl, NH_4Cl, $MgCl_2.6H_2O$, $CaCl_2$ anh., Erzeugnisse p.a. von ,,Reactivul" oder ,,Merck". Die Konzentration der Lösungen der stark hygroskopischen Li, Mg und Ca-Salze wurde auch durch Titration des Cl-Ions geprüft.

Bestimmung der Löslichkeit der Polymeren. Zu gleichen Volumen der obigen verschieden konzentrierten Elektrolytlösungen wurde tropfenweise eine 2%-ige P.V.A.-Lösung bis zum Erscheinen des Polymerniederschlages zugefügt. Die Löslichkeitsschwelle des sich in Lösung befindenden Polymers wird durch Wiedererrechnung der Kozentration des Elektrolytes festgestellt.

Die Zähigkeitsbestimmungen wurden bei 25° ± 0,05° in einem Ostwald-Kapilarviskosimeter durchgeführt. Die Ergebnisse wurden auf Grund von(H_2O bei 25°) $\eta = 0{,}8903$ cP berechnet. Die Korrekturen der kynetischen Energie wurden vernachlässigt (Fließdauer des Wassers 60,0 Sek.). Die Wiederholbarkeit der Ergebnisse der Zähligkeitsbestimmungen war besser als ± 0,2%.

ERGEBNISSE

Die Tabelle Nr. 1 enthält die Ergebnisse der Aussalzung des P.V.A. bei 25° mit NaCl, KCl und NH_4Cl. Im Falle $MgCl_2$ und $CaCl_2$ wurde kein P.V.A.-Niederschlag bemerkt.

Tabelle 1

Konzentration des Elektrolytes dem Polyvinylalkohol-Ausfällungspunkt entsprechend

9,13	0,260	10,82	0,181	15,07	0,461
6,26	0,610	7,86	0,470		

Tabelle Nr. 2 enthält die Ergebnisse der Zähigkeitsbestimmungen der P.V.A.-Lösungen in Gegenwart von folgenden Elektrolyten: NaCl, KCl, NH_4Cl, LiCl, MgCl, $MgCl_2$, $CaCl_2$ — bei 25°.

DISKUSSIONEN

Der Aussalzungseffekt kann durch Übereinanderlegen der Hydrationsprozesse der Ionen und der unterschiedlichen Polarisation des Wassers und der Nichtelektrolytmoleküle, folglich größtenteils rein elektrostatische Effekte, aber auch durch spezifische Lösungseffekte und Dispersionseffekte erfolgen. * bei einer Konzentration der Polymerlösung von 0,8%,

Die für die Löslichkeit des P.V.A. erhaltenen Werte entsprechen dem Setchenow Gesetz

$$\lg \frac{s}{s_0} = km$$

wo $k < 0$ für die Aussalzung (salting out) mit der im allgemeinen anerkannten Regel übereinstimmend, s und s_0 die Löslichkeit des Polymers in der Elektrolytlösung von Molalität m, beziehungwseise $m = 0$.

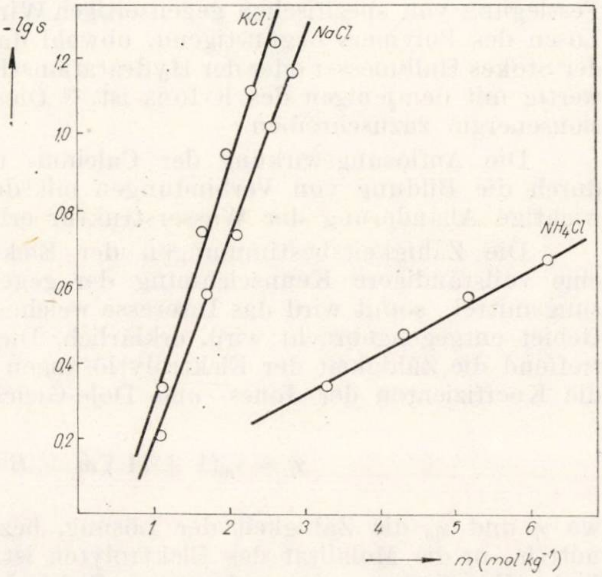

Abb. 1. – Prüfung der Setchenow'schen Gleichung.

Abb. 1 stellt die lineare Variation des lg s abhängend von der Molalität der Elektrolyten NaCl, KCl und NH_4Cl dar, die Gültigkeit des Setchenow-Gesetzes bestärkend und ergibt für die Aussalzungskonstanten bei 25°C die Werte :

für KCl $k = -0{,}65(\pm 0{,}02)\mathrm{Kg\,Mol^{-1}}$;
für NaCl $k = -0{,}55\,(\pm 0{,}02)\mathrm{Kg\,Mol^{-1}}$;
für NH_4Cl $k = -0{,}11\,(\pm 0{,}01)\mathrm{Kg\,Mol^{-1}}$

(für den entsprechenden Konzentrationsbereich).

Im Falle der Elektrolyten $MgCl_2$ und $CaCl_2$ konnte keine Aussalzungsschwelle festgestellt werden bis $c = 2\%$ Polymer.

Diese Werte ermöglichen die beiläufige Berechnung der freien Überführungs-Enthalpie aus dem Wasser in die Elektrolytlösung des Polymers :

$$\Delta G = -\mathrm{RT}\ln\frac{\gamma_0}{\gamma} = -\mathrm{RT}\ln\frac{s}{s_0} = -2{,}3\,\mathrm{RT}\,km$$

wo γ_0 und γ die Aktivitäts-Koeffizienten des Polymers in Wasser bezw. in der Elektrolytlösung darstellen.

Für m = 1 Mol Kg^{-1} Elektrolyt ergibt sich bei 25°

ΔG (1m KCL Lösung) = +3700 ± 100 $J.mol^{-1}$

ΔG (1m NaCl Lösung) = + 3100 ± 100 $J.mol^{-1}$

ΔG (1m NH_4Cl Lösung) = + 650 ± 50 $J.mol^{-1}$ (extrapoliert).

Die berechneten Werte stimmen nicht genau mit den freien Überführungs-Enthalpien überein, sie ermöglichen jedoch die unmittelbare Festlegung von spezifischen gegenseitigen Wirkungen des NH_4^+-Ions, das Lösen des Polymers begünstigend, obwohl das ionische Potential, bezw. der Stokes Halbmesser oder der Hydratations-Halbmesser praktisch gleichwertig mit demjenigen des K-Ions ist.[22] Diese Effekte sind der Dispersionsenergie zuzuschreiben.

Die Auflösungswirkung der Calcium- und Magnesium-Ione kann durch die Bildung von Verbindungen mit den P.V.A. oder durch eine wichtige Abänderung der Wasserstruktur erläutert werden.

Die Zähigkeitsbestimmungen der Elektrolytlösungen ermöglichen eine vollständigere Kennzeichnung der gegenseitigen Wirkung Ion-Lösungsmittel, somit wird das Interesse welches in der letzten Zeit diesem Gebiet entgegengebracht wird, erklärlich. Die theoretischen Studien betreffend die Zähigkeit der Elektrolytlösungen versuchen im wesentlichen die Koeffizienten der Jones- und Dole-Gleichung[23] zu deuten

$$\eta = \eta_0(1 + A \sqrt{m} + B\, m)$$

wo η und η_0 die Zähigkeit der Lösung, beziehungsweise des Lösungsmittels, m die Molalität des Elektrolyten ist, während A und B spezifische Koeffizienten des aufgelösten Elektrolyten sind. Diese Gleichung wurde sehr gut studiert, besonders um eine Beziehung zwischen den Werten von A oder B und den Eigenschaften der Ionen festzustellen.

In zahlreichen Studien[24–26] wurde bewiesen, daß das Glied $A\sqrt{m}$ von der ionischen Wechselwirkung bestimmt ist und mittels der Debye-Hückel-Theorie berechnet werden kann.[27] Ohne eine präzise theoretische Erklärung ist man zu dem Schluß gekommen, daß B das Resultat der Wechselwirkung Ion-Lösungsmittel bezeichnet.

Im allgemeinen ist $\frac{A}{B} \ll 1$,[28] so daß das Glied welches A enthält bei Konzentrationen über 2.10^{-3} m vernachlässigt werden kann, während die Gleichung linearen Charakter bekommt:

$$\frac{\eta - \eta_0}{\eta_0} = Bm$$

Somit ist die unmittelbare Berechnung des Wertes des Koeffizienten B möglich. Abb. 2 ist die graphische Darstellung der Gleichung für LiCl, NaCl, KCl, NH_4Cl bei verschiedenen Konzentrationen *c* des P.V.A. Es muß beobachtet werden, daß im Falle von Lösungen in reinem Wasser ($c = 0$) die Werte der Koeffizienten *B* mit den bekannten Werten übereinstimmen,[29-31] während unter dem Einfluß des Polymers der Wert von B sinkt, in Übereinstimmung mit Abb. 3.

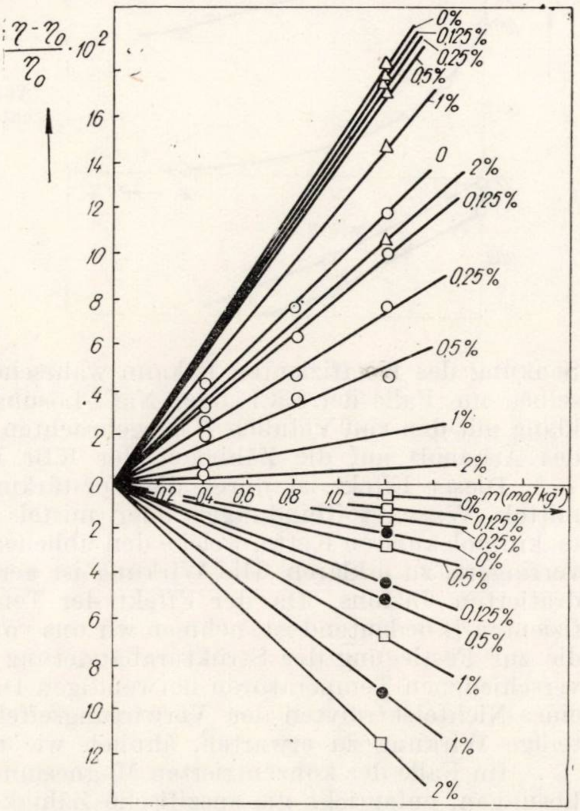

Abb. 2. — Graphische Darstellung der Gleichung $\frac{\eta - \eta_0}{\eta_0} = Bm$ für Elektrolytlösungen bei 20°: Δ — LiCl; ○ — NaCl; ● — KCl; □ — NH_4Cl.

Die Anzahl der Studien betreffend die Wirkung der Nichtelektrolyten auf die Zähigkeit der wässerigen Elektrolytlösungen ist gering.[32]

[31] V. Asmus, *Z. Naturforsch.* **49**, 589 (1949).

[32] B. Oliver und A. Campbell, *Canad. J. Chem.*, **47**, 4207 (1969).

Es ist der bedeutende Effekt des Polymers auf die Struktur der Lösung im Falle NaCl zu bemerken und mit dem Falle der anderen Elektrolytlösungen in welchen die Wirkung ähnlich ist, zu vergleichen. Die Senkung des Koeffizienten B kann wahrscheinlich zu negativen Werten, selbst im Falle der LiCl- oder NaCl-Lösungen führen. Dies ist im Einklang mit den von Vidulich [33] dargebrachten Daten im Falle der Wirkung des Äthanols auf die Zähigkeit der KBr Lösungen.

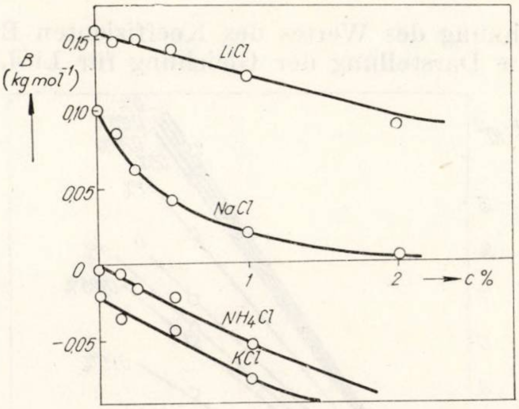

Abb. 3. — Abhängigkeit des Koeffizienten B der Elektrolytlösungen von der Konzentration des P.V.A.

Dieser Effekt ist durch die Verstärkung der Struktur von P.V.A. mittels Wasserstoffbindungen oder mittels hydrofoben Bindungen der makromolekularen Kette, welche den üblichen Effekt der Ionen im Wasser verringert, zu erklären. Die Wirkung ist geringer im Falle des stark hydratierten Li-Ions. Da der Effekt der Temperatur im Falle des Koeffizienten B bedeutend ist, nehmen wir uns vor in einem weiteren Studium die zur Festlegung der Strukturabänderung der geprüften Lösungen bei verschiedenen Temperaturen notwendigen Daten festzulegen. Bei Zugabe eines Nichtelektrolyten der Verwirrungseffekte ausübt, ist eine gegenteilige Wirkung zu erwarten, ähnlich wie beim Dioxan. [32]

Im Falle der konzentrierten Magnesiumchlorid- und Calciumchlorid-Lösungen, entspricht die spezifische Zähigkeit einer polinomialen Gleichung der From:

$$\frac{\eta - \eta_0}{\eta_0} = Bm + Cm^2 + Dm^3 + \dots$$

welche auch der Wechselwirkung der in der Lösung befindlichen Ionen entspricht (Abb .4).

Auch in diesen Fällen ist eine Senkung der Koeffizienten B im Zwischenraum $m = 0 \dots 2$ Mol.Kg^{-1} zu beobachten, doch ist diese Senkung bei der Polymerzugabe viel geringer als im Falle der Li^+, Na^+, K^+, NH_4^+-Ionen, wegen dem kräftigen Feld der Mg^{2+} und Ca^{2+}-Ionen.

---

[33] G. VIDULICH, G. ANDRADE, P. BLANCHETTE und T. GILLIGAN, *J. Phys. Chem.* **73**, 1621 (1969).

Wie schon früher bemerkt wurde, entspricht der Wert des Koeffizienten B der Wechselwirkung Lösungsmittel-Ion und kann eine Bewertung des durch das Ion hervorgerufenen Ordnungs- bezw. Unordnungsgrades der Lösungsmittelstruktur ermöglichen.[5,34] So haben die Li^+, Na^+, Ca^{2+}, Mg^{2+}-Ionen in polymerlosem Wasser positive B-Koeffizienten, was einem ordnungshervorrufenden Effekt entspricht, während NH_4^+, K^+, Cl^--Ionen negative (verhältnismäßig kleine) Koeffizienten haben, folglich wirken sie Verwirrung-hervorrufend auf die Struktur des Wassers. In einigen Veröffentlichungen wurden sogar die Ausdrücke „positive oder negative Hydratation“ eingeführt, um diese Effekte zu bezeichnen.

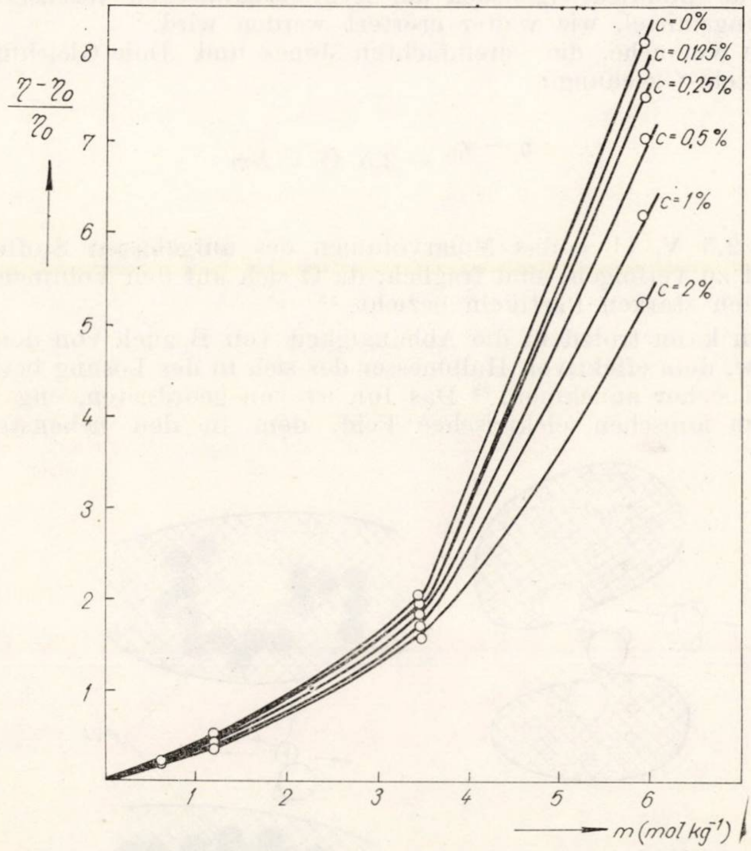

Abb. 4. — Abänderung der spezifischen Viskosität der $CaCl_2$-Lösungen bei 20°.

Eigentlich muß in diesem Falle der Begriff „Ordnung-hervorrufend“ und „Verwirrung-hervorrufend“ oder „Strukturierung“ und „Entstruk-

[34] H. Rüterjans, F. Schreiner, V. Sage und T. Ackerman *J. Phys. Chem.* **73**, 986 (1969).

turierung“ mehr als ein dem Sinken bezw. Wachsen der freien Translationsmöglichkeiten der Wasserstoffmoleküle entsprechender Begriff angesehen werden, also als ein sich in der Zeit abspielender Durchschnittseffekt. Das entspricht eigentlich der hydrodynamischen Wechselwirkung Ion-Lösungsmittel, wie weiter erörtert werden wird.

Die Versuche, die vereinfachten Jones und Dole-Gleichung mit der Einstein-Gleichung :

$$\frac{\eta - \eta_0}{\eta_0} = 2{,}5\ \emptyset = Bm$$

wo $B = 2{,}5$ V, (V = das Molarvolumen des aufgelösten Stoffes) vergleichend zu verfolgen, sind fraglich, da $\emptyset$ sich auf den Volumenteil der sphärischen starken Partikeln bezieht. [35]

Man kann trotzdem die Abhängigkeit von B auch von dem Volumen bezw. dem effektiven Halbmesser des sich in der Lösung befindenen Iones als sicher annehmen. [22] Das Ion ist von geordneten, eng verbundenen, im ionischen, elektrischen Feld, dem in den nebenstehenden Schemen (Abb. 5) angegebenen Möglichkeiten gemäß orientierten Wassermolekülen, umgeben. Diese Schemen ermöglichen die Deutung der Strukturverstärkung durch die relative Verminderung der Translationsmöglichkeit der Wassermoleküle in der Elektrolytlösung und der in P.V.A. enthaltenden Elektrolytlösung.

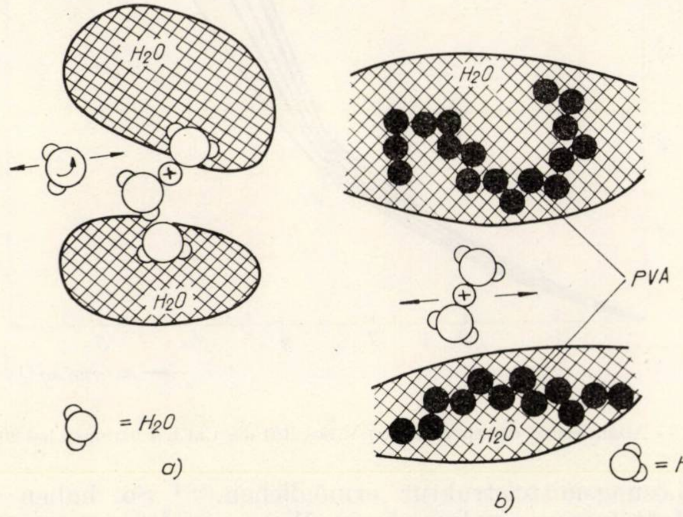

Abb. 5. — Strukturmodell der Elektrolytlösungen in Wasser (a) und in P.V.A.-Lösungen (b).

Die erste von orientierten Molekülen gebildete Schicht, deren Dicke von der Intensität des elektrischen Feldes abhängt, folglich von dem

---

[35] B. Breslau und J. Miller, *J. Phys., Chem.* **74**, 5, 1057 (1970).

Halbmesser des Kristalls und von der Ladung, ist von einer Schicht von strukturlosen Molekülen umgeben und dann folgen in der bei flüssigem Wasser üblichen Struktur gebundene Wassermoleküle.

Man kann annehmen, daß im Falle der positiven Werte des Koeffizienten B der Hydratationsdurchmesser des Ions der ersten im elektrischen ionischen Feld geordneten Schicht entspricht, während die zweite Schicht unterschiedlich ist im Vergleich zu dem Falle der negativ-wirkenden Ione ($B < 0$), wo diese zweite Schicht in zerstreuter Form bis in die Nähe des Ions eingedrungen ist, was selbstverständlich den verhältnismäßig kleineren Halbmessern des in der Lösung hydratierten-Ions (K^+, Rb^+, Cs^+, NH_4^+, Cl^-, Br^-), [22] oder im Falle der großen polyatomischen Ione einer kleinen oberflächlichen elektrischen Dichte entspricht. Sicherlich werden die Wassermoleküle der ersten Schicht nur von Ionen mit starken elektrischen Feldern, folglich mit kleinen Kristallhalbmessern gerodnet, was zu hydratierten Ionen mit großen Halbmessern führt, den Werten von $B > 0$ entsprechend.

Die Ionen welche in der Lösung kleine Halbmesser besitzen mit einer kleinen Hydratation, üben bedeutende elektrische Wirkungen aus, indem sie das pseudo-tetraedrische Gitter des Wassers zerreißen oder schwächen und somit ein Sinken der Zähigkeit der Lösung hervorrufen.

Der Einfluß des Nichtelektrolyten P.V.A. äußert sich in allen Fällen (sowohl für die Elektrolyten mit $B > 0$ sowie für $B < 0$) wie schon erwähnt, im Sinken der B-Werte, im Bereich der beobachteten Konzentrationen und zeigt somit eine Veränderung der Hydratationsfähigkeit durch Verminderung der Dimensionen des hydratierten Ions an, folglich eine Verbreiterung der zerstreuten, ungeordneten Schicht, da die Struktur des Wassers durch die Erweiterung des Volumens oder der Anzahl der Inseln mit pseudotetraedrischer Struktur des Wassers, sowohl durch den hydrophoben Effekt der Polymerkette als auch dem Effekt der polaren OH-Gruppen zufolge, welche direkt mit dem Wasserstoffbindungengitter verbunden sind, verstärkt wird. Diese Effekte lösen den Einfluß des elektronischen, ionischen Feldes, welches die molekulären Dipole des Wassers in der ersten ionischen Hydratationsschicht ordnet, auf; gleichfalls können diese Wirkungen den verhältnismäßig kleineren, bei $MgCl_2$ und $CaCl_2$ (Abb. 4) beobachteten Einfluß erläutern, wo das kationische elektrische Feld hohe Werte erreicht.

Andererseits stimmt diese Erläuterung mit der linearen Variation des Koeffizienten B in Abhängigkeit von der partiell molaren, auf den Gaszustand bezogenen Hydratationsentropie der Ionen S_g^0 überein:

$$S_h^0 = S_{aq}^0 - S_g^0 < 0$$

was auf ein Zunehmen der Hydratationsentropie S_g^0 mit dem Abnehmen des B-Wertes hindeutet. [22] Tatsächlich entspricht die Regelung in der ersten Schicht dem Sinken der Hydratationsentropie der Ione.

Es muß andererseits erwähnt werden, daß im allgemeinen eine gewisse Ungewißheit bezüglich des Ausdruckes „Reißen der Wasserstoff-bindung“ herrscht, gleichwertig mit dem Verwirrungs- bezw. Ordnungs-Effekt. Im reinen, flüssigen Wasser kann man bei 0°, 10—15% bewegliche Wasserstoffbindungen schätzen (Reißen und Wiederbildung) im Vergleich zu 0% im Eis bei derselben Temperatur.[36]

Das flüssige reine Wasser besteht somit aus regelmäßigen (quasikristallinen) Zonen, wo die Wasserstoffbindungen andauernd reißen und sich wieder bilden. Das elektrisch ionische Feld hat einerseits die Orientierung der Dipole der einfachen oder der verbundenen Moleküle im Kontaktgebiet der geordneten „Inseln“ zur Folge und andererseits bewirkt es das Zerreißen des Gitters auf größeren oder kleineren Strecken, bezw. das Ansteigen des Prozentsatzes an einfachen Molekülen, was ein Wachsen der Translationsmöglichkeit (in Übereinstimmung mit der obigen Darstellung) zur Folge hat. Dieser Effekt herrscht im Falle der Ione welche in der Lösung ein starkes Feld aufweisen, folglich ähnlich den oben angedeuteten Ionen, eine kleine relative Hydratation besitzen, vor; dieser letztere Effekt kann mit Zerfallwirkung bezeichnet werden und ist der Wirkung des Anstiegs der Temperatur ähnlich (z.B. bei 300° erhält dieser Prozentsatz den beiläufigen Wert von 60%, während bei 370° der Wert 100% erreicht).[36]

Im Falle des polaren Nichtelektrolyten vom P.V.A.-Typus wächst die Anzahl oder die Fläche der quasi-kristallinen „Inseln“ zum Nachteil der Verwirrungszonen, wodurch die Möglichkeiten des allgemeinen Ordnungseffektes des elektrischen ionischen Feldes verringert werden. Abbildung 5 stellt ein annäherndes Schema des Falles Elektrolytlösung und Elektrolytlösung mit Nichtelektrolytzugabe, als Strukturerzeuger, vom Typus P.V.A., dar. Gewiß kann das Sinken des B-Koeffizienten, bezw. das Steigen der Hydratationsentropie oder des effektiven Hydratationshalbmessers der hydrodynamischen Wechselwirkung, nicht einer linearen Variation entsprechen, außer im Falle eines bestimmten Konzentrationsbereiches (siehe Abb. 3 und).[37] Die obigen Werte hängen von der Intensität des effektiven ionischen elektrischen Feldes ab, z.B. im Falle NaCl (Abb. 4) und streben asymptotisch nach einem Grenzwert des hydrodynamischen Wechselwirkungseffektes Elektrolyt-Wasser-Nichtelektrolyt.

Es kann noch erwähnt werden, daß im Falle der Ione mit kleinem Kristall-Halbmesser, z.B. Li^+, Na^+, die Leerräume in dem „offenen“ Quasi-Kristallgitter des Wassers ihr Eindringen in diese Hohlräume ermöglichen. Das Ergebnis ist ein Wachsen des Gleitwiderstandes, da die Kontaktflächen der Verwirrungszonen sich durch die Bildung von Keilen verkleinern (Abb. 5).

Andere Gesichtspunkte der Wechselwirkung in Lösungen Elektrolyt-Wasser-P.V.A. können festgestellt werden mittels der Werte der grundmolaren Viskositätszahl, oder Grenzviskosität welche mit Hilfe der Gleichung:

$$[\eta] = \lim_{c \to 0} \frac{\eta - \eta_0}{\eta_0} = \lim_{c \to 0} \frac{\eta_{sp}}{c}$$

---

[36] G. Haggis, J. Hasted und T. Buchanan, *J. Chem. Phys.* **20**, 1452 (1962).

[37] H. Frank und M. Evans, *J. Chem. Phys.* **13**, 507 (1945).

bestimmt wird, wo c die Konzentration des Polymers darstellt η_0 und η sind die Zähigkeiten des den Elektrolyt bezw. Polymer enthaltenden Lösungsmittels. Die Huggins'sche Gleichung stellt die reduzierte Zähigkeit dar:

$$\eta_r = \frac{\eta_{sp}}{c} = [\eta] + k[\eta]^2 c + \ldots$$

wo die Konstante k die hydrodynamische Wechselwirkung in der Lösung darstellt.

Unsere experimentalen Bestimmungen ermöglichen die Feststellung der grundmolaren Viskositätszahl im Falle der Lösungen NaCl—P.V.A. in Wasser bei 20° mittels der Diagramme Abb. 6 und 7.

Man kann somit den Wert der grundmolaren Viskositätszahl der P.V.A.-Lösung im Wasser bestimmen, $[\eta] = (0{,}68 \pm 0{,}02)$ (100 g/g). Im Falle der NaCl-Lösungen ($m = 0{,}4-1{,}2$ Mol/Kg), sinkt $[\eta]$, doch bleibt sie praktisch in diesem Konzentrationsbereich identisch mit $[\eta] = 0{,}62 \pm 0{,}2$ (100 g/g). Im Falle der P.V.A.-Lösungen in $CaCl_2$ schwankt die grundmolare Viskositätszahl bedeutend: nach einem Anstieg von 0,68 auf 0,74 im Falle $m = 0{,}6$, bemerkt man ein bedeutendes Sinken bis auf $(0{,}46 \pm 0{,}02)$ 100 g/g bei $m = 6$ Mol. Kg^{-1}, folglich in konzentrierten Elektrolytlösungen. Die Variationen der grundmolaren Viskositätszahl mit der Konzentration des Elektrolyten in der Lösung ist mittels der Kurven in Abbildung 8 dargestellt.

Die Kurven der P.V.A.-Lösungen in anderen Elektrolyten wurden nicht dargestellt; es ist leicht ersichtlich, daß im Falle der LiCl-Lösungen ($m = 1{,}2$ Mol. Kg^{-1}) die Verminderung der grundmolaren Viskositätszahl unwesentlich ist $[\eta] = (0{,}68-0{,}67)$ 100 g/g; Im Falle de NH_4Cl-Lösungen ($m = 1{,}2$ Mol. Kg^{-1}) entspricht die grundmolare Viskositätszahl beiläufig $[\eta] = (0{,}66)$ 100 g/g aber bei KCl-Lösungen ($m = 1{,}2$ Mol. Kg^{-1}) bestimmt man annähernd $[\eta] = (0{,}58 \pm 0{,}04)$ 100 g/g. Im Falle der MgCl-Lösungen $m = 1{,}2$ bezw. 3,5 Mol.Kg^{-1}) ist im Bereich der P.V.A.-Konzentration von 0—0,5% eine bedeutende Verminderung der reduzierten Zähigkeit $\eta sp/c$ bemerkbar, was zu wichtigen Werten für $[\eta]$ führen könnte.

Im allgemeinen kann der Effekt den die Elektrolyten auf den Wert $[\eta]$ ausüben durch die Verringerung des hydrodynamischen Halbmessers $\sqrt{\overline{r^2}}$ des in der Lösung befindenden Makromoleküls dessen Molekularmasse M ist, gedeutet werden, der bekannten Theorie entsprechend. [38]

$$[\eta] = \Phi \frac{(\overline{r^2})^{\frac{3}{2}}}{M}$$

---

[38] P. Flory und T. Fox, *J. Amer. Chem. Soc.* **73**, 1904 (1951).

wo $\varnothing$ eine allgemeine Konstante Flory des Lösungsmittels ist. Die obige Gleichung weist auf das in größerem Maße möglich Zusammenballen der makromolekularen Kette in Gegenwart von Elektrolyten, und zwar weniger im Falle der Li^+, Na^+-Ionen, wo die Hydratation die Intensität des elektrischen ionischen Feldes verkleinert, und mehr im Falle der K^+-Ionen wegen der reduzierten Hydratation sowie bei konzentrierten Ca^{2+}-Lösungen. Im Falle des $CaCl_2$-Elektrolyten kann das Ansteigen der grundmolaren Viskositätszahl im Bereich von $m = 0-0{,}6$ Mol.Kg^{-1} (Abb. 8) durch das von dem Erscheinen von negativen Ladungen an gewissen Stellen der Kette hervorgerufene Ausdehnung der makromolekularen Kette gedeutet werden, folglich durch Entstehung von Verbindungen Ca^{2+} – Makromolekularkette oder Ca^{2+} – verschiedene Makromolekular ketten. Diese „anionische" Ausdehnung der Kette kann von der von Takahashi und Nagasawa [39] hingewiesenen Art sein. Diese Erläuterung

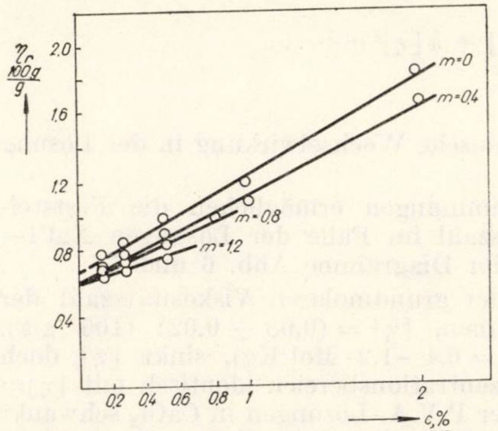

Abb. 6. — Bestimmung der Grenzviskosität $[\eta]$ von NaCl-P.V.A.-Lösungen in Wasser bei 20°.

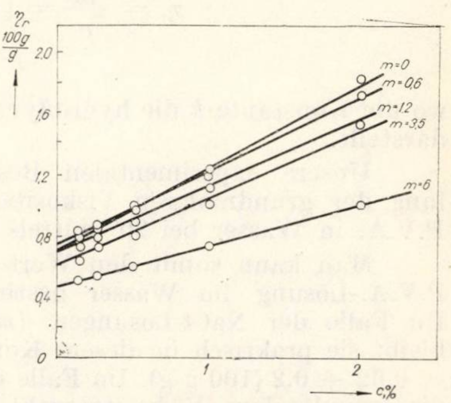

Abb. 7. — Bestimmung der Grenzviskosität $[\eta]$ von $CaCl_2$-P.V.A.-Lösungen in Wasser bei 20°.

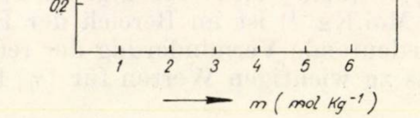

Abb. 8. — Abhängigkeit der $[\eta]$ von der Konzentration der CaNl und $CaCl_2$ Elektrolyten bei 20°.

---

[39] A. TAKAHASAHI und M. NAGASAWA, *J. Amer. Chem. Soc.* **86**, 543, (1964).

ist auch mit den annähernden Werten der Konstante k (hydrodynamische Wechselwirkungskonstante) der Huggins'schen Gleichung in Übereinstimmung; k steigt von 0,85 im Falle NaCl ($m = 1{,}2$ Mol.Kg^{-1}) bis zu 0,96 (100 g/g) im Falle $CaCl_2$ ($m = 1{,}2$ Mol.Kg^{-1}). Dieser Anstieg zeigt das Vorhandensein von elektrostatischen abstoßenden Wechselwirkungen zwischen den Ketten oder im Inneren einer Polymerkette.

Abschließend kann bemekrt werde, daß unserer Meinung nach das Ansteigen der grundmolaren Viskositätszahl allen Ionen gemeinsam ist, in einem gewissen Bereich von kleinen Konzentrationen. Dieser Bereich ist für jedes Ion spezifisch, abhängig von den elektrostatischen Effekten (Ladung, Kristallhalbmesser und Hydratation) und von den Dispersionseffekten (Polarisierbarkeit). Dieser von der „anionischen" Ausdehnung hervorgerufene Anstieg der grundmolaren Viskositätszahl bei kleinen Konzentrationen des Polymers kann auch den oben angegebenen Effekt der Reibungsverminderung erklären.

Revue Roumaine de Chimie, **19**, *5*, 903–910 (1974)

KINETICS OF EMULSION POLYMERIZATION OF VINYL ACETATE IN THE PRESENCE OF POLYVINYL ALCOHOL

VICTORIA DIMONIE, D. DONESCU, MARIANA MUNTEANU, C. HAGIOPOL and I. GAVĂT
Institute of Macromolecular Chemistry "P. Poni",
Section "Polymerization Processes", Bucharest, Str. Dumbrava Roşie N^0 18, Romania

Received November 12, 1973

The kinetics of emulsion polymerization of vinyl acetate (VAc) was studied in the presence of polyvinyl alcohol (PVA) and of hydrogen peroxide, in the redox system. The dependence of the maximum rate of polymerization on the initial concentrations of VAc and hydrogen peroxide is of the form $R_{\max} \sim [\mathrm{VAc}]_0^1$, $R_{\max} \sim [\mathrm{H_2O_2}]_0^{1/2}$. Under these conditions, the existence of some intensive chain-transfer reactions with PVA, noticed through the decrease of the polymerization rate and formation of an important amount of gel as the emulsifier concentration increases, has been emphasized. The effect of reaction conditions on composition and Fikentscher constant (*K* value) of the obtained polymers was determined.

1. INTRODUCTION

Relatively few studies have been published with regard to the kinetics and mechanism of emulsion polymerization of vinyl acetate in the presence of high-molecular emulsifiers [1].

Emulsion polymerization of VAc shows some deviations from the quantitative theory of Smith and Ewart,[1,2] owing essentially to the greater solubility in water of this monomer than that of other monomers. At the same time, the polyvinyl acetate macroradical shows a high reactivity towards chain transfer agents [3].

When using macromolecular compounds as emulsifiers for the polymerization of VAc, an unexpected kinetic effect has been noticed: the rate of reaction decreases with the increase of the initial concentration of emulsifier [2].

In the case of using PVA as emulsifier, literature data show apparent disagreements due to the choice by the respective authors of extreme ranges of parameter variation: low molecular weights of PVA, [4] monomer concentrations below the limit of solubility of VAc in water, small PVA concentrations [5].

In the present work, the kinetic effects of monomer, emulsifier and initiator concentrations were studied, working in the range of high monomer concentration under conditions similar to those of industrial processes, and with a high molecular weight PVA. The effect of these parameters on the structure of the polymers obtained was also studied.

2. EXPERIMENTAL

2.1. MATERIALS

Vinyl acetate, commercial reagent, was purified on a high efficiency column. No traces of aldehydes could be identified after reactification.

Polyvinyl alcohol of the "Rodoviol" type was utilized as aqueous solution of 8 to 10% concentration, from which suspensions remaining undissolved were removed by centrifuging. The polyvinyl alcohol contains 9% acetate groups and has a molecular weight of 151,000, determined by the viscometric method.[6]

The polyvinyl alcohol solutions were also characterized from the point of view of surface tension, the dependence of which on concentration was established by using a torsion balance and is given in figure 1.

The resulting dependence is characteristic to the formation of a highly ordered arrangement without the appearance of micelles.

Hydrogen peroxide, a "Chemapol" product, was used in a solution of 30% concentration.

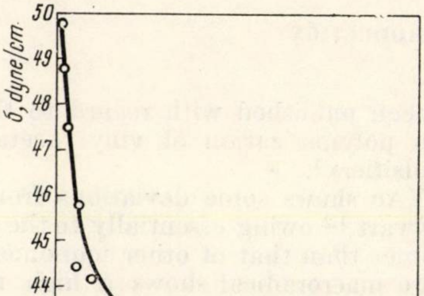

Fig. 1. — Variation of the surface tension of PVA aqueous solutions with concentration at 63°C.

Iron (II) sulfate, a "Reactivul" product, was used in aqueous freshly prepared solution.

2.2. POLYMERIZATION CONDITIONS

Polymerizations were performed at 63±0.5°, in a four-necked flask equipped with thermometer, dropping funnel, reflux cooler and mechanical stirrer.

The procedure was the following; the polyvinyl alcohol solution was introduced into the polymerization flask, distilled water was then added to adjust to the desired concentration. It was heated on the water bath to the polymerization temperature. After thermostating, formic acid was added up to pH = 3, then the iron (II) sulfate solution and, subsequently, the vinyl acetate drop by drop for 10 minutes. The moment when hydrogen peroxide was introduced was considered the zero moment of the reaction. In all the polymerizations, the overall reaction volume, the stirring speed and the rate of addition of reactants were maintained constant.

During polymerization, samples were withdrawn to determine gravimetrically the conversion and to analyse the polymer obtained.

2.3. POLYMER ANALYSIS

From the samples taken in the course of polymerization, films were obtained by drying at room temperature and were subjected to successive extractions in water and in benzene at boiling for 5 to 6 hours each, obtaining finally 3 fractions. The amounts of polymer soluble in water, soluble in benzene and insoluble in benzene were determined gravimetrically.

The water soluble fraction was analysed from the point of view of chemical composition by determining the acetate groups.

The *K* value of the polymer separated from the fraction soluble in benzene was determined according to the Fikentscher equation [7] by means of the viscometric measurements of 0.5% solutions in benzene:

$$\frac{1}{c}\log \eta_{\text{rel}} = k + \frac{75\,k^2}{1 + 1.5\,kc}\,; \qquad K = k.10^3$$

3. RESULTS AND DISCUSSION

The emulsion polymerization of VAc in the presence of PVA has a characteristic course, in three stages.

In figure 2 a kinetic curve is represented, and the existence of an accelaration period of the polymerization rate of 15 to 30 minutes can be noticed, followed by an interval of linear variation of the conversion with time, up to values in the range of 70 to 90%, the rate of polymerization decreasing subsequently.

During the second stage of the reaction, the polymerization rate ($R_{\max}$) depends linearly on the initial monomer concentration (figure 3).

$$R_{\max} \sim [M]_0^{\,1.0}$$

This evolution in time, typical of other emulsion polymerization processes too, may be interpreted in the following way: in the first stage, monomer — polymer particles are formed in which the polymerization takes place, and the number of which in the volume unit is proportional to the initial concentration of monomer. In the second stage the concentration of these polymerization loci remains constant [8], the polymerization rate being determined by the processes of the monomer diffusion to the growing macroradicals.

---

[7] A. Smith, "Addition Polymers. Formation and Characterization", London, 1968, p. 200.

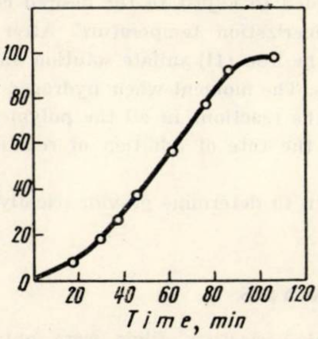

Fig. 2. — Time-conversion curve for the polymerization of VAc at 63°C.

$[VAc]_0 = 3.44$ mole/l; $[PVA]_0 = 35.4$ g/l; $[H_2O_2]_0 = 3 \times 10^{-3}$ mole/l; $[FeSO_4]_0 = 5.85 \times 10^{-5}$ mole/l

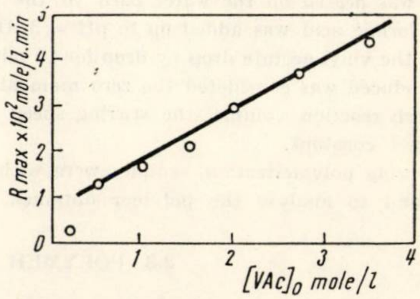

Fig. 3. — Dependence of the maximum polymerization rate on the monomer initial concentration at 63°C.

$[PVA]_0 = 35.4$ g/l; $[H_2O_2]_0 = 3 \times 10^{-4}$ mole/l; $[FeSO_4]_0 = 5.85 \times 10^{-5}$ mole/l.

For VAc concentrations below its limit of solubility in water, the polymerization does not take place by the same mechanism, the polymerization rate being smaller than the rates at higher monomer concentrations, and comparable to those found for aqueous solution polymerization [9a].

Along with the increase of the polymerization rate, due to a greater initial concentration of monomer, an increase of the molecular weight of the formed polymer was also noticed (figure 4).

It is already known that in the emulsion polymerization of VAc in the presence of PVA there exists the possibility of formation of graft copolymers owing to the transfer reactions of the polyvinyl acetate macroradical to the emulsifier [9b,10]

Some information about the grafting process were obtained by investigating the variation in time of the weight of polymer fractions resulting from the extractions in water and in benzene.

If graft reactions had not occurred, the weight of the fraction soluble in water would have had to correspond to the amount of PVA introduced into the reaction.

Actually, by following the variation of the water-soluble fraction in the course of the conversion of monomer to polymer, an increase of this fraction by 35 to 55% of the amount of PVA initially introduced into the system, was observed (figure 5).

[8] D. N. French, *J. Polymer Sci.*, **32**, 395 (1958).

[9] a G. E. Ham, "Vinyl Polymerization", vol. 1 (part II), Marcel Dekker, New York, 1969, p. 89;

b ibid, vol 1 (part I) 1967, p. 288.

[10] F. D. Hartley, *J. Polymer Sci.*, **34**, 397 (1959).

As can be seen in figure 5, the dependence of the water-soluble fraction on conversion is always represented by a curve having a maximum, the position of the maximum depending upon the experimental conditions.

From the determination of the acetate groups, carried out on the polymer extracted in aqueous phase, it resulted that with the advancing of the process, the content of PVA in this fraction is continuously diminishing (figure 5, dotted line).

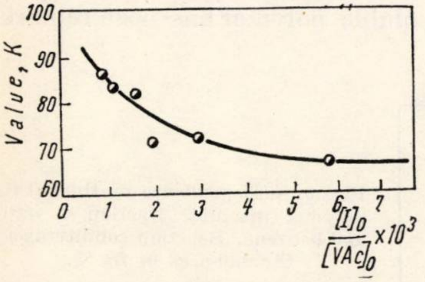

Fig. 4. — Variation of the *K* value of the polymer fraction soluble in benzene with the molar ratio initiator/monomer. Reaction conditions are the same as in fig. 3.

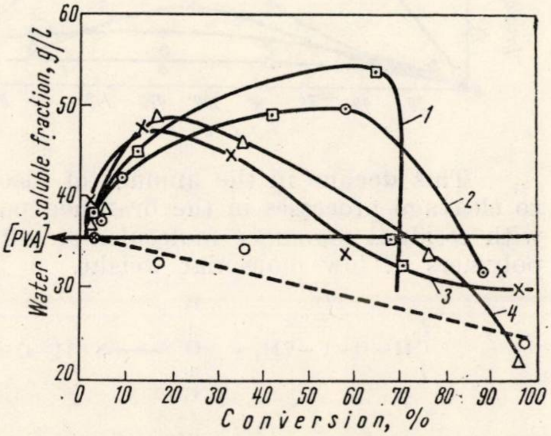

Fig. 5. — Variation of the water soluble fraction with conversion. Reaction conditions are the same as in fig. 3.
$[VAc]_0$ = *1* – 1.0; *2* – 1.5; *3* – 2.72; *4* – 3.44 mole/l. – – – : the weight of PVA extracted in water soluble fraction.

That means that the PVA part on which grafting has occurred very intensively is contained in the fraction insoluble in water.

In the same way the variation in time of the fraction soluble in water may also be interpreted, this fraction increasing at the beginning due to the formation of graft polymers of VAc on PVA which still contain a sufficient number of OH groups to ensure its solubility in water. The decrease of the fraction soluble in water, in a later stage, is due to the progress of the grafting process, this leading to the formation of the polymer insoluble in water and benzene.

The change in position of the maximum depending on the experimental conditions may be explained in a similar way. At great initial concentrations of monomer, i.e. small PVA/VAc ratios, a strongly grafted polymer is formed right from the start and in consequence the maximum is shifted towards lower conversions. The situation is different for small initial concentrations of monomer, when grafting occurs with lower rate, the insolubilization of PVA appearing at substantially higher conversions, of 60 to 70%.

It has been observed that, during synthesis, the insoluble fraction increases in all the cases, the increase being more marked in the experiments wherein the $[PVA]_0/[VAc]_0$ ratio is low (figure 6). In these experiments, a decrease of the amount of insoluble polymer has been remarked, during the last reaction stage.

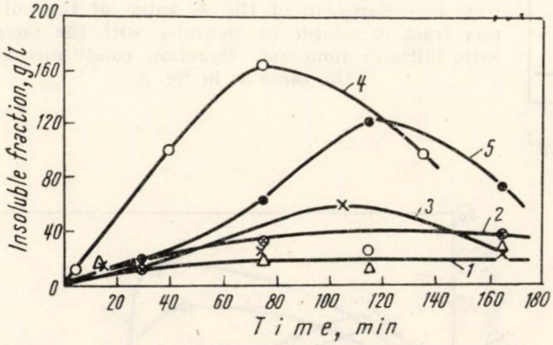

Fig. 6. — Dependence on time of the polymer insoluble fraction in water and benzene. Reaction conditions are the same as in fig. 3.

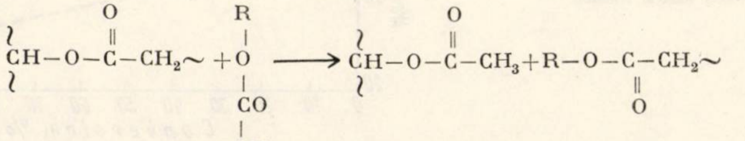
$[VAc]_0$: *1* – 0.5; *2* – 1.0; *3* – 2.0; *4* – 2.72; *5* – 3.44 mole/l.

This decline in the amount of insoluble polymer may be ascribed to cleavage processes in the branched polymer due to transesterification with residual monomer molecules or with acetate groups of the homopolymers of low molecular weight.



$$\underset{\wr}{\overset{\wr}{\mathrm{CH}}}-\mathrm{O}-\overset{\mathrm{O}}{\overset{\|}{\mathrm{C}}}-\mathrm{CH_2}\sim+\underset{\substack{|\\ \mathrm{CO}\\ |\\ \mathrm{CH_3}}}{\overset{\substack{\mathrm{R}\\ |}}{\mathrm{O}}}\longrightarrow\underset{\wr}{\overset{\wr}{\mathrm{CH}}}-\mathrm{O}-\overset{\mathrm{O}}{\overset{\|}{\mathrm{C}}}-\mathrm{CH_3}+\mathrm{R}-\mathrm{O}-\underset{\substack{\|\\ \mathrm{O}}}{\mathrm{C}}-\mathrm{CH_2}\sim$$

To verify the assumption stated, the loss of weight of the insoluble fraction treated with benzene and formic acid (blank-assay) or with benzene, formic acid and ethyl acetate was followed. The same sample was twice treated with ethyl acetate. These results are shown in table 1.

Table 1

Treatment of polymer fraction insoluble in water and benzene with ethyl acetate
Reaction conditions: 0.6 g polymer, 70 g benzene solution of ethyl acetate and 0.5 % HCOOH: 3 hours at 65°C

	Concentration of ethyl acetate %	Loss of weight %
Blank assay	—	0
First treatment	2.5	6.8
Second treatment	2.5	4.2

A determining influence on the development of the polymerization reaction is exerted by the concentration of polyvinyl alcohol. It is a peculiarity of this process, that in the ranges of reactant concentrations studied, the rate of polymerization diminished with the increase of polyvinyl alcohol concentration. This diminishing is the more marked, the lower the monomer concentration.

The data obtained, which are in apparent disagreement with the general theory of emulsion polymerization, according to which the rate of polymerization increases with the raise in emulsifier concentration, can be explained in the following way : the decrease of the rate of reaction with the increase of emulsifier concentration is due to the lower reactivity of the radical being formed as a result of the transfer reaction to PVA. The ratio between the concentrations of the two radical types usually appearing in the reaction medium, i.e. the active VAc radical and the less active PVA radical, will depend upon the relative concentrations of the two reactants PVA and the monomer, the overall number of radicals in the volume unit remaining constant.

In this way, at low monomer concentrations, this ratio will change in favour of inactive radicals and, in consequence, the decrease in the rate of reaction at the same time with the increase of PVA concentration will be the most marked ($R_{\max} \sim [\mathrm{PVA}]_0^{-2.4}$). With the increase of monomer concentration, the concentration of active radicals will proportionally increase, the negative effect of the increase of PVA concentration on the polymerization rate being less marked ($R_{\max} \sim [\mathrm{PVA}]_0^{-0.4}$).

In all cases, the effect of the increase of the polymerization rate with the increase of PVA concentration is marked by these transfer processes which lead to the diminishing of the rate of polymerization.

In order to check this hypothesis, in a separate series of experiments a strong chain — transfer agent (diallyl-ether [11]) was introduced in view of diminishing the importance of the chain-transfer reactions to the emulsifier. Under these conditions, the dependence of the polymerization rate upon PVA concentration is represented by a curve with a maximum (figure 7). Within the range of low PVA concentrations, on the ascending part of the curve, the emulsifier effect of PVA prevails. As the PVA concentration increases above a certain value, the weight of the chain transfer reactions to PVA increases, this having as effect the diminishing of the polymerization rate.

In a paper to be published, the authors found that diallyl ether also shows a retardation effect in the emulsion polymerisation of vinyl acetate in the presence of PVA [12].

When the two variations of the rate of polymerization for the same initial concentration of monomer (2 moles/l) in the absence and in the presence of a chain transfer agent are compared in the latter case the cumulative effect of the two transfer processes is noticed.

The existence of the chain transfer to the emulsifier (PVA) has also been proved by measurements made on the *K* value of the polymer fraction soluble in benzene. The molecular weight of polyvinyl acetate is noticeably influenced by the polyvinyl alcohol concentration (figure 8).

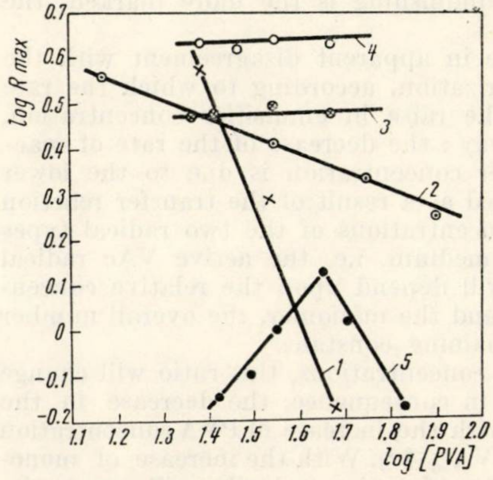

Fig. 7. — Relationship between log R_{max} and log (PVA) for the polymerization of VAc at 63°C.

$[H_2O_2]_0 = 3 \times 10^{-3}$ mole/l; $[FeSO_4]_0 = 5.85 \times 10^{-5}$ mole/l. $[VAc]_0$: *1* – 1.5; *2* – 2.0; *3* – 2.7; *4* – 3.5 mole/l. *5* – – $[VAc]_0$ = 2.0 mole/l and $[\text{diallylether}]_0 = 6 \times 10^{-3}$ mole/l.

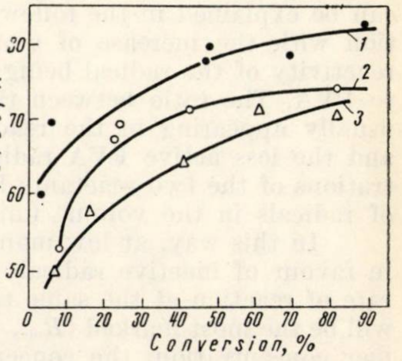

Fig. 8.— Dependence of the *K* value of the polymer fraction soluble in benzene on conversion.

$[VAc]_0$ = 2.0 mole/l; $[H_2O_2]_0 = 3 \times 10^{-3}$ mole/l $[FeSO_4]_0 = 5.85 \times 10^{-5}$ mole/l; temp. 63°C. $[PVA]_0$; *1* – 35.4 g/l; *2* – 56.1 g/l; *3* – 80 g/l.

The reaction order with respect to the initiator (hydrogen peroxide) concentration has a value of 0.5 over the entire range of concentrations investigated. The results are shown in figure 9 and are in good agreement with those found in literature [5,13].

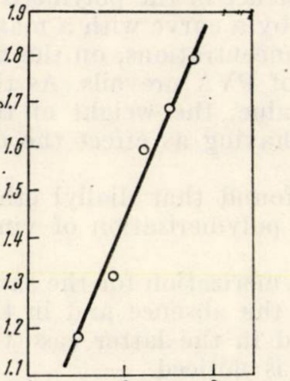

Fig. 9. — Relationship between log R_{max} and log [initiator]

$[VAc]_0$ = 1.5 mole/l; $[APV]_0$ = 35.4 g/l, temp. 63°C. $[H_2O_2]_0$ / $[FeSO_4]_0$ = ct.

As it results from the above mentioned data, in the case of the vinyl acetate polymerization, in the presence of a high molecular weight emulsifier, clear differences are appearing compared to the polymerization with low molecular weight emulsifiers, concerning both the process kinetics and the structure of the polymers formed. These particularities are due both to the frequent transfer reactions to the macromolecular emulsifier and especially to the specific character of the macromolecular aggregates formed in PVA solution [14]. These aggregates, which contain one or more emulsifier molecules, allow the penetration of the monomer into their interior constituting thus the main locus of polymerization.

RESEARCHES IN THE TERPOLYMERIZATION FIELD. IV*.

PRELIMINARY THEORETICAL STRUCTURAL STUDIES OF SOME BINARY COPOLYMERS

ADELAIDA LIGA, I. NEGULESCU and CR. SIMIONESCU
Institute of Macromolecular Chemistry "P. Poni",
Aleea Gr. Ghica Vodă 41 A, Jassy, Romania

Received May 19, 1973

Based on kinetical and probability relationships, the main structural features of some binary vinyl copolymers are presented : distribution of different length sequences, sequence mean length, alternation degree etc.

The copolymerization theory of vinyl monomers was elaborated many years ago [1], being strongly supported by a lot of experimental findings. The majority of these studies referred to the composition of copolymers. Only few papers on the microstructure of macromolecular chains were published, owing to some technical difficulties.

Since the equations predicting the distribution of the sequence length are based on the same supposition as that of the copolymer composition, without any supplementary hypothesis, it is reasonable to consider the computed structural details as correct. The kinetic and statistic studies on the copolymerization led to the already known relationships concerning the existence probability of different kinds of sequences. [1-11]

In this work the results obtained by applying the classical copolymerization theory on some structural parameters of low conversion copolymers such as : acrylonitrile (M_1) — methacrylic acid (M_2), acrylonitrile (M_1) — methyl methacrylate (M_3) and methacrylic acid (M_2) — methyl methacrylate (M_3)[12] are presented.

1. PROBABILITIES OF THE ADDITION TYPES IN THE PROPAGATION STEP

1.1. EXPRESSIONS DERIVED FROM THE CLASSICAL THEORY OF COPOLYMERIZATION

According to the simplest scheme for copolymerization of two monomers M_i and M_j and admitting that the propagation step is a simple Markov process and the macromolecular chain is long enough (without taking into account the effects of initiation and termination steps), the four rates of the chain growth reactions are :

$$\begin{aligned} v_{ii} &= k_{ii}\,[m_i^{\cdot}]\,[M_i] \\ v_{ij} &= k_{ij}\,[m_i^{\cdot}]\,[M_j] \\ v_{jj} &= k_{jj}\,[m_j^{\cdot}]\,[M_j] \\ v_{ji} &= k_{ji}\,[m_j^{\cdot}]\,[M_i] \end{aligned} \tag{1}$$

where $[m_i^{\cdot}]$ and $[m_j^{\cdot}]$ represent concentrations of the growing chain ends of the type M_i and M_j respectively, $[M_i]$ and $[M_j]$ are the initial monomer concentrations.

In terms of these amounts, the probabilities of the four addition types ("conditional" or "transition" probabilities) may be expressed as follows[13] :

$$\begin{aligned} P_{ii} &= \frac{k_{ii}\,[m_i^{\cdot}][M_i]}{k_{ii}\,[m_i^{\cdot}]\,[M_i] + k_{ij}[m_i^{\cdot}]\,[M_j]} = \frac{r_{ij}[M_i]}{r_{ij}\,[M_i] + [M_j]} = \frac{r_{ij}F}{r_{ij}\,F+1} \\ P_{ij} &= \frac{k_{ij}\,[m_i^{\cdot}][M_j]}{k_{ii}\,[m_i^{\cdot}]\,[M_i] + k_{ij}\,[m_i^{\cdot}]\,[M_j]} = \frac{[M_j]}{r_{ij}\,[M_i] + [M_j]} = \frac{1}{r_{ij}\,F+1} \\ P_{ji} &= \frac{k_{ji}\,[m_j^{\cdot}]\,[M_j]}{k_{jj}\,[m_j^{\cdot}]\,[M_j] + k_{ji}\,[m_j^{\cdot}]\,[M_i]} = \frac{[M_j]}{r_{ji}\,[M_j] + [M_i]} = \frac{1}{1+\frac{r_{ji}}{F}} \\ P_{jj} &= \frac{k_{jj}\,[m_j^{\cdot}][M_j]}{k_{jj}\,[m_j^{\cdot}][M_j] + k_{ji}\,[m_j^{\cdot}]\,[M_i]} = \frac{r_{jj}\,[M_j]}{r_{ji}\,[M_j] + [M_i]} = \frac{r_{ji}}{r_{ji}+F} \end{aligned} \tag{2}$$

---

[12] CR. I. SIMIONESCU, N. ASANDEI and A. LIGA, *Makromol. Chem.*, **110**, 278 (1967).

[13] G. GOLDFINGER and T. KANE, *J. Polymer Sci.*, **3**, 462 (1948).

where r_{ij} and r_{ji} are the reactivity ratios of the monomers and F represents initial monomer ratio $[M_i]/[M_j]$.

1.2. THE ADDITION PROBABILITIES BASED ON THE CONVENTIONAL PARAMETER *R*

The run number[10] R is the average number of closed monomer sequences of both types per 100 consecutive monomer units and it may be expressed by :

$$R = \frac{200}{2 + r_{ij}F + \frac{r_{ji}}{F}} \tag{3}$$

Using this parameter, the probabilities of the addition types are as follows :

$$\begin{aligned} P_{ii} &= \frac{[m_i] - R/2}{[m_i]} \\ P_{ij} &= \frac{R}{2\,[m_i]} \\ P_{ji} &= \frac{R}{2\,[m_j]} \\ P_{jj} &= \frac{[m_j] - R/2}{[m_j]} \end{aligned} \tag{4}$$

where $[m_i]$ and $[m_j]$ represent the monomer concentrations in the copolymer.

In tables 1–3 the results concerning the values of the probabilities obtained for the three copolymers by using eqs. (2) and (4) are summarized. The reactivity ratios were[12] :

$$r_{12} = 0.093 \qquad r_{13} = 0.15 \qquad r_{23} = 0.92$$

$$r_{21} = 2.5 \qquad r_{31} = 1.09 \qquad r_{32} = 0.6$$

One can see that by using both eq. (2) and eq. (4) the results are almost identical.

2. THEORETICAL DISTRIBUTION OF DIFFERENT LENGTH SEQUENCES

In order to determine the distribution function of different length sequences, one has to mind that for the appearance of a sequence of -n- "m_i" units, the addition reaction of M_i to the growing chain C

$$C - m_i^{\cdot} + M_i \tag{5}$$

(the probability of which is P_{ii}) must be repeated for $(n - 1)$ times. The probability of these $(n - 1)$ successive additions is P_{ii}^{n-1}. This sequence is interrupted by the addition of a M_j unit, with P_{ij} probability, or $(1 - P_{ii})$ respectively. The probability that a sequence of m_i should contain -n- terms (or the fraction of all the sequences constituted from -n- terms) is[14] then:

$$P(m_i)_n = P_{ii}^{n-1} \cdot (1 - P_{ii})$$

and (6)

$$P(m_j)_n = P_{jj}^{n-1} \cdot (1 - P_{jj})$$

The distribution functions of different length sequences, evaluated by eq. (6) for the three copolymers, are recorded in tables 4–6.

---

[14] T. Alfrey and G. Goldfinger, *J. Chem. Phys.*, **12**, 322 (1944).

One can point out, as a general remark, that the existence probability of long m_i sequences increases with the content of M_i monomer in the copolymer composition.

3. DISTRIBUTION OF MONOMER UNITS IN DIFFERENT LENGTH SEQUENCES

From all units of a certain type (m_i) in a very long chain, the molar fraction of "n" length sequences is [6]:

$$\varphi(m_i, n) = \frac{nP(m_i)_n}{\sum_{n=1}^{\infty} nP(m_i)_n} = \frac{nP_{ii}^{n-1} \cdot P_{ij}}{\sum_{n=1}^{\infty} nP_{ii}^{n-1} \cdot P_{ij}} \tag{7}$$

which finally becomes

$$\varphi(m_i, n) = \frac{nP_{ii}^{n-1} \cdot (1 - P_{ii})}{1/P_{ij}} = nP_{ii}^{n-1}(1 - P_{ii})^2 \tag{8}$$

and respectively

$$\varphi(m_j, n) = nP_{jj}^{n-1}(1 - P_{jj})^2 \tag{9}$$

One can also see from the above tables that at a high content of a certain monomer in copolymers (i.e., over 50%), the most part of that monomer units appears in superunitary sequences

$$(n > 1).$$

3.1. DISTRIBUTION OF MONOMER UNITS IN COMPOSITIONAL TRIADS

In a binary copolymer with M_i and M_j units, each monomer may be the center of some triads of the type $M_iM_iM_i$, $M_jM_iM_i$ ($M_iM_iM_j$) or $M_jM_iM_j$ in the case of M_i and $M_jM_jM_j$, $M_jM_jM_i$ ($M_iM_jM_j$) or $M_iM_jM_i$ in the case of M_j, respectively. The molar fractions of these monomer units from the center of the triads are given by [3]:

$$\begin{aligned} F_{iii} &= P_{ii}^2 \\ F_{jjj} &= P_{jj}^2 \end{aligned} \tag{10}$$

$$\begin{aligned} F_{jii}(F_{iij}) &= 2P_{ii}(1 - P_{ii}) \\ F_{ijj}(F_{jji}) &= 2P_{jj}(1 - P_{jj}) \end{aligned} \tag{11}$$

$$\begin{aligned} F_{jij} &= (1 - P_{ii})^2 \\ F_{iji} &= (1 - P_{jj})^2 \end{aligned} \tag{12}$$

The F_{iii}, F_{jii} and F_{jij} functions of the above binary copolymers are plotted in figure 1 for different initial compositions.

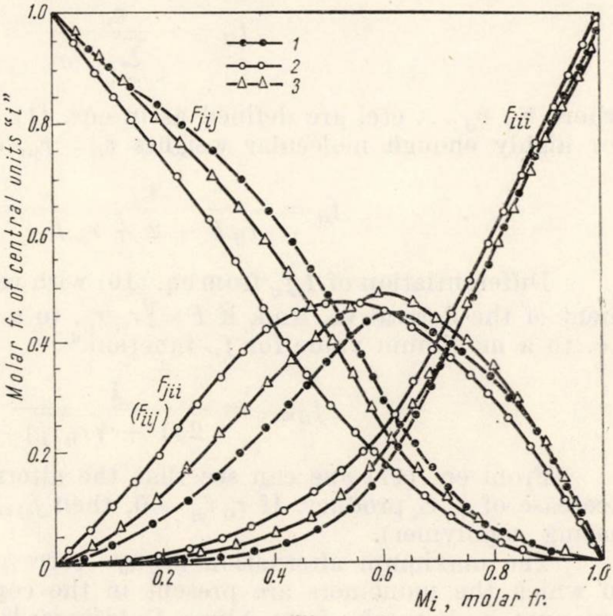

Fig. 1.— Molar fraction of central -*i*- units in compositional triads *versus* the monomer content in the feed ($i \neq j$; i, $j = 1, 2, 3$).
1 – acrylonitrile (1)-methacrylic acid (2) copolymer *2* – acrylonitrile (1)methyl methacrylate (3) copolymer *3* – methacrylic acid (2)-methyl methacrylate (3) copolymer.

4. MEAN SEQUENCE LENGTH

The number-average length of sequences can be defined as [9]:

$$\mu_i = \sum_{n=1}^{\infty} nP(m_j\, m_i^n\, m_j) / \sum_{n=1}^{\infty} P(m_j\, m_i^n\, m_j) \tag{13}$$

where $P(m_j m_i^n m_j)$ is the appearance probability of a sequence composed of $(n + 2)$ units, i.e., of a sequence composed of -n- units of m_i having one m_j unit at each extremity. Finally, for any statistical chain of m_i and m_j units, eq. 13 takes the forms:

$$\begin{aligned} \mu_i &= 1/P_{ij} \\ \mu_j &= 1/P_{ji} \end{aligned} \tag{14}$$

According to eqs. (14), the shortest average length of a sequence is 1 (one monomer unit), a case which characterizes the copolymers with a reduced content of the monomer concerned (tables 4–6).

5. ALTERNATION DEGREE OF THE COPOLYMERS

As measure of the alternation of the monomer units in a given copolymer, the fraction of bonds between nonidentical monomer units can be taken (f_{ij}). The alternation is highest when this fraction is maximum. The f_{ij} function can be expressed by:

$$f_{ij} = \frac{v_{ij}}{\sum\limits_{i,\, j=1,\, 2} v_{ij}} \tag{15}$$

where v_{ii}, v_{ij} ... etc. are defined as in eqs. (1). Finally, considering that for highly enough molecular weights $v_{ij} = v_{ji}$, eq. (15) becomes:

$$f_{ij} = \frac{1}{r_{ij}F + 2 + r_{ji}/F} = f_{ji} \tag{16}$$

Differentiation of $1/f_{ij}$ from eq. (16) with respect to F and the annulment of the derivative, lead, if $F = \sqrt{r_{ji}/r_{ij}}$, to a minimum value for $1/f_{ij}$, i.e. to a maximum value for f_{ij} function[6]:

$$f_{ij\,\text{max.}} = \frac{1}{2\,(1 + \sqrt{r_{ij}\,r_{ji}})} \tag{17}$$

From eq. (17) one can see that the alternation increases with the decrease of $r_{ij}\,r_{ji}$ product. If $r_{ij}\,r_{ji} \to 0$, then $f_{ij\,\text{max.}} = 0.5$ (perfectly alternating copolymer).

The maximum alternation always corresponds to the composition in which the monomers are present in the copolymer in equimolecular amounts, as it results from Alfrey-Goldfinger[15] and Mayo-Lewis's equation[16].

The corresponding alternation degrees of our copolymers are presented in fig. 2.

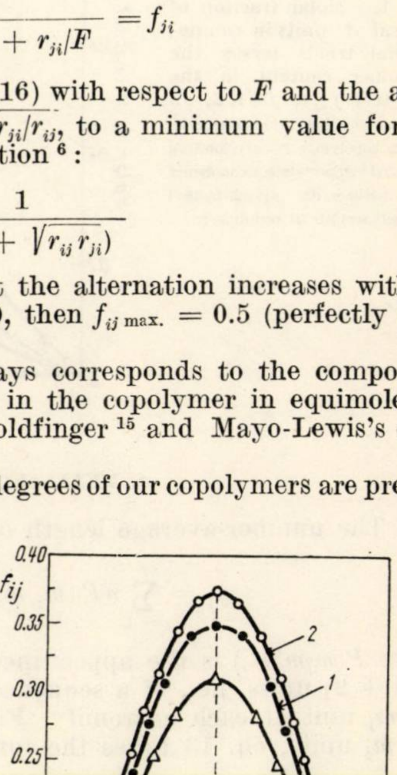

Fig. 2. — Alternation degrees (f_{ij}) — composition (M_i) dependence in the copolymers

1 – acrylonitrile(1)-methacrylic acid(2) copolymer
2 – acrylonitrile(1)-methyl methacrylate(3) copolymer
3 – methacrylic acid(2)-methyl methacrylate(3) copolymer.

---

[15] T. Alfrey and G. Goldfinger, *J. Chem. Phys.*, **12**, 205 (1944).

[16] F. R. Mayo and F. M. Lewis, *J. Amer. Chem. Soc.*, **66**, 1594 (1944).

The values of $f_{12\max.}$ and $f_{13\max.}$ (0.33 and 0.35, respectively) show that in equimolar acrylonitrile (1) — methacrylic acid (2) and acrylonitrile (1) — methyl methacrylate (3) copolymers, the four types of bonds do not appear with equal percentage (the addition of the other monomer being preferred in the case of acrylonitrile radical). The values of $f_{23} = 0.29$ for methacrylic acid (2) — methyl methacrylate (3) copolymer suggests somewhat equal rates for the four addition types of the propagation step.

The experimental check of a part of these calculations, by the NMR spectroscopy data, will be presented in a subsequent work.

STUDIES ON THE POLYMER + PLASTICIZER MEMBRANE-ELECTRODE. XI*.

INFLUENCE OF THE PLASTICIZER OF THE PVC ON ITS ELECTRODE BEHAVIOUR

ELENA HOPÎRTEAN, C. LITEANU and ANA MAŞA
"Babeş-Bolyai" University, Chair of Analytical Chemistry,
str. Arany János 11, Cluj, Romania

Received June 15, 1973

The paper deals with E-pH electrode functions as well as the results obtained at the acid-base potentiometric titration, using for indicating electrode the PVC-membrane plastified by a series of plasticizers : dibutylphthalate, dioctylphthalate, diisooctylphthalate, C_7-C_9 phthalate, $C_{10}-C_{11}$ phthalate, dibutylsebacate, diisooctylsebacate, benzylbutylphthalate and bis (2-ethylhexyl) phthalate. The accuracy of the titrations is expressed in comparison with the results obtained with the glass electrode.

A series of former papers have dealt with the obtention, [1] the analytical evaluation [2-8] and the working mechanism [9] of the PVC-tricresylphosphate membrane-electrode. We have shown that the plasticizer is the active electrode component of this type of membranes. [9,10] The paper aims to extend this study to the electrode behaviour of the PVC-membrane according to the plasticizer used. The $E-$pH electrode functions were established for different plasticizers (dibutylphthalate, dioctylphthalate, dibutylsebacate, etc.) and the membrane-electrodes obtained in the acid-base potentiometric titration were turned to account.

EXPERIMENTAL

1. OBTENTION OF MEMBRANE-ELECTRODES

The PVC-membranes plastified with : dibutylphthalate, dioctylphthalate, diisooctylphthalate, C_7-C_9 phthalate, $C_{10}-C_{11}$ phthalate, dibutylsebacate, diisooctylsebacate, benzylbutylphthalate and bis (2-ethylhexyl) phthalate, were obtained according to the procedure described in a former paper [1]. The membrane-electrodes were obtained by attaching the membranes in bubble form at the end of a glass tube using 10^{-3} N HCl for inner solution and a saturated calomel electrode (SCE) as inner reference electrode.

2. *E*-pH ELECTRODE FUNCTION.

Using the MV–11 pH-meter, we have measured the e.m.f. of the following electrolytic chain :

SCE | inner solution | membrane | test solution | SCE

We have made use, as standard test solutions, of solutions with different pH, of HCl–KC and KOH–KCl, of a constant ionic strength ($J = 0.1$ M). The pH of the test solutions was meaured with the glass electrode. The *E*-pH dependence, i.e. the electrode function, was provedl or each membrane-electrode. Figure 1 gives the electrode functions obtained for the membranes with C_7-C_9 phthalate and $C_{10}-C_{11}$ phthalate for plasticizers, as well as the electrode function of the tricresylphosphate membrane. [2]

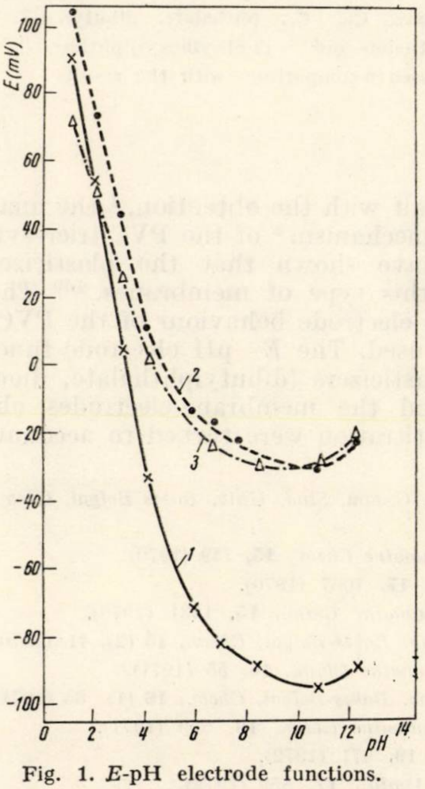

Fig. 1. *E*-pH electrode functions.
1, PVC-tricresylphosphate ; *2*, PVC – C_7-C_9 phthalate ; *3*, PVC – $C_{10}-C_{11}$ phthalate.

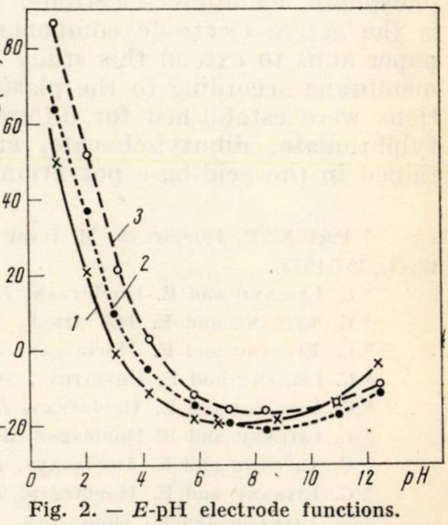

Fig. 2. — *E*-pH electrode functions.
1, PVC-dibutylphthalate ; *2*, PVC-dioctylphthalate ; *3*, PVC-diisooctylphthalate.

In the 1–4.5 and 6.5–12.5 pH intervals, the sensitivity of the two phthalates towards the H^+ ions is comparable to that of tricresylphosphate, and lower than this in the 4.5–6.5 pH interval. Figure 2 gives the electrode functions of the membranes obtained with the following plasticizers: dibutylphthalate, dioctylphthalate and diisooctylphthalate. The slope of these electrode functions has noticeable values (20–22 mV/pH) in the 1–4.5 pH interval. We must meanwhile point out, as in the case of the electrode functions in figure 1, the sign change of the electrode function slope in the alkaline domain. The electrode obtained with diisooctylsebacate has shown a similar electrode behaviour. The PVC-membrane plasticized with benzylbutylphthalate, bis (2-ethylhexyl) phthalate and dibutylsebacate have shown a less pronounced electrode behaviour.

3. ACID-BASE POTENTIOMETRIC TITRATIONS

3.1. *HCl titration with KOH.* The titration curves obtained are given in figures 3 and 4. In every case, the equivalence points are marked by a clear potential jump, the behaviour of membranes with C_7-C_9 phthalate and $C_{10}-C_{11}$ phthalate being outstanding.

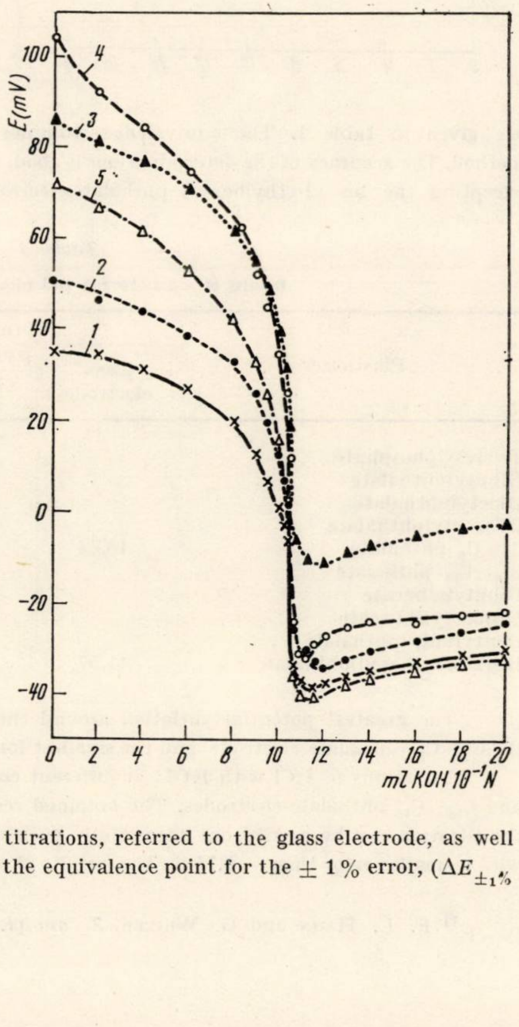

Fig. 3. — Titration of $\sim 3.3 \times 10^{-2}$N HCl with 10^{-1}N KOH.
1, **PVC-dibutylphthalate**; *2*, **PVC-dioctylphthalate**; *3*, **PVC-diisooctylphthalate**; *4*, **PVC – C_7 – C_9 phthalate**; *5*, **PVC-C_{10}–C_{11} phthalate.**

The data about the accuracy of the titrations, referred to the glass electrode, as well as the size of the potential variation around the equivalence point for the ± 1% error, ($\Delta E_{\pm 1\%}$

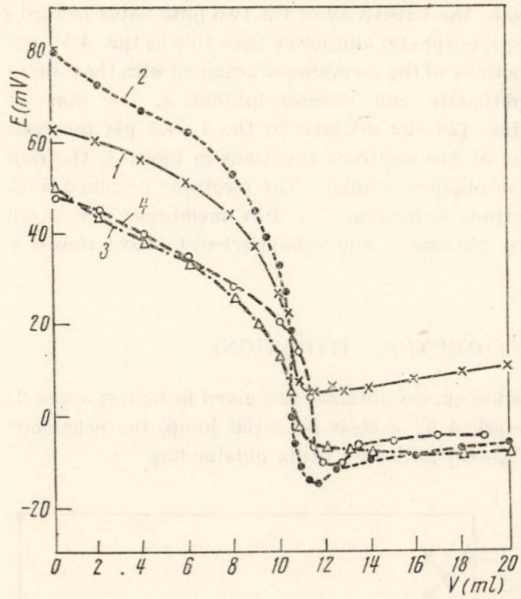

Fig. 4. — Titration of $\sim 3.3 \times 10^{-2}$N HCl with 10^{-1}N KOH.

1, PVC-dibutylsebacate; *2*, PVC-diisooctylsebacate; *3*, PVC-benzylbutylphthalate; *4*, PVC-bis(2-ethylhexyl)phthalate.

are given in table 1. The equivalence volumes were calculated by the Hahn-Weiler[11] method. The accuracy of the determinations is good, the recorded errors being less than − 0.5 %, excepting the bis (2-ethylhexyl) phthalate-electrode.

Table 1

Results of $\sim 3.3 \times 10^{-2}$ N HCl with 10^{-1} N KOH titration

Plasticizer	V_e (ml) glass electrode	V_e (ml) PVC + plasticizer membrane-electrode	Error (%)	$\Delta E_{\pm 1\%}$ (mV)
Tricresylphosphate	10.64	10.62	−0.19	79
Dibutylphthalate		10.61	−0.28	23
Dioctylphthalate		10.62	−0.19	27
Diisooctylphthalate		10.59	−0.45	28
C_7-C_9 phthalate		10.61	−0.28	50
$C_{10}-C_{11}$ phthalate		10.61	−0.28	30
Dibutylsebacate		10.61	−0.28	13
Diisooctylsebacate		10.61	−0.28	25
Benzylbutylphthalate		10.59	−0.45	8
Bis(2-ethylhexyl)phthalate	11.57	11.34	−1.10	11

The greatest potential variation around the equivalence point (50 mV) was recorded for the C_7-C_9 phthalate-electrode and the smallest for the benzylbutylphthalate-electrode (8 mV).

Titrations of HCl with KOH at different concentrations were carried out using C_7-C_9 and $C_{10}-C_{11}$ phthalate-electrodes. The obtained results are given in table 2. It is found that the titration can be carried out successfully even at an acid concentration of $\sim 3.3 \times 10^{-4}$ N, with a smaller error than − 0.75 %. The results of a HCl with KOH titration carried out in the

	$\sim 3.3\times 10^{-4}$N	10^{-3}N	8.35	8.33	−0.24	6

CONCLUSIONS

The study carried out shows that the following plasticizers have a good electrode behaviour : dibutylphthalate, dioctylphthalate, diisooctylphthalate, C_7-C_9 phthalate, $C_{10}-C_{11}$ phthalate, and diisooctylsebacate, while the membranes plasticized with dibutylsebacate, benzylbutylphthalate and bis(2-ethylhexyl)phthalate have less pronounced electrode properties. We have found that the nature of the ester acid, as well as that of the alcohol, influences the electrode behaviour.

The response speed of all the electrodes is very good(3—4 seconds), a fact allowing their use in automatic acid-base potentiometric titrations.

NOTE POUR LES AUTEURS

La *Revue Roumaine de Chimie* publie des articles en anglais, français, russe, allemand ou espagnol. Les auteurs sont priés d'envoyer des articles, notes, communications et comptes rendus inédits.

Les manuscrits seront dactylographiés à deux intervalles. Les tableaux seront dactylographiés sur feuilles séparées, de même que la légende des figures. Les diagrammes seront tracés à l'encre de Chine sur papier calque. Les tableaux et les figures seront numérotés par des chiffres arabes, en nombre strictement nécessaire. Prière de ne pas inscrire les mêmes données dans les tableaux et les figures. Les formules chimiques seront incluses dans le texte ; en outre, elles seront transcrites sur des feuilles séparés. Les auteurs sont priés d'indiquer les caractères italiques (en soulignant les lettres au crayon), ainsi que tout autre caractère spécial. L'ordre des références bibliographiques sera celui de leur mention dans le texte ; le nom de l'auteur sera précédé de l'initiale du prénom ; les publications périodiques seront présentées suivant les prescriptions internationales. Les références seront ajoutées à la fin de l'article ; elles paraîtront comme des notes, au bas de la page. Le texte sera précédé d'un résumé comprenant 15 lignes au maximum.

L'entière responsabilité du contenu des articles appartient aux auteurs. On publie des articles dus aux collaborateurs roumains ou étrangers. Les auteurs recevront 50 tirés à part.

KINETICS AND MECHANISM OF DIPHENYLDIAZOMETHANE RADIOLYSIS IN BENZENE SOLUTION

TATIANA ONCESCU and MIHAI CONTINEANU

Department of Physical Chemistry, University of Bucharest,
Bd. Republicii 13, Bucharest, Romania

Received October 3, 1973

The kinetics of diphenyldiazomethane radiolysis in benzene solution shows that the reaction order varies with the concentration of the solution. It was thus established that the mechanism involving energy transfer from excited benzene molecules to diphenyldiazomethane molecules is predominant in dilute solutions while a direct interaction of radiations with the substance occurs in concentrated solutions.

In his radiochemical studies, Dainton[1] reported in 1965 the fact that excited solvent molecules, capable of activating the molecules of the dissolved substances by energy transfer, also participate in some solutions irradiated, besides the radicalar and ionic mechanism, which is typical of radiochemical reactions. The present paper deals with a system which confirms such a behaviour.

EXPERIMENTAL

Diphenyldiazomethane benzene solutions of various concentrations (10^{-3}, 4.12×10^{-3} 2×10^{-2}, 0.1 and 1 moles/l were irradiated, using a 15 Ci (Co^{60}) radiation source. A 15 Ci and a 10,000 Ci Co^{60} source was used for the concentration of 3 moles/l respectively for the solid samples. Dosimetry was performed by means of a Fricke dosimeter [2-4] and the energies obtained are presented in table 1.

A UNICAM SP 800 spectrophotometer was used for measuring the absorbance of the irradiated solutions at $\lambda = 540$ nm (in the diphenyldiazomethane absorption band) which permitted the determination of the solution concentration after each irradiation time, knowing the absorption molar coefficient ($k_{540} = 94$). Diphenyldiazomethane was prepared by oxidizing the appropriate hydrazone according to the method indicated in the literature.[5]

Table 1

The dose calculation by the Fricke dosimeter method

Initial concentration moles/l	10^{-3}	4.12×10^{-3}	2×10^{-2}	0.1	1	3
Volume of the irradiated solution (cm^3)	12	6	2.5	1	1	0.5
Dose eV/g.min	1.0×10^{17}	1.77×10^{17}	2.03×10^{17}	2.5×10^{17}	2.5×10^{17}	5.5×10^{17}

RESULTS AND DISCUSSION

No significant differences were found by irradiating solid diphenyldiazomethane at a 15 Ci source (a temperature of 20°) for a long period of time (96 hours), dissolving subsequently the sample in benzene and measuring its absorption in both visible and ultraviolet, compared to the nonirradiated reference sample. This shows that the solid phase radiolysis occurs at a very reduced, almost negligible rate on irradiation at this dose.

However, diphenyldiazomethane in benzene solution, irradiated at a temperature of 20°, decomposes more rapidly as the solution becomes more dilute, as follows below.

Solutions having concentrations of 10^{-3} and 4.12×10^{-3} moles/l that is, the most dilute ones within the range of concentrations being prepared, verify a first-order kinetics. As an example, table 2 reflects the values of the rate constants obtained for solutions having a concentration of 10^{-3} moles/l.

Table 2

Unimolecular rate constant and radiochemical yield for the radiolysis of dilute solutions

t min	ε	$C \times 10^3$ moles/l	$k_1 \times 10^5$ s^{-1}	G

900	0.05	0.132	3.85	0.60

$(k_1)_a = 3.66 \times 10^{-5}$

$A^{\frac{1}{2}}$ order-kinetics is verified on irradiation of more concentrated solutions : 2×10^{-2}, 10^{-1} and 1 moles/l. A solution with a concentration of 10^{-1} moles/l is presented in table 3.

Table 3

Fractionary rate constant and radiochemical yield characteristic for the radiolysis of the moderate concentration solutions

t min	ε	$C \times 10^3$ moles/l	$k_{\frac{1}{2}} \times 10^7$ moles$^{\frac{1}{2}}$/l$^{\frac{1}{2}}$s^{-1}	G
0	1.90	101.0	—	—
900	1.44	76.6	1.52	6.4
1470	1.19	63.3	1.49	6.05
1770	1.05	55.9	1.53	6.02
2880	0.69	36.7	1.46	5.26
4320	0.28	14.9	1.51	4.72

$(k_{\frac{1}{2}})_a = 1.49 \times 10^{-7}$

In order to study the radiolysis both in highly concentrated solutions 3 moles/l and in the solid substance, we used a stronger source, namely a 10,000 Ci one. In this case, decomposition occurs according to a first-order kinetics.

Table 4 shows the rate constant radiolysis in the case of a 3.12 moles/l diphenyldiazomethane solution and table 5 refers to the solid state.

Table 4

Unimolecular rate constant for the radiolysis of concentrated solutions

t hours	C moles/l	$k_1 \times 10^6$ s^{-1}
0	3.08	—
48	2.25	1.80
72	1.94	1.78
76	1.83	1.90
97	1.65	1.78
123	1.54	1.57
146	1.36	1.55
148	1.34	1.56
169.5	1.27	1.45
220	0.95	1.48

$(k_1)_a = 1.65 \times 10^{-6}$ s^{-1}

Table 5

Unimolecular rate constant of the radiolysis in the solid state

t hours	$C \times 10^2$ moles/l	$k_1 \times 10^6$ s^{-1}
0	5.0	
71.5	3.3	1.64
95	2.77	1.73
121	2.2	1.89
144	1.7	2.12
162	1.62	1.93
168	1.59	1.88
189.5	1.38	1.88
191.5	1.14	2.13

$(k_1)_a = 1.85 \times 10^{-6}$

The last column in tables 2, 3 and 4 refers to the values of the chemical yields calculated by the relation:

$$G = \frac{\Delta C}{I} 100$$

where ΔC is the concentration diminution (the number of converted moles/cm³) and I is the dose in eV/cm³.

The reaction final products resulting from the radiolysis of the concentrated solutions were identified by IR spectra as being benzophenone and benzophenonazine.

Benzophenone, revealed by the presence of $\rangle C = O$ frequency at 1665 cm^{-1}, forms in small amounts by benzophenonazine, the predominant final product, for reasons shown in a previous paper [6].

The same reaction products, benzophenonazine and benzophenone, were also isolated by irradiating a 3.12 moles/l concentrated solution. The melting point (164°) determined for benzophenonazine, was identical to that indicated in the literature. Thus, in accordance with these final products obtained by irradiation, the total reaction may be the following :

$$(C_6H_5)_2 - CN_2 \overset{\gamma}{\rightsquigarrow} (C_6H_5)_2 - C = N - N = C - (C_6H_5)_2 + (C_6H_5)_2CO + N_2$$

Three reaction mechanisms were developed in respect of the concentration of the irradiated solution.

a) DILUTE SOLUTIONS

In this case it is assumed that the reaction takes place by means of the excited benzene molecules formed by interaction with radiations. It is therefore an indirect mechanism.

---

[6] T. Oncescu, M. Contineanu and G. Bălăceanu, *Rev. Roumaine Chim.*, **17**, 213 (1972).

Let us denote the benzene molecules by B ; the interaction between γ radiations and benzene may be illustrated as follows :

$$B \overset{\gamma}{\rightsquigarrow} B^{+} + e^{*}.$$

The resulting electron loses its energy on the way causing at the same time the triplet-state excitation of the encountered benzene molecules[7-10] so that, at a certain distance of B^{+} the electron becomes thermalized (e_t)

$$B + e \rightarrow B^{T} + e_t$$

The coulombian interaction between the parent ion and the thermalized electron is sizeable due to the small dielectric constant (non-polar) so that this electron will very likely be recaptured by the positive ion, leading again to triplet-state excited benzene molecules

$$B^{+} + e_t \rightarrow B^{T}$$

The latter either transfer their energy to the dissolved diphenyldiazomethane molecules which decompose, or become extinct through collision with similar molecules. Under these conditions, the following processes are very probable :

$$4B \overset{k_0 I}{\rightsquigarrow} 4B^{T} \tag{a}$$

$$4D \overset{k_0' I}{\rightsquigarrow} 4D^{T} \tag{b}$$

$$D \overset{k_0'' I}{\rightsquigarrow} R + N_2 \tag{c}$$

$$2B^{T} \xrightarrow{k_1} 2B \tag{d}$$

$$B^{T} + B \xrightarrow{k_2} 2B \tag{e}$$

$$B^{T} + D \xrightarrow{k_3} B + D^{T} \tag{f}$$

$$2D^{T} \xrightarrow{k_4} 2D \tag{g}$$

$$D^{T} + D \xrightarrow{k_5} 2D \tag{h}$$

[9] M. Inokuti, *Isotopes and Radiation*, **1**, 82 (1958).

[10] W. G. Burns, R. B. Cundall, P. A. Griffiths and W. R. Marsh, *Trans. Faraday Soc.*, **64**, 129 (1968).

$$D^T + B \xrightarrow{k_6} D + B \tag{i}$$

$$D^T \xrightarrow{k_7} R + N_2 \tag{j}$$

$$R + D \xrightarrow{k_8} C \tag{k}$$

$$R + O_2 \xrightarrow{k_9} RO_2 \tag{l}$$

$$RO_2 + D \xrightarrow{k_{10}} B_z \tag{m}$$

where D, C, B_z represent the diphenyldiazomethane, benzophenonazine and benzophenone molecules, respectively, and R and CO_2 are the radicals $(C_6H_5)_2\dot{\underset{\cdot}{C}}$ and $(C_6H_5)_2CO_2$.

The reaction rate of the diphenyldiazomethane radiolysis is written :

$$\frac{dC_D}{dt} = -4k_0' I C_D - k_0'' I C_D - k_3 C_{B^T} C_D + 2k_4 C_{D^T} + k_5 C_{D^T} C_D + \\ + k_6 C_{D^T} C_B - k_8 C_R C_D - k_{10} C_{RO_2} C_D \tag{1}$$

By applying the approximation according to which the intermediate concentrations of D^T, B^T, R, RO_2 are stationary, we obtain :

$$\frac{dC_{D^T}}{dt} = 4k_0' I C_D + k_3 C_{B^T} C_D - 2k_4 C_{D^T} - k_5 C_{D^T} C_D - k_6 C_{D^T} C_B - k_7 C_{D^T} = 0 \tag{2}$$

$$\frac{dC_{B^T}}{dt} = 4k_0 I C_B - 2k_1 C_{B^T} - k_2 C_{B^T} C_B - k_3 C_{B^T} C_D = 0 \tag{3}$$

$$\frac{dC_R}{dt} = k_0'' I C_D + k_7 C_{D^T} - k_8 C_R C_D - k_9 C_R C_{O_2} = 0 \tag{4}$$

$$\frac{dC_{RO_2}}{dt} = k_9 C_R C_{O_2} - k_{10} C_{RO_2} C_D = 0 \tag{5}$$

By adding up (1) with (2) and subtracting (4), it results :

$$\frac{dC_D}{dt} = -2k_0'' I C_D - 2k_7 C_{D^T} \tag{6}$$

From (3) we obtain:

$$C_{B^T} = \frac{4k_0 IC_B}{2k_1 + k_2C_B + k_3 C_D} \tag{7}$$

which, introduced in (2), leads to:

$$C_{D^T} = \frac{4k_0' IC_D (2k_1 + k_2C_B + k_3C_D) + 4k_0k_3IC_B C_D}{(2k_1 + k_2 C_B + k_3 C_D)(2k_4 + k_5 C_D + k_6 C_B + k_7)} \tag{8}$$

By introducing relations (7) and (8) in (1), we obtain:

$$\frac{\mathrm{d}C_D}{\mathrm{d}t} = -2k_0 IC_D - 2k_7 \frac{4k_0' I C_D (2k_1 + k_2C_B + k_3C_D) + 4k_0 k_3 IC_B C_D}{(2k_1 + k_2C_B + k_3C_D)(2k_4 + k_5 C_D + k_6C_B + k_7)} \tag{9}$$

In the case of dilute solutions, processes (b) and (c), which refer to the direct interaction of diphenyldiazomethane molecules with the radiation are negligible and (g) and (h), concerning the deactivation of excited diphenyldiazomethane molecules, are also highly improbable compared to the other processes in the considered sequence, that is:

$$k_3C_D \ll 2k_1 + k_2C_B$$

$$k_5 C_D + 2k_4 \ll k_6 C_B + k_7$$

Under these conditions, equation (9) becomes:

$$-\frac{\mathrm{d}C_D}{\mathrm{d}t} = 2k_7 \frac{4k_0 k_3 IC_B C_D}{(2k_1 + k_2 C_B)(k_6 C_B + k_7)} = K C_D \tag{10}$$

that is the differential equation of a first-order reaction.

Our experimental results, as reflected in table 2, confirm such a kinetics. Also, equation (10) accounts for the fact that the radiolysis in a dilute solution depends on the excitation of solvent molecules (a) and on its energy transfer on diphenyldiazomethane molecules which become decomposed (f) and (j).

b) CONCENTRATED SOLUTIONS AND SOLIDS

This case rules out the processes involving the solvent molecule, namely: (a), (d), (e), (f) and (i) which simplify equation (9), where, if condition

$$2k_5 C_D \ll 2k_4 + k_7$$

is formed, we obtain:

$$-\frac{\mathrm{d}C_D}{\mathrm{d}t} = \left(2k_0'' I + 2k_7 \frac{4k_0' I}{2k_4 + k_7}\right) C_D \tag{11}$$

It results from this equation that the reaction rate is proportional to the concentration of diphenyldiazomethane as required by the first-order kinetic equation, verified by the rate constant presented in table 4.

This equation also shows that the reaction depends primarily on the direct interaction of radiations with diphenyldiazomethane molecules. The same behaviour is obtained by studying the radiolysis of the solid substance (table 5). It must be pointed out that a dependence of C_D concentration on t was found when irradiating a very concentrated solution (3.12 moles/l) or the solid state, as it results from figure 1.

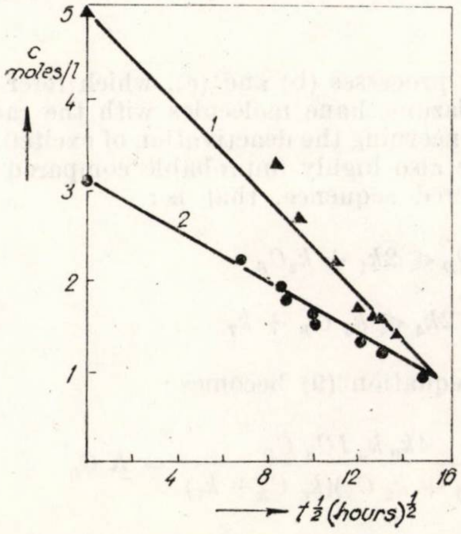

Fig. 1. — Plotting of the diphenyldiazomethane concentration versus $t^{1/2}$: *1*, for a 3.42 moles/l solution; *2*, for a solid sample.

Such a dependence suggests also the concomitant existence in kinetic handling, of a diffusion process which we have not implied. This may account for the larger error factors found in determining the rate constant in these situations (25–30%) compared to those determined in more dilute solutions (5–12%).

c) INTERMEDIATE CONCENTRATION SOLUTIONS

The results of the study performed for solution with an intermediate concentration which verify a 1/2 order kinetics (table 2) are presented in table 6.

The second column gives the times corresponding to a 65% conversion, which increase with the diphenyldiazomethane concentration.

Table 6

The constancy of the $k_{1/2}$ rate constant for the range of moderate concentrations solutions

t hours	C moles/l	$k_{\frac{1}{2}} \times 10^6$ $\text{moles}^{\frac{1}{2}}\ \text{l}^{\frac{1}{2}}\ \text{s}^{-1}$
163	1	1.25
58	10^{-1}	1.49
24	2×10^{-2}	1.44

In column 3, which presents the mean values of k rate constants, the rate constant is noticed as remaining practically constant although the concentration varied 50 times. This may be explained by the fact that the number of excited molecules increases correspondingly with the increase in the concentration of diphenyldiazomethane. At the same time the deactivation of the excited molecules clustered along the trajectories of the secondary electrons is favoured. As a result of the action of these two antagonistic processes, the rate constant does not vary with the initial concentration, which forces us to admit that processes (b) and (g) are in equilibrium :

$$2\text{D} \underset{k_4}{\overset{k_0' I}{\rightleftarrows}} 2\text{D}^{\text{T}}$$

where from results the equality :

$$2k_0' I C_D = k_4 C_{D^T}^2$$

whence :

$$C_{D^T} = \left(\frac{2k_0' I}{k_4}\right)^{1/2} C_D^{1/2} \tag{12}$$

If (12) is introduced in (6), it results :

$$\frac{dC_D}{dt} = -\,2\,k_0''\,IC_D - 2k_7\left(\frac{2k_0' I}{k_4}\right)^{1/2} C_D^{1/2} \tag{13}$$

This equation justifies the $\frac{1}{2}$ reaction order verified by our experimental data, if the first term, which refers to the formation of radicals by direct interaction between molecules and the radiation (process c) is neglected. This result shows that the radiolysis of a benzene solution of diphenyldiazomethane in this range of concentration 2×10^{-2}—1 moles/l occurs mainly owing to the excited diphenyldiazomethane molecules resulted both from direct interaction (b) and from the process involving energy transfer (f).

RADIOLYSIS OF THE COMPLEX OXALATES IN AQUEOUS SOLUTIONS. III [1,2]

THE INFLUENCE OF SOME OH SCAVENGERS ON THE RADIOLYSIS OF POTASSIUM TRISOXALATOCOBALTATE IN NEUTRAL AQUEOUS SOLUTION

J. PĂUN and TATIANA MEMETEA

University of Bucharest, Radiation Chemistry Laboratory, Bd. Republicii 13, Bucharest

Received October 10, 1973

The influence of some OH free radical scavengers such as Br^- and SCN^- ions and aliphatic alcohols on the radiochemical decomposition yield $G(-[Co(C_2O_4)_3]^{3-})$ in neutral aqueous solution has been studied. The presence of *t*-butyl alcohol in a concentration up to 0.1 M does not change the $G(-[Co(C_2O_4)_3]^{3-})$ value, suggesting that OH free radical does not take part in the radiolytic process of $[Co(C_2O_4)_3]^{3-}$ ion. The Br^- and SCN^- ions added to the solution strongly decrease the $G(-[Co(C_2O_4)_3]^{3-})$ yield due to the oxidation of cobaltous complex ion formed from the radiolysis of cobaltic complex, by the Br and SCN radicals : $X^- + OH \rightarrow$ $\rightarrow X + OH^- (X^- = Br^-, SCN^-)$; $[Co(C_2O_4)_2]^{2-} + X\cdot \xrightarrow{C_2O_2^{4-}} [Co(C_2O_4)_3]^{3-} + X^-$.

In previous papers [1,2] we investigated the radiolysis of potassium trisoxalatocobaltate in aqueous solutions in various conditions. The predominant process in the decomposition of the complex ion was suggested to be the reduction of this ion by the reactions with hydrated electron and hydrogen atom.

In order to complete the understanding of the radiolytic mechanism we studied the influence of some selective OH scavengers such as : Br^- and SCN^- ions, isopropyl and t — butyl alcohol on the decomposition kinetics.

EXPERIMENTAL

Potassium trisoxalatocobaltate was synthesized by the method described in the literature.[3] The solutions were prepared with triply distilled water. All the reagents being of ana-

[3] S. P. L. Sörensen, *Z. anorg. Chem.*, **11**, 1 (1896).

lytical purity, were used as such. In all the runs we used a constant concentration of the complex of 2×10^{-3}M.

The radiolysis was performed in the presence as well as in the absence of the air. The deaeration was carried out by bubbling purified argon for 30 minutes or by freezing-pumping cycles whenever needed.

The irradiation was carried out in a $\gamma - Co^{60}$ facility of the mobile source type with telemanipulation, of 500 Ci initial activity and 20 Ci/g specific activity. The dosimetry was carried out by chemical method using Fricke dosimeter.

The kinetics of the decomposition of the complex was followed by spectrophotometrical method, recording the decrease of the optical density at 595 nm during irradiation.

The overall zero order rate constant was calculated by relation :

$$k_0 = \frac{a}{E_0} \, \frac{\Delta E}{\Delta t} \tag{I}$$

where :

a is the initial solute concentration,

E_0 the optical density of the unirradiated solution,

ΔE the change in the optical density for irradiation time Δt.

RESULTS

The rate of the radiochemical decomposition of the complex ion in neutral aqueous solution in the presence of Br^- and SCN^- ions as selective OH scavengers is decreasing, the zero order kinetic law being maintained, in the presence of air as well as in its absence. The higher the concentration of the added scavenger, the slower the decomposition rate of the complex ion.

Figures 1 and 2 show the decrease of the optical density of the deaerated solution containing Br^- and SCN^- ions, during irradiation.

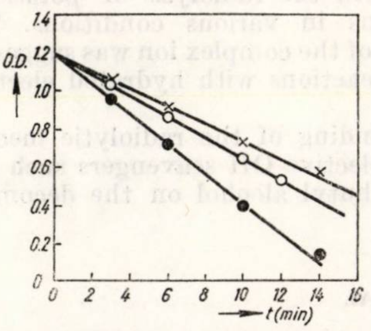

Fig. 1. — The influence of Br^- ions on the decomposition rate of $K_3[Co(C_2O_4)_3]$ in the absence of air. $K_3[Co(C_2O_4)_3]$ 2×10^{-3} M without scavenger ; O KBr 2×10^{-3} M added ; × KBr 10^{-2}M added. Dose rate 9.12×10^{19} eV/hg

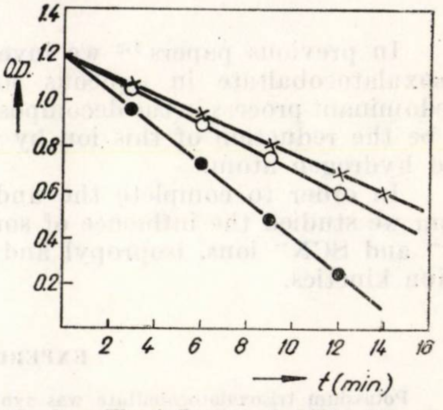

Fig. 2. — The influence of SCN^- ions on the decomposition rate cf $K_3[Co(C_2O_4)_3]$ in the absence of air. $K_3[Co(C_2O_4)_3]$ 2×10^{-3}M without scavenger ; O KSCN 2×10^{-3} M added ; X KSCN 10^{-2} added. Dose rate 9.12×10^{19} eV/hg.

The diminution of the radiochemical yield $G(-[(CoC_2O_4)_3]^{-3})$ and of the overall zero order constant (k_0) as a function of the scavenger concentration in the presence and the absence of the air is listed in table 1.

Table 1

The influence of Br^- and SCN^- ion on the G and k_0 values in the radiolysis of aqueous aerated and deaerated $K_3[Co(C_2O_4)_3]$ solutions of 2×10^{-3} M complex concentration

Scavenger conc (M)	KBr				KSCN			
	Argon		Air		Argon		Air	
	G	$k_0 \times 10^9$ (mol/cm³ s)	G	$k_0 \times 10^9$ (mol/cm³ s)	G	$k_0 \times 10^9$ (mol/cm³ s)	G	$k_0 \times 10^9$ (mol/cm³ s)
0	4.95	2.41	3.19	1.30	4.90	2.41	3.19	1.30
2×10^{-3}	3.60	1.51	2.64	1.12	3.27	1.38	2.42	1.02
10^{-2}	3.13	1.31	2.20	0.92	2.85	1.20	2.02	0.85

As can be seen from table 1, the SCN^- ion is more effective in reducing the $G(-[Co(C_2O_4)_3]^{3-})$ and k_0, both in the presence and the absence of the air. If the radiolysis is performed at a lower dose rate namely 6.73×10^{18} eV/h/g, a change of the slope will take place after 6% decomposition as is shown in figure 3.

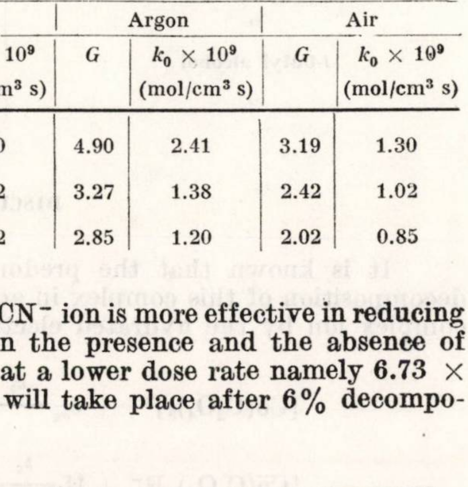

Fig. 3. — The influence of Br^- ions on the decomposition of $K_3[Co(C_2O_4)_3]$ deaerated solutions; ● $K_3Co(C_2O_4)_3$ without scavenger; O KBr 10^{-3} M added; X KBr 10^{-2} M added. Dose rate 6.73×10^{18} eV/hg

The radiochemical yield of the decomposition of the complex does not change in the presence of isopropyl alcohol concentrations up to 10^{-2}M and is slightly enhanced if the concentration of the alcohol is 10^{-1} M, as can be seen from table 2. *T*-butyl alcohol has no influence on $G(-[Co(C_2O_4)_3]^{3-})$ value even at concentration as high as 2×10^{-1} M.

Table 2

The influence of some aliphatic alcohols on the decomposition yield of the complex ion in aqueous 2×10^{-3} M solution

Scavenger	Scavenger concn.	$G(-[Co(C_2O_4)_3]^{3-})$
—		4.95 ± 0.05
isopropyl alcohol	10^{-2}	5.68
,,	10^{-1}	6.42
t-butyl alcohol	2×10^{-2}	4.90
,,	2×10^{-1}	5.00

DISCUSSION

It is known that the predominant process in the radiochemical decomposition of this complex in aqueous solution is the reduction of the complex ion by the hydrated electron and hydrogen atom:

$$[Co(C_2O_4)_3]^{3-} + e_{aq} \xrightarrow{k_1} [Co(C_2O_4)_2]^{2-} + C_2O_4^{2-} \quad (1)$$

$$[Co(C_2O_4)_3]^{3-} + H \xrightarrow{k_2} [Co(C_2O_4)_2]^{2-} + C_2O_4^{2-} + H^+ \quad (2)$$

From the pulse radiolysis data[4] it is known that $k_1 = 1.3 \times \times 10^{10} M^{-1}s^{-1}$, which indicates that $[Co(C_2O_4)_3]^{3-}$ ion is a good e_{aq} scavenger.

Recently, Shagisultanova[5] found for k_2 a value of $4.6\times10^6 M^{-1}s^{-1}$ by the method of introducing into the solution hydrogen atoms produced by electrodeless high frequency discharge in molecular hydrogen.

The above mentioned behaviour of the complex decomposition in the presence of *t*-butyl alcohol supports the fact that the free OH radicals do not take part in the complex decomposition. This assumption is also supported by our previous experiments[2] showing that the accumulation of hydrogen peroxide in the solution of the complex is linear with dose, $G(H_2O_2)$ being the same as in pure water.[6]

The slight increase in the decomposition yield of the complex in the presence of isopropylalcohol (table 2) is due to the reduction of the complex ion by the free radical $CH_3\dot{C}(OH)CH_3$, coming from reaction (3), between isopropylalcohol and the OH radical:

$$CH_3CH(OH)CH_3 + OH \longrightarrow CH_3\dot{C}(OH)CH_3 + H_2O \quad (3)$$

---

[4] J. Baxendale and A. Swallow, *Nature*, **201**, 468 (1964).

[5] G. Shagisultanova, *Khimia Vysokii Energhii* (russian edition), **5**, 187 (1971).

[6] A. Allen, *Radiation Res. Suppl.*, **4**, 54 (1964).

When the complex is irradiated in the presence of Br^- and SCN^- ions, these are quantitatively scavenging the free OH radicals by reactions (4) and (5):

$$Br^- + OH \xrightarrow{k_5} Br + OH^- \tag{4}$$

$$SCN^- + OH \xrightarrow{k_6} SCN + OH^- \tag{5}$$

From the data given in literature $k_4 = 10^9 M^{-1} s^{-1}$ [7] and $k_5 = 1.08 \times \times 10^9 M^{-1} s^{-1}$.[8] Recent works [9] have reported the identification of Br and SCN radical by E.S.R. method.

The decrease of the decomposition yield is due in this situation to the oxidation of $[Co(C_2O_4)]^{2-}$ ion resulted from the reaction (1) and (2), by the entities Br and SCN:

$$[Co(C_2O_4)_2]^{2-} + Br. \xrightarrow{C_2O_4^{2-}} [Co(C_2O_4)_3]^{3-} + Br^- \tag{6}$$

$$[Co(C_2O_4)_2]^{2-} + SCN. \xrightarrow{C_2O_4^{2-}} [Co(C_2O_4)]^{3-} + SCN^- \tag{7}$$

The stronger diminution of the decomposition yield in the presence of SCN^- scavenger (table 1) suggests that this ion has an ability of oxidation higher than that of Br^- ions. If the scavenger is Br^- ion, at both dose rate mentioned, in the presence of air as well as at the lower dose rate in the absence of air, a decrease of the slope (fig. 3) will be noticeable after a certain dose. This phenomenon support also the idea of a lower oxidation ability of Br^- ions expressed by the higher amount of $[Co(C_2O_4)_2]^{-2}$ ions required for reaction (6) to become more effective.

The lower extent of complex decomposition in aerated solution in the presence of Br^- or SCN^- ions is due to the fact that hydrogen peroxide builds up in a resonable concentration which results in a competition between reactions (6), (7) and (8), (9).

$$Br + H_2O_2 \rightarrow Br^- + H^+ + HO_2. \tag{8}$$

$$SCN + H_2O_2 \rightarrow SCN^- + H^+ + HO_2. \tag{9}$$

[9] D. Behar and R. Fessenden, *J. Phys. Chem.*, **76**, 1706 (1972).

The decrease of the $G(-[Co(C_2O_4)_3]^{3-})$ yield may also be due to the capture of hydrogen atom by the Br^- and SCN^- ion, but these reactions are less probable than those involving OH free radicals. On the other hand, Draganič showed recently that the reaction $Br^- + H$ is relatively slow having a rate constant of $3.3 \times 10^7\ M^{-1}s^{-1}$.[10]

These qualitative remarks will constitute the starting point for a quantitative treatment of the process in order to get a better understanding of the contribution of reactions (6) and (7).

ÉTUDE DU SPECTRE VIBRATIONNEL, INFRAROUGE ET RAMAN, DU PYROPHOSPHATE DE PLOMB (IV) — PbP_2O_7

R. HUBIN

Université de Liège, Institut de Chimie. Sart Tilman par B-4000, Liège 1, Belgique

Reçu le 10 octobre 1973

Le spectre vibrationnel, infrarouge et Raman, du pyrophosphate de plomb (IV) est interprété en considérant une symétrie D_{3d} pour le groupement P_2O_7 (pont P—O—P linéaire). Dans une approche simplifiée du problème, le groupement P_2O_7 est décomposé en trois entités indépendantes au point de vue vibrationnel (deux pyramides PO_3 de symétrie C_{3v} et un pont central P—O—P linéaire), ce qui constitue une approximation due à Bues et Gehrke. Ensuite, le groupement P_2O_7 est considéré lui-même comme une entité au point de vue vibrationnel, ce qui permet de montrer qu'il est justifié de recourir à la dite approximation, comme cela a été fait dans de précédents articles consacrés à l'étude du spectre vibrationnel de pyrophosphates, pyroarséniates et pyrovanadates.

INTRODUCTION

Le pyrophosphate de plomb IV — PbP_2O_7 — est isotype [1] des composés cubiques $M^{IV}P_2O_7$ (M^{IV} = Si, Sn, Ti, Zr...) dont la structure a été déterminée par Lévi et Peyronel [2]; l'étude du radiogramme X de poudre de ces composés a permis à ces auteurs de les rattacher au système cubique à faces centrées : ils ont proposé un modèle de structure de groupe spatial T_h^6 avec une maille unitaire comportant 40 « atomes » (28 oxygène, 8 phosphore et 4 ions métalliques). De cette étude de Lévi et Peyronel découlent deux conclusions importantes : l'hexacoordinence de l'élément tétravalent par rapport à l'oxygène et l'existence d'un groupement P_2O_7 de symétrie D_{3d} (avec un angle $\widehat{P—O—P}$ de 180°).

Cependant, Wittmann et coll.[3] ont été amenés à envisager, pour les pyrophosphates d'éléments tétravalents, l'existence d'une maille élémentaire cubique plus grande, ayant un paramètre triple de celui de la maille élémentaire de Lévi et Peyronel. En effet, le diagramme X de poudre de ces composés révèle, à côté des raies intenses observées par Lévi et Peyronel et caractéristiques de la petite maille, la présence de raies d'intensité beaucoup plus faible, qu'il est impossible de justifier par la maille de Lévi et Peyronel. L'interprétation de ces raies exige l'adoption d'une maille triple de cette maille élémentaire.

[3] A. Wittmann, H. Völlenkle et H. Nowotny, *Monatsh.*, **94**, 956 (1963).

L'existence d'une grande maille cubique repose la question de la valeur de l'angle $\widehat{P-O-P}$ dans le groupement P_2O_7. En effet, les raisons de symétrie imposant le caractère rectiligne de la liaison $P-O-P$ dans la petite maille n'existent plus dans la maille triple. Ainsi, il est nécessaire d'envisager un angle $\widehat{P-O-P}$ différent de 180° dans le cas du pyrophosphate cubique de thorium pour pouvoir interpréter le spectre infrarouge de ce composé[4] dont l'isotypie avec les autres pyrophosphates cubiques d'éléments tétravalents est pourtant établie par la diffraction des rayons X.

Nous avons cependant pu montrer[5] que, dans le cas de PbP_2O_7, le spectre infrarouge témoignait d'une symétrie D_{3d} pour le groupement P_2O_7.

Le but de cet article est de proposer, tout d'abord, une interprétation du spectre Raman de PbP_2O_7 en utilisant l'approximation de Bues et Gehrke,[6] comme nous l'avons fait en ce qui concerne son spectre infrarouge[5]; ensuite, nous renoncerons à cette approximation, afin de proposer une interprétation plus rigoureuse des spectres infrarouge et Raman de ce composé.

PARTIE EXPÉRIMENTALE

Le spectre infrarouge a été enregistré dans le domaine 200 à 1300 cm^{-1} à l'aide d'un appareil Beckman IR 12 à double faisceau et, dans le domaine 70 à 200 cm^{-1} à l'aide d'un appareil Cameca à simple faisceau. La méthode des pastilles d'iodure de potassium a été utilisée (6 mgrs de substance sont dispersés dans 0,9 gr de KI). Un appareil Coderg PH 1 a été utilisé pour l'enregistrement du spectre Raman. La raie excitatrice est la 6328 Å produite par un laser He—Ne de marque «Spectra Physics».

MODES NORMAUX DE VIBRATION DU GROUPEMENT P_2O_7

L'APPROXIMATION DE BUES ET GEHRKE [6]

Bues et Gehrke ont montré par le calcul et la mesure de distances phosphore — oxygène que les liaisons $P-O$ dans le pont central étaient 33% plus faibles que les liaisons $P-O$ dans les groupes PO_3 latéraux (dans le cas de pyrophosphates, dans le cadre d'une étude d'ensemble de phosphates condensés); en première approximation, ces ensembles peuvent, dès lors, être considérés comme indépendants au point de vue vibrationnel : cette approximation permet de décomposer le schéma $O_3P-O-PO_3$ en deux parties indépendantes :

— le pont central P—O—P présentant les modes normaux de vibration d'un groupe XO_2 linéaire (dans le cas d'une symétrie D_{3d} du groupement P_2O_7);

— les pyramides latérales PO_3 présentant les modes normaux de vibrations d'ensembles XO_3 dont la symétrie est C_{3v} dans le cas d'une symétrie D_{3d} du groupement P_2O_7.

Le dénombrement des vibrations de ces ensembles permet de déterminer les vibrations d'un groupement P_2O_7 ; le couplage des vibrations des deux groupes PO_3 de chaque groupe P_2O_7 occasionne, en outre, le dédoublement de chacune des fréquences de vibration des groupes PO_3 : les unes pour lesquelles les deux groupes PO_3 vibrent en opposition de phase (affectées d'un indice ′), les autres pour lesquelles les deux groupes PO_3 vibrent en phase (non affectées d'un indice particulier).

Les représentations de symétrie désignent parmi ces vibrations celles qui sont actives en infrarouge et en Raman (tableau 1).

Tableau 1

Modes normaux de vibration d'un groupement P_2O_7 de symétrie D_{3d}

Classe de symétrie	A_{1g}	A_{2u}	E_g	F_u
Eléments de symétrie conservés	toute la symétrie	axe ternaire 3 plans axe binaire	un plan centre	aucun élément
Activité en infrarouge activité en Raman	inactif *actif*	*actif* inactif	inactif *actif*	*actif* inactif
Mouvements s'y rattachant	ν_s POP ν_s PO_3 δ_s PO_3	ν_{as} POP ν'_s PO_3 δ'_s PO_3	ν'_{as} PO_3 δ'_{as} PO_3	δ_s POP ν_{as} PO_3 δ_{as} PO_3

En renonçant à cette approximation, le groupe P_2O_7 est considéré comme une entité indécomposable au point de vue vibrationnel ; la théorie des groupes permet un classement des modes normaux de cette entité :

$$\Gamma_{(D_{3d})} = 3\,A_{1g} + 1\,A_{1u} + 3\,A_{2u} + 3\,E_g + 4\,E_u$$

Cependant, lorsque le groupe P_2O_7 est considéré dans le réseau cristallin de PbP_2O_7,[7] la symétrie réelle, due à l'entourage, devient C_{3i} ; la répartition des modes normaux de vibration devient alors :

$$\Gamma_{(C_{3i})} = 3\,A_g + 4\,A_u + 3\,E_g + 4\,E_u$$

---

[7] R. S. Halford, *J. Chem. Phys.*, **14**, 8 (1946).

La différence entre les symétries D_{3d} et C_{3i} est donc très faible : toutes deux présentent un centre de symétrie (ce qui signifie que toute vibration active en infrarouge sera inactive en Raman et vice-versa) et, en fait, le passage de l'une à l'autre n'entraîne que les légères variations suivantes dans la répartition des modes normaux de vibration dans les classes de symétrie :

$$\begin{array}{lcl} \underline{D_{3d}} & & \underline{C_{3i}} \\ 3\,A_{1g} & \longrightarrow & 3\,A_g \\ 1\,A_{1u} & \searrow & \\ & & 4\,A_u \\ 3\,A_{2u} & \nearrow & \\ 3\,E_g & \longrightarrow & 3\,E_g \\ 4\,E_u & \longrightarrow & 4\,E_u \end{array}$$

Ce schéma montre qu'il est possible de continuer à travailler en ne considérant que la symétrie locale (D_{3d}) du groupe P_2O_7.

Sur la base d'une symétrie D_{3d}, Mooney et coll.[8] ont calculé les valeurs des différentes fréquences de vibration. Ce calcul, assez complexe, ne peut être basé que sur des constantes de force estimées de façon assez grossière. Nous comparerons ces valeurs aux valeurs des fréquences des vibrations observées dans les spectres infrarouge et Raman.

INTERPRÉTATION DU SPECTRE RAMAN DE PbP_2O_7 (en utilisant l'approximation de B. et G.)
